## Committee of Publication :

H. E. ARMSTRONG, Ph.D., F.R.S.  
W. CROOKES, F.R.S.  
F. R. JAPP, M.A., Ph.D., F.R.S.  
A. K. MILLER, Ph.D.  
HUGO MÜLLER, Ph.D., F.R.S.  
W. H. PERKIN, Ph.D., F.R.S.

S. U. PICKERING, M.A.  
R. T. PLIMPTON, Ph.D.  
W. J. RUSSELL, Ph.D., F.R.S.  
J. MILLAR THOMSON, F.R.S.E.  
T. E. THORPE, Ph.D., F.R.S.

## Editor :

C. E. GROVES, F.R.S.

## Sub-Editor :

A. J. GREENAWAY.

## Abstractors :

H. BAKER.  
CHICHESTER H. BELL, M.B.  
D. BENDIX.  
C. H. BOTHAMLEY.  
B. H. BROUGH.  
C. F. CROSS.  
A. H. FISON.  
J. FLETCHER.  
W. D. HALLIBURTON, M.D., B.Sc.  
J. P. LAWS.  
D. A. LOUIS.  
T. MAXWELL, M.D., B.Sc.  
N. H. J. MILLER, Ph.D.  
G. H. MORRIS, Ph.D.

J. M. H. MUNRO, D.Sc.  
A. PHILIP.  
E. W. PREVOST, Ph.D.  
R. ROUTLEDGE, B.Sc.  
M. J. SALTER.  
C. SPURGE, B.A.  
JAMES TAYLOR, B.Sc.  
A. THILLOT.  
L. T. THORNE, Ph.D.  
H. K. TOMPKINS, B.Sc.  
V. H. VELEY, M.A.  
W. C. WILLIAMS, B.Sc.  
W. P. WYNNE, B.Sc.

## ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS:—

### *General and Physical Chemistry.*

|  | PAGE |
|--|------|
| STROUMBO. Production of White Light by Mixing the Colours of the Spectrum . . . . .                          | 1    |
| LIEBERMANN (C.) and S. v. KOSTANECKI. Spectra of the Methyl-derivatives of Hydroxyanthraquinone . . . . .    | 1    |
| VERNEUIL (A.). Preparation of Calcium Sulphide with a Violet Phosphorescence . . . . .                       | 2    |
| BOISBAUDRAN (L. DE). Fluorescence of Manganese Compounds . . . . .   | 3    |
| BOISBAUDRAN (L. DE). Fluorescence of Bismuth Compounds . . . . .   | 4    |
| LUVINI (J.). Electrical Conductivity of Gases and Vapours . . . . .  | 4    |
| WINKELMANN (A.). Relation of the Conductive Capacity of Gases to Temperature . . . . .                       | 5    |
| GRAETZ (L.). Electrical Conductivity of Solids at High Pressures . . . . .                                   | 5    |
| SCHIFF (R.). Specific Heats of Homologous Series of Liquid Organic Compounds . . . . .                       | 6    |
| BLAREZ (C.). Saturation of Normal Arsenic Acid with Barium Hydroxide . . . . .                               | 7    |
| BLAREZ (C.). Saturation of Arsenic Acid with Calcium and Strontium Oxides . . . . .                          | 8    |
| DE FORCRAND. Sodium Glycerolate . . . . .  | 8    |
| SCHIFF (R.). Heat of Evaporation of Homologous Carbon Compounds . . . . .                                    | 9    |
| MEISSNER (F.). Heat evolved when Powders are Moistened . . . . .   | 9    |
| ZEHNDER (L.). Determination of the Sp. Gr. of Soluble Substances . . . . .                                   | 9    |
| BERTHELOT and ANDRÉ. Tension of Dissociation of Ammonium Hydrogen Carbonate . . . . .                        | 10   |
| BERTHELOT and ANDRÉ. Decomposition of Ammonium Hydrogen Carbonate by Water, &c. . . . .                      | 11   |
| DUCLAUX (E.). Chemical Changes produced by Sunlight . . . . .  | 93   |
| EDER (J. M.). Practical Methods of Photographing the Spectrum . . . . .                                      | 93   |
| HABERMANN (J.). Electrolysis of Carbon Compounds . . . . .   | 94   |
| BERTHELOT. Thermochemistry of Phosphates . . . . .   | 94   |
| GAL (H.) and E. WERNER. Heat of Neutralisation of Homologous and Isomeric Acids . . . . .                    | 95   |
| GAL (H.) and E. WERNER. Heats of Neutralisation of Malonic, Tartronic, and Malic Acids . . . . .             | 96   |
| BERTHELOT. Thermochemistry of Reactions between Magnesia Salts and Ammonia . . . . .                         | 96   |
| STOHMANN (F.), P. RODATZ, and H. HERZBERG. Heats of Combustion and Formation of Homologous Phenols . . . . . | 98   |
| DE LANDERO and R. PRIETO. Some Laws of Chemical Combination . . . . .  | 99   |
| HUNT (T. S.). Law of Volumes in Chemistry . . . . .  | 99   |
| LESCŒUR (H.). Velocity of Dissociation . . . . .   | 100  |
| RAMSAY (W.) and S. YOUNG. Nature of Liquids . . . . .  | 100  |

**Production of White Light by Mixing the Colours of the Spectrum.** By STROUMBO (*Compt. rend.*, 103, 737—738).—The spectrum is produced by means of a prism which is arranged so that it can rotate about an axis parallel with its faces. When the prism is made to rotate with sufficient rapidity, the spectrum is replaced by a band of white light. The extreme red of the spectrum, however, always remains coloured, because whilst all the other colours pass their position of minimum deviation, the red, which is the least refrangible, does not become mixed with any other colours. It is advisable to intercept this portion of the spectrum by means of a small screen.

C. H. B.

**Spectra of the Methyl-derivatives of Hydroxyanthraquinone.** By C. LIEBERMANN and S. v. KOSTANECKI (*Ber.*, 19, 2327—2332).—The compounds are best examined in solution in pure concentrated sulphuric acid. The eight known dihydroxyanthraquinones can be distinguished from one another by the spectra of their sulphuric acid solutions.

The methyl homologues have almost exactly the same properties as the original substances, and as this analogy extends to the spectra it is often possible to determine the constitution with very small amounts of substances. The difference in the spectra caused by the substitution of one methyl-group is extremely small, but this difference increases visibly with the number of methyl-groups.

The relation of chrysophanic acid to chrysazine, previously suggested (*Annalen*, 183) on the strength of their similar chemical properties, is supported in a striking manner by the spectra of the two compounds.

A table of spectra of methyl homologues and the compounds from

which they are derived, and tables showing the relation of the trihydroxyanthraquinones to each other and to their methyl-derivatives, are given (compare also Krüss, Abstr., 1885, 949).

N. H. M.

**Preparation of Calcium Sulphide with a Violet Phosphorescence.** By A. VERNEUIL (*Compt. rend.*, 103, 600—603).—20 grams of finely powdered calcium oxide prepared by heating the very dense shell of *Hypopus vulgaris*, is intimately mixed with 6 grams of sulphur and 2 grams of starch; and 8 c.c. of a solution of 0.5 gram of basic bismuth nitrate and 100 c.c. of absolute alcohol acidified with a few drops of hydrochloric acid, are added. The mixture is exposed to the air until the greater part of the alcohol has evaporated, and is then heated in a covered crucible at a cherry-red heat for 20 minutes. When completely cooled, the upper layer of calcium sulphate is removed, and the calcined mass powdered and again heated at the same temperature for 15 minutes. If the temperature has not risen too high, the product is granular and friable; if powdered a second time, the brilliancy of the phosphorescence is considerably diminished. The violet colour of the phosphorescence is due to the presence of the small quantity of bismuth.

The phosphorescence of calcium sulphide is not materially increased by the presence of 0.1 per cent. of the sulphides of antimony, cadmium, mercury, tin, copper, lead, uranium, platinum, zinc, or molybdenum, but these substances impart a bluish-green or yellowish-green tinge to the phosphorescence. Sulphides of cobalt, nickel, iron, and silver diminish the phosphorescence, whilst manganese produces the orange shade observed by Becquerel.

A mixture of calcium oxide 100 parts, sulphur 30 parts, starch 10 parts, and lead acetate 0.035 part, yields a sulphide with a beautiful yellowish-green phosphorescence, but if the proportion of lead acetate is increased to 0.4 part, the green colour disappears and the phosphorescence becomes yellowish-white, and diminishes considerably in intensity. With 1.6 part of lead acetate, the yellow tint is more marked, and with 3.5 parts the phosphorescence is orange-yellow. With a greater proportion of the lead salt, the product has a greyish tint and does not phosphoresce at all.

Calcium sulphide obtained by reducing the pure sulphate in a current of hydrogen or carbonic oxide, shows no phosphorescence, and that prepared by heating the sulphate with starch shows only very slight phosphorescence; hence it would seem that pure calcium sulphide is not phosphorescent, and that the phenomenon is due to the presence of small quantities of silica, magnesium, phosphates, and alkalis derived from the shells from which the lime is prepared.

As a general rule, substances which cause the calcium sulphide to frit slightly when heated, increase the brilliancy of the phosphorescence.

The product obtained by heating a mixture of strontium carbonate 100 parts, sulphur 30 parts, and arsenious oxide 5 parts, shows a greenish-blue phosphorescence if the strontium carbonate has been prepared from the chloride and ammonium carbonate, but the phosphorescence is greenish-yellow if the strontium carbonate has

been precipitated by means of sodium carbonate. The difference is due to the retention of a small quantity of alkali by the strontium carbonate.

C. H. B.

**Fluorescence of Manganese Compounds in a Vacuum under the Influence of the Silent Discharge.** By L. DE BOISBAUDRAN (*Compt. rend.*, **103**, 468—471).—All the sulphates used in these experiments were heated to dull redness, and the carbonates and oxides were strongly heated.

Manganese sulphate alone, and trimanganese tetroxide prepared from the carbonate, show no fluorescence.

Calcium sulphate alone gives a feeble fluorescence with a continuous spectrum, but if it contains a trace of manganese sulphate it gives a brilliant green fluorescence, the spectrum of which consists of a broad band which begins at about 6600, attains its maximum intensity at about 5400, and fades away between the blue and the violet.

Calcium carbonate alone shows a feeble fluorescence, but if mixed with a small quantity of manganese, it shows a brilliant orange-yellow fluorescence characterised by a band which begins about 6700, attains its maximum intensity at about 5890, and fades away at 5260. This fluorescence is much more strongly marked than that observed with the sulphates.

Magnesium sulphate alone gives a faint greenish fluorescence, but if mixed with manganese sulphate it gives a brilliant red fluorescence characterised by a band which begins nebulously at about 6720, attains its maximum at 6200, and fades away at about 5540.

Magnesium carbonate mixed with manganese shows the same fluorescence as the sulphates.

Zinc sulphate alone shows a feeble rose-coloured fluorescence, but if mixed with manganese sulphate it shows an orange-red fluorescence, which is characterised by a band which begins nebulously at 6720, attains a maximum at about 6280, and fades away near 5380.

Cadmium oxide alone or mixed with manganese oxide gives no fluorescence. Cadmium sulphate alone shows only a feeble pale greenish-yellow fluorescence, but if it is mixed with manganese sulphate it gives a very brilliant yellowish-green fluorescence, the spectrum of which consists of a broad band which begins at 6620, attains its maximum at 5590, and fades away at about 4560. This is the most brilliant of all the manganese fluorescences.

Strontium sulphate alone shows a pale lilac fluorescence with a continuous spectrum, and the carbonate or oxalate after being strongly heated shows a blue fluorescence. These fluorescences are not materially affected by the presence of manganese.

Lead sulphate alone gives a feeble violet fluorescence, but if mixed with manganese sulphate it gives a beautiful yellow fluorescence characterised by a band which begins at about 6560, attains its maximum at 5620—5760, and ends at 5310—5260. Lead oxide, whether pure or mixed with manganese, gives no notable fluorescence.

Beryllium sulphate alone gives a somewhat marked green fluorescence, but if it is mixed with a trace of manganese sulphate the fluorescence is stronger and is yellowish-green. It gives a spectrum

consisting of a fairly brilliant band which begins at 6690, attains a maximum at 5640, and fades away at 4840—4800. An excess of beryllium sulphate prevents the development of the manganese fluorescence.

The character of the fluorescence and the position and character of the bands in its spectrum vary with the nature of the substance with which the manganese is mixed. These fluorescences constitute an extremely delicate test for manganese.

C. H. B.

**Fluorescence of Bismuth Compounds.** By L. DE BOISBAUDRAN (*Compt. rend.*, 103, 629—631).—Bismuth sulphate alone, previously heated to dull redness, shows no fluorescence when subjected to the action of the silent electrical discharge in a vacuum, but the admixture of small quantities of this salt with various other sulphates confers upon them the power of fluorescing under these conditions. In all cases, the sulphates were previously heated to dull redness. If the proportion of bismuth is gradually increased, the fluorescence at first increases in brilliancy, attains a maximum, then becomes weaker, and finally disappears even whilst the proportion of bismuth is still very small.

With calcium sulphate, the fluorescence is orange-red, and its spectrum consists of a band which begins very nebulously at 6730, attains its maximum intensity at 6140, and fades away gradually at about 5780. With strontium sulphate, the fluorescence is orange, and is more brilliant than with the calcium salt. Its spectrum consists of a band which begins very nebulously at 6640, attains its maximum intensity at 5980, and fades away at about 5637. With barium sulphate, the fluorescence is redder than with calcium sulphate, and is characterised by a band which begins nebulously at 6540, attains its maximum intensity at about 6220, and fades away gradually at 5840—5850. With magnesium sulphate, the fluorescence is still redder but is not so brilliant as in the preceding cases. It is characterised by a band which begins nebulously at 6750—6760, attains its maximum intensity at 6320—6330, and fades gradually away at about 5860. The fluorescence of the corresponding oxides is not appreciably affected by the presence of bismuth oxide. No fluorescence was observed with zinc, cadmium, and lead sulphates, or zinc and cadmium oxides, in the presence of bismuth.

The spectrum of this fluorescence is a more delicate test for bismuth than the spark spectrum.

C. H. B.

**Electrical Conductivity of Gases and Vapours.** By J. LUVINI (*Compt. rend.*, 103, 495—497).—The author's experiments, combined with those of previous investigators, show that gases and vapours at any temperature or pressure are perfect insulators, and cannot be electrified by internal friction or friction with solids and liquids. Measurements were made by observing the divergence between a pith ball suspended by cocoon silk and a brass sphere suspended in the same way in an atmosphere of the gas to be examined, both sphere and pith ball being electrified. The gases used were air saturated with moisture at various temperatures between

16° and 100°, moist hydrogen, moist carbonic anhydride, mercury vapour at 100°, vapour of ammonium chloride, air heated by burning charcoal and by a candle flame, smoke from a smouldering candle-wick, vapours from burnt sugar, incense, &c.

The belief that gases at very low pressures or high temperatures are conductors arises from a confusion between resistance to a *disruptive* discharge and resistance to a *conductive* discharge.

All theories in which gases and vapours are regarded as conductors or capable of being electrified by friction must be abandoned.

C. H. B.

**Relation of the Conductive Capacity of Gases to their Temperature.** By A. WINKELMANN (*Ann. Phys. Chem.* [2], 29, 68—113).—In these experiments, the conductive capacity is determined by means of three horizontal copper plates immersed in the gas and separated from one another by glass balls, the upper and lower plates being maintained at fixed and different temperatures. The temperature of each plate was indicated by a delicate thermometer.

The results obtained are—

|  |          |
|--|----------|
| For air, mean of four experiments . . . . .      | 0·00206. |
| „ carbonic anhydride, four experiments . . . . . | 0·00366. |
| „ hydrogen, two experiments . . . . .            | 0·00206. |

The heat given off by a plate immersed in a gas is different according to its orientation, hence that given off by a given area cannot be determined from the rate of cooling of the whole.

H. K. T.

**Electrical Conductivity of Solid Substances at a High Pressure.** By L. GRAETZ (*Ann. Phys. Chem.* [2], 29, 314—330).—Hitherto our knowledge of the conductivity of electrolytes is derived for the most part from results obtained with the substances in the dissolved and not in the fused condition. Although it is *a priori* to be expected that the law governing these phenomena in the case of a homogeneous media would be of a simpler character than those in the case of heterogeneous media, namely, a solution of salt in water, yet the result of experience is the reverse.

The only generalisation at present deduced is that solid substances are not conductors at low temperatures, but their conductivity commences at temperatures far below the melting point, and increases with the temperature.

If then this increase of conductivity is due to an increase of molecular mobility and of the number of molecular impacts, increase of pressure without alteration of temperature should be effective to a like degree. In the paper, this point is examined by means of a compression apparatus, capable of giving a pressure of upwards of 4000 atmospheres. The results are given for the halogen-compounds of lead and silver, and for sodium nitrate. The substances examined are divisible into two classes, in the one of which, with application of maximum pressure, the resistance rapidly decreases to a constant point, and in the other this minimum resistance is, under the same condition, only attained after several hours. To the former class

belong the halogen-compounds of silver, to the latter those of lead and sodium nitrate. In the paper full details are given of the apparatus used, and of the methods of experiments; the results are tabulated.

V. H. V.

**Specific Heats of Homologous Series of Liquid Organic Compounds.** By R. SCHIFF (*Annalen*, **234**, 300—337).—The author has determined the specific heats of a large number of hydrocarbons, acids, alcohols, and ethereal salts, at different temperatures, and has arrived at the following results. All the ethereal salts of fatty acids of the formula  $C_nH_{2n}O_2$ , have the same specific heat at the same temperature.

The specific heat of these substances at  $t$  is represented by the equation  $Kt = 0.4416 + 0.00088t$ , and the mean specific heat between  $t$  and  $t'$  by  $Ct - t' = 0.4416 + 0.00044(t + t')$ .

|   | $Kt =$                         |
|---|--------------------------------|

| Acetic acid .....                                 | } 0.440 + 0.001418 <i>t</i> .  |
| Propionic acid .....                              |                                |
| Butyric acid.....                                 | } 0.4352 + 0.001418 <i>t</i> . |
| Isobutyric acid.....                              |                                |
| Valeric acid .....                                |                                |
| Formic acid .....                                 | 0.4966 + 0.000709 <i>t</i> .   |

Pawlewsky (Abstr., 1883, 276) has pointed out that the critical temperature of the ethereal salts of the fatty acids is  $182^\circ$  higher than their boiling point.

The author divides the distance between the absolute zero and the critical temperature of an ethereal salt into 100 equal parts, which he terms critical degrees.

In the table (p. 7)  $LX_{cr}$  represents 60 of these critical degrees;  $K_{LX}$  the true specific heat at this temperature;  $D_{LX}$  the sp. gr. at this temperature, and  $KD_{LX}$  the product of these two values.

Equal volumes of these substances have the same specific heat at the same “critical degree.”

The author disputes the accuracy of the conclusions which De Heen (*Physique comparée*, 39) draws from his researches on this subject, and he also criticises the results obtained by v. Reis.

|                           | LX cr. | K <sub>LX</sub> . | D <sub>LX</sub> . | KD <sub>LX</sub> . |

W. C. W.

### Saturation of Normal Arsenic Acid with Barium Hydroxide.

By C. BLAREZ (*Compt. rend.*, 103, 746).—The developments of heat accompanying the addition of successive equivalents of barium hydroxide to a dilute solution of arsenic acid are given in the following table:—

|                         |         |
|-------------------------|---------|
| 1st equivalent develops | + 14·00 |
| 2nd „ „                 | + 27·75 |
| 3rd „ „                 | + 43·25 |
| 4th „ „                 | + 43·50 |
| 5th „ „                 | + 44·00 |

The phenomena are not similar to those observed when arsenic acid is neutralised by alkalis, lime, or strontia. Cochineal and helianthin change when the first function of the acid is somewhat more than neutralised, but phenolphthaleïn indicates accurately the neutralisation of the second acid function. Even in presence of four or five equivalents of baryta, the precipitate is tribarium arsenate, a result different from that obtained when arsenic acid is neutralised with lime or strontia, or when orthophosphoric acid is neutralised with baryta.

C. H. B.

**Saturation of Arsenic Acid with Calcium and Strontium Oxides.** By C. BLAREZ (*Compt. rend.*, **103**, 639—640).—The heat developed by the saturation of a normal solution of arsenic acid by means of calcium or strontium oxide in aqueous solution is given in the following table :—

|                                   | Calcium<br>oxide. | Strontium<br>oxide. |
|-----------------------------------|-------------------|---------------------|
| First equivalent . . . . .        | 14.5              | 14.17               |
| Second equivalent . . . . .       | 12.5              | 12.33               |
| Third           "       . . . . . | 2.52              | 3.88                |
| Fourth         "       . . . . .  | 0.28              | 1.03                |
| Fifth           "       . . . . . | 0.25              | —                   |

Neutralisation with the first equivalent is distinctly indicated by cochineal, but less distinctly by methyl-orange, and neutralisation with the second equivalent is indicated fairly well by phenolphthalein. The arsenate precipitated on addition of three equivalents of base is somewhat variable in composition, but approximates to the tribasic salt. With four and five equivalents, the precipitated arsenate is somewhat basic. The much greater tendency of calcium and strontium arsenates to dissociate in presence of water, distinguishes them from the corresponding phosphates.

**Sodium Glycerolate.** By DE FORCRAND (*Compt. rend.*, **103**, 596—599).—Sodium glycerolate,  $C_3H_7NaO_3$ , was prepared by Lett's method (*Ber.*, **5**, 159). Heat of solution at  $16^\circ$ ,  $C_3H_7NaO_3, C_2H_6O$ ,  $-1.08$  cal.;  $C_3H_7NaO_3$ ,  $+1.07$ . From these values, and the heat of solution and neutralisation of glycerol, and the heat of solution of alcohol as determined by Berthelot, it follows that—

and hence—

This result confirms the view that the substitution of sodium takes place in the glycerol and not in the ethyl alcohol.

and lastly—

This result shows that the formation of  $C_3H_7NaO_3, C_2H_6O$  is

exothermic, whilst the precipitation of  $C_3H_7NaO_3$  alone would be endothermic.

The alkaline glycerolates possess a somewhat general property of uniting with one molecule of monohydric alcohols to form crystallisable compounds. The thermochemical data show that polyhydric alcohols yield more stable derivatives than monohydric alcohols.

C. H. B.

### Heat of Evaporation of Homologous Carbon-compounds.

By R. SCHIFF (*Annalen*, 234, 338—350).—The author uses an apparatus partly constructed of silver, which is so arranged as to prevent the vapour of the boiling liquid being superheated, and also to ensure the dryness of the vapour before it enters the calorimeter, two points to which sufficient attention has not been directed in the different forms of apparatus used by Berthelot (*Mécanique Chimique*, 1, 289), Brix (*Ann. Chim. Phys.*, 55), and Depretz (*Ann. Chim. Phys.*, 24, 323).

The author's tabulated results show that the heat of evaporation decreases as the molecular weight increases. In the case of isomerides, the substance with the lowest boiling point has the lowest heat of evaporation. The results confirm Trouton's statement that the molecular heats of evaporation are proportional to the absolute temperature at which the evaporation takes place (*Phil. Mag.* [5], 18, 84). The coefficient of expansion at  $0^\circ$  is inversely proportional to the absolute temperature of the boiling point under the normal pressure.

W. C. W.

**Development of Heat when Powders are Moistened.** By F. MEISSNER (*Ann. Phys. Chem.* [2], 29, 114—131).—The author uses two experimental methods, a thermometric and a calorimetric. In the first, weighed quantities of the carefully dried powder and of water are brought together in a small glass vessel, their temperature having been carefully noted before mixing. The rise in temperature produced is recorded from time to time by a delicate thermometer immersed in the mixture. The second set of experiments were conducted in a Bunsen's calorimeter. The substances experimented on were ignited silica, "magnesia alba," glass powder, emery and animal charcoal with water, benzene, amyl alcohol, and glycerol.

For water and silica, the author finds a rise in temperature of  $3.8$ — $4.5^\circ$  C., with initial temperatures ranging from  $0$ — $19^\circ$ ; this result is contrary to that of Jungk (*Ann. Phys. Chem.*, 125, 292), who states that with initial temperatures below  $4^\circ$  there is absorption of heat.

The author considers that the development of heat is due to the expansion of the colloïd when moistened, or that potential molecular energy is converted into heat.

H. K. T.

**Determination of the Specific Gravity of Soluble Substances.** By L. ZEHNDER (*Ann. Phys. Chem.* [2], 29, 249—263).—In this paper, a simple method for the determination of the specific gravity of soluble substances is described, by means of which results accurate to the one-thousandth part can be readily obtained. The principle of it is as follows:—The substance to be determined is weighed

in the pyknometer, and the latter is then placed in an inverted position under water, so that the solid substance falls out, the air from the pyknometer being at the same time collected by a funnel provided with a bent tube, and completely filled with water; from this funnel the air is retransferred to the pyknometer, which is then again weighed; thus is obtained the weight of a volume of water equal to that occupied by the weight of the substance taken, which relation gives directly the specific gravity. To collect the displaced air, the pyknometer is inverted under a funnel provided with a delivery-tube, twice bent, and ending in a capillary opening, by means of which the air is again decanted into the pyknometer.

This method requires the following determinations: the weight of the substance whose sp. gr. is to be determined, the weight of the water replaced by it, and the capacity of the pyknometer; the difference between them is the volume of air; this is corrected for differences of temperature and pressure during the determination, and the corrected volume of air subtracted from the capacity of the pyknometer gives the corrected volume occupied by the substance; on dividing the weight of the substance by the latter value, the specific gravity is obtained. The special precautions to be adopted are discussed in full, and determinations are given of common salt and sugar candy, the results of which are fairly satisfactory.

V. H. V.

### **Tension of Dissociation of Ammonium Hydrogen Carbonate.**

By BERTHELOT and ANDRÉ (*Compt. rend.*, **103**, 665—671).—The decomposition of ammonium hydrogen carbonate by water increases only very slightly with an increase in the proportion of water, and the maximum change is not effected until after a considerable lapse of time. The heat of dissolution of 1 gram-mol. in 25 litres of water is — 6.85 cal.; whilst the heat of dissolution in 6—8 litres is — 6.2 cal.

Perfectly dry ammonium hydrogen carbonate has no sensible tension of dissociation at ordinary temperatures in presence of air, ammonia, or carbonic anhydride, under a pressure of two-thirds of an atmosphere. Even when a current of these gases is passed over the salt, the evidence of any dissociation is extremely slight. That the salt does, however, possess a distinct, though extremely small, vapour-tension, is shown by the fact that if it is left in a closed space over sulphuric acid, the latter increases in weight, and crystals of ammonium hydrogen sulphate form on the edge of the dish containing it.

These results are materially affected by the presence of very small quantities of water. If the water is entirely in the state of vapour, it exerts but little influence on the vapour-tension of the salt, but the effect is much greater in presence of liquid water, and if the salt is placed in a closed space in which there is also a vessel containing water, the latter increases in weight owing to absorption of ammonia.

The three constituents of the salt do not play the same part in its dissociation. Carbonic anhydride and ammonia are without influence on its vapour-tension at the ordinary temperature, whilst water determines its decomposition independently of the ordinary laws of dissociation.

G. H. B.

**Decomposition of Ammonium Hydrogen Carbonate by Water and Diffusion of the Ammonia through the Atmosphere.** By BERTHELOT and ANDRÉ (*Compt. rend.*, 103, 716—721).—A concentrated solution of ammonium carbonate, containing ammonia and carbonic anhydride in the ratio 1 : 1·85, was placed in a closed space, which also contained a vessel with a known weight of water. The atmosphere contained carbonic anhydride, but no appreciable quantity of ammonia. At first, the quantity of carbonic anhydride absorbed by the water in the second vessel was relatively greater than the quantity of ammonia, but after about eight days the distribution of ammonia and carbonic anhydride was uniform in both vessels. Similar results were obtained with dilute solutions, and it follows that pure water, in an atmosphere containing a small quantity of ammonia and a relatively much larger quantity of carbonic anhydride, tends to reform the acid carbonate, a result probably due to the fact that the carbonic anhydride, by reason of its greater insolubility, maintains a higher tension in the atmosphere. The diffusion of ammonia from water to air in presence of carbonic anhydride does not take place in accordance with the same laws as the diffusion in the absence of any gas which can combine with the ammonia. The rate of diffusion of free ammonia from its aqueous solution into the air is very much more rapid than the diffusion of ammonia in combination with carbonic acid. The diffusion of free ammonia is accelerated by the presence of sulphuric acid, which absorbs the alkali from the atmosphere, but the presence of this acid has very little effect on the diffusion of ammonia from a solution of the carbonate, and the effect is less the more dilute the solution.

In presence of an excess of carbonic anhydride, the transference of ammonia through the atmosphere to an aqueous liquid takes place in a manner entirely different from the similar transference of ammonia in presence of an inert gas. The latter is conditioned by the tension of the ammonia in the solutions, whilst the former depends on the relative tensions of the carbonic anhydride in the liquids and the surrounding atmosphere. It is, in fact, the diffusion of the carbonic anhydride which regulates the decomposition of the ammonium hydrogen carbonate and the transference of the ammonia through the atmosphere.

**Conversion of Calcium Hypochlorite into Calcium Chlorate.** By G. LUNGE (*J. Soc. Chem. Ind.*, 4, 722—724).—It has already been shown by the author that the reaction  $6\text{CaOCl}_2 = 5\text{CaCl}_2 + \text{Ca}(\text{ClO}_3)_2$  does not take place completely and without considerable loss of oxygen, except in presence of an excess of chlorine, although that chlorine does not appear in the equation. The author's experiments point to the following conclusions:—The most

favourable way of converting hypochlorite into chlorate is to raise the temperature of the solution, and simultaneously have an excess of chlorine present therein. A large excess of chlorine is useless, perhaps injurious, for the yield of chlorate. On the large scale, it is not necessary to raise the temperature by artificial means, the heat produced by the reaction being sufficient to complete it. The conversion at the ordinary temperature proceeds almost at once to the limit of about 70 per cent., but subsequently makes very slow progress, so that it is impracticable to wait for its completion without heating.

D. B.

**A Crystalline Silico-carbonate from Soda Liquors.** By C. RAMMELSBURG (*Chem. Ind.*, 9, 110—111).—Two specimens of crystals removed from the pump of a carbonating tower at the “Hermannia” Chemical Works at Schönebeck had the following composition:—

|     | CO <sub>2</sub> . | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | CaO.  | Na <sub>2</sub> O. | H <sub>2</sub> O. |
|-----|-------------------|--------------------|----------------------------------|-------|--------------------|-------------------|
| I.  | 22.75             | 14.99              | 7.38                             | 13.28 | 22.37              | 19.23 = 100       |
| II. | 21.50             | 15.00              | 8.03                             | 12.41 | 21.66              | 21.40 = 100       |

Allowing for adhering soda liquor, these numbers lead to the formula  $\text{Na}_{15}\text{Ca}_6\text{Al}_2(\text{Si,C})_{21}\text{O}_{63} + 30\text{H}_2\text{O}$ , or the substance is a compound of the isomorphous normal carbonates and silicates

The crystals are rhombic, exhibiting the form of the primary pyramid with its acuter terminal edges truncated, or frequently a tabular form due to the development of the end face; the ratio of the axes is 0.5295 : 1 : 1.73.

These crystals were first observed in 1880, but the specimen then analysed contained an admixture of gay-lussite, and the silica and alumina were not recognised as essential constituents. M. J. S.

**Sodium-calcium Carbonates from the Soda Manufacture.** By C. REIDEMEISTER (*Chem. Ind.*, 9, 111).—In the *Chemische Industrie* for 1884 the author described the rhombic crystals analysed by Rammelsberg (see preceding Abstract) as a hydrated sodium calcium carbonate. They are now found to occur in both the crude and carbonated liquors. In the former, in which formerly only gay-lussite had been recognised, they have now been observed with crystals of gay-lussite deposited on their surfaces. The gay-lussite crystals are chiefly deposited from liquors in process of cooling; the silico-carbonate from those undergoing slow evaporation. M. J. S.

**Double Nitrites of Cæsium and of Rubidium.** By T. ROSENBLADT (*Ber.*, 19, 2531—2535).—The double nitrite of cæsium and cobalt,  $3\text{CsNO}, \text{Co}(\text{NO}_2)_3 + \text{H}_2\text{O}$ , is formed by boiling equal parts of cobalt nitrate and sodium acetate in water (15 parts), filtering, and adding to the cold solution first acetic acid (20 parts), and then a strong solution of sodium nitrite until the liquid has an orange colour, it is then filtered, and treated with a solution of a

cæsium salt. The double salt  $3\text{RbNO}_2, \text{Co}(\text{NO}_2)_3 + \text{H}_2\text{O}$  is prepared in a similar manner. They are both lemon-coloured crystalline salts, and resemble in their behaviour Fischer's potassium-compound, except in their solubility in water, the cæsium salt dissolving only in 20,100 parts of water at  $17^\circ$ , and the rubidium salt in 19,800 parts of water. The method employed in analysing these compounds is described.

Thallium also yields a double salt with cobalt nitrite; it is a red crystalline compound, soluble in 23,810 parts of water.

N. H. M.

**Decomposition of Glass by Carbonic Anhydride condensed on its Surface.** By R. BUNSEN (*Ann. Phys. Chem.* [2], 29, 161—165).—Formerly the author attributed the absorption of carbonic anhydride by glass-wool rather to an interpenetration of the glass by the molecules of the liquefied gas rather than to any chemical change (*Abstr.*, 1884, 146). This view would also be confirmed by the observations on the stability of glass towards the most concentrated hydrochloric acid. However, if the glass-wool be damp, whereby the absorption of the gas is remarkably increased (*Abstr.*, 1885, 867), the possibility of a chemical change is not precluded. Accordingly the glass (49.453 grams) used in the experiment was exhausted with water, and a residue obtained from it corresponding to the decomposition of 2.882 grams of glass, or 5.83 per cent. of the whole. Even if the chemical change consists in the production at first of sodium carbonate, which would take up a further quantity of carbonic anhydride, corresponding with the formation of sodium hydrogen carbonate, which on subsequent heating would again be driven off, yet all the carbonic anhydride absorbed cannot be accounted for in this way. The phenomenon is thus not only one of chemical change, but also of absorption, the particular degree of each of which cannot be estimated.

If, then, carbonic acid can decompose glass, the same is to be expected of water. Observations in the course of experiments on the determination of the tension of aqueous vapour at high temperatures are quoted to show that glass tubes containing water-vapour when heated at  $88^\circ$  are converted into a white porcelain-like mass, and that their inner diameter is diminished by one-tenth.

V. H. V.

*Note.*—On the decomposition of glass by carbonic anhydride under high pressures compare Pfaundler (*Abstr.*, 1885, 868).

V. H. V.

**Purification of Yttria.** By L. DE BOISBRAUDAN (*Compt. rend.*, 103, 627—629).—A comparatively very pure sample of yttria was subjected to 32 series of fractionations by means of ammonia. The product of the last precipitation of the thirty-second series showed a less brilliant fluorescence than the original earth, and the bands of  $Z\alpha$  and  $Z\beta$  in the spectrum had diminished considerably in intensity, whilst the bands of samarium retained their original vigour. The colour of the fluorescence had changed from yellowish-green to orange-yellow.

This last precipitate was submitted to 26 series of fractionations by means of oxalic acid. The brilliancy of the fluorescence continu-

ally diminished, but, contrary to the phenomena observed during the first fractionation, the samarium bands diminished in intensity much more rapidly than the bands of  $Z\alpha$  and  $Z\beta$ . The earth from the oxalate precipitated at the end of the fifth fractionation showed very faintly the citron band and the double green band of  $Z\alpha$  and  $Z\beta$ , with a trace of the red bands of samarium. The oxalate from the twenty-sixth fractionation yielded a very white earth which showed a trace of the citron band of  $Z\alpha$ , but none of the red, green, blue, and violet bands in the spectrum described by Crookes. This yttria gave no fluorescence when mixed with lime, but its hydrochloric acid solution gave a brilliant spark spectrum of yttrium.

The sulphate prepared from the last precipitate from the fractionation with oxalic acid gave a rose-coloured fluorescence due to the presence of a trace of bismuth.

C. H. B.

**Heating and Cooling of Cast Steel.** By OSMOND (*Compt. rend.*, 103, 743—746).—The phenomena which accompany the heating and cooling of cast steel were investigated by means of a thermo-electric couple connected with an aperiodic galvanometer.

Barrett observed that when a bar of hard iron is cooled from a white heat there is a sudden development of heat at dull redness, and the magnetic properties of the iron change abruptly. He distinguished this phenomenon by the name *recalcescence*. Chatelier and Pinchon found that at about  $700^{\circ}$  a molecular modification of pure iron is formed.

The author's experiments show that as the proportion of carbon increases from 0.16 to 1.25 per cent. the temperature at which the molecular alteration takes place falls, whilst the point of recalcescence rises, until in hard steel the two points coincide. The rate at which heating takes place has no influence on the temperature at which the two changes take place, but these temperatures are affected by the rate of cooling, and are lower the greater the rapidity with which cooling takes place. In quick tempering, no such phenomena are observed; the heat corresponding with the non-effected changes remains in the iron. The two critical points also fall somewhat if the initial temperature of heating is raised. During annealing after tempering, the latent heat of tempering is liberated gradually and not abruptly.

C. H. B.

**Tungsten.** By T. KNIESCHE (*Chem. Zeit.*, 10, 1067—1068).—In treating tungsten ores, sodium tungstate is first obtained, then from this tungstic acid, which in its turn is reduced at a temperature of  $1600^{\circ}$  to metallic tungsten. The preparation of the chemically pure metal is simply a question of time; any way, as obtained at present, it is useful in steel making. It must be added only when the iron is in a perfectly fluid state. Sodium tungstate is used for rendering inflammable materials fireproof.

D. A. L.

**Titanium.** By O. v. PFORDTEN (*Annalen*, 234, 257—299).—The sulphides of those metals which have a strong affinity for oxygen cannot be obtained in the pure state by passing carbon bisulphide over the metallic oxides at a red heat, but they can be prepared by the

action of pure sulphuretted hydrogen on the metallic chlorides. The gas must be passed through chromous chloride to remove traces of oxygen, and is then dried by means of phosphoric oxide. The author disputes Thorpe's statement (*Trans.*, 1885, 492) that sulphuretted hydrogen can be dried by passing the gas through sulphuric acid. At the ordinary temperature, sulphuretted hydrogen reduces titanous chloride to titanous chloride; at a higher temperature, a compound is precipitated, which is probably a sulphochloride. Crystals of titanium disulphide,  $TiS_2$ , are deposited when sulphuretted hydrogen and the vapour of titanium tetrachloride are passed through a red-hot tube from which atmospheric air has been carefully expelled. The bisulphide is not attacked by hydrogen at a red heat in the presence of an excess of sulphuretted hydrogen. At a red heat, it is oxidised completely by carbonic anhydride, and it splits up into the sesquisulphide,  $Ti_2S_3$ , and sulphur in an atmosphere of hydrogen or nitrogen. The sesquisulphide is a metallic grey substance, insoluble in sodium hydroxide solution; it dissolves in nitric and strong sulphuric acids with a green coloration. The author is of opinion that the sesquisulphide described by Thorpe (*loc. cit.*) is an impure substance, and that its green colour is due to the presence of vanadium.

The sesquisulphide is reduced to monosulphide by hydrogen at a higher temperature than that at which refractory glass softens. The crystals of the monosulphide are dark red. Dilute nitric acid attacks the monosulphide with difficulty; in other respects, this substance resembles the sesquisulphide.

W. C. W.

**Atomic Weight of Germanium.** By L. DE BOISBAUDRAN (*Compt. rend.*, 103, 452—453).—Winkler's recent determination of the atomic weight of germanium, 72.32 (*Abstr.*, 1886, 985), agrees perfectly with the value calculated by the author from the wave-lengths of the lines in the germanium spectrum (*Abstr.*, 1886, 768). The law of proportionality between the variations in the atomic weights of the elements, and the variations in the wave-lengths of the lines in their respective spectra, thus receives further confirmation.

C. H. B.

**Gold Oxides.** By G. KRÜSS (*Ber.*, 19, 2541—2549).—Aurous oxide,  $Au_2O$ , could not be obtained in the pure state by any of the known methods. It is prepared by treating the double bromide of gold with aqueous sulphurous acid at  $0^\circ$  until the intense red colour of the bromide has disappeared. The colourless solution of aurous bromide so formed is warmed with potash, which causes a separation of aurous hydroxide. The oxide is dark violet when moist, greyish-violet when dry; when freshly precipitated, it dissolves in cold water, yielding an indigo-coloured solution with a brownish fluorescence; it is insoluble in hot water. The solution has a characteristic absorption spectrum showing a band at  $\lambda = 587.0$ . Hydrochloric and hydrobromic acids convert it into gold and the corresponding auric compounds; other acids have no action. The hydroxide parts with water at  $200^\circ$ , and at  $250^\circ$  gives up its oxygen.

Aurosoauric oxide,  $Au_2O_2$  (compare Schottländer, *Abstr.*, 1883, 853),

is prepared by gradually heating pure auric hydroxide up to  $160^{\circ}$  until the weight remains constant. It is a fine dark yellowish-brown powder, is very hygroscopic, and can only be kept over phosphoric anhydride. When heated above  $173^{\circ}$ , it gives off oxygen.

Auric oxide,  $\text{Au}_2\text{O}_3$ , is conveniently obtained by treating auroauric chloride (1 part) with water (50 parts), boiling the solution, and adding finely powdered magnesia alba, stirring the whole time, until the red colour of the auric chloride has disappeared. The gold trihydroxide is filtered, mixed with water (20 parts), treated with nitric acid, sp. gr. 1.4 (10 parts), and left for 24 hours. The residue, after filtering, is mixed with an equal amount of water and nitric acid, and heated for six hours at  $100^{\circ}$ . The undissolved portion is now free from magnesia, and is washed with water to remove nitric acid. The pure auric hydroxide has a yellowish-brown colour when moist, and is rather readily soluble in nitric acid. When kept for weeks over phosphoric anhydride, it is converted into aurylie hydroxide,  $\text{AuO}\cdot\text{OH}$ , and when carefully heated yields auric oxide.

The so-called "purple oxide of gold" appears to be gold in a finely divided state.

The author was unable to obtain Prat's gold superoxide and Figuier's auric acid (*Compt. rend.*, **70**, 844), or any other oxide of gold than the three described. This behaviour of gold is in accordance with the position (between platinum and mercury) assigned to it in the periodic arrangement of the elements.

N. H. M.

**Solubility of some Gold Compounds.** By T. ROSENBLADT (*Ber.*, **19**, 2535—2538).—The following table shows the amounts of the anhydrous double salts contained in 100 parts by weight of aqueous solution at the given temperatures:—

|                   | $10^{\circ}$ . | $20^{\circ}$ . | $30^{\circ}$ . | $40^{\circ}$ . | $50^{\circ}$ . | $60^{\circ}$ . | $70^{\circ}$ . | $80^{\circ}$ . | $90^{\circ}$ . | $100^{\circ}$ . |
|-------------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|-----------------|
| $\text{NaAuCl}_4$ | 58.2           | 60.2           | 64.0           | 69.4           | 77.5           | 90.0           | —              | —              | —              | —               |
| $\text{LiAuCl}_4$ | 53.1           | 57.7           | 62.5           | 67.3           | 72.0           | 76.4           | 81.0           | 85.7           | —              | —               |
| $\text{KAuCl}_4$  | 27.7           | 38.2           | 48.7           | 59.2           | 70.0           | 80.2           | —              | —              | —              | —               |
| $\text{RbAuCl}_4$ | 4.6            | 9.0            | 13.4           | 17.2           | 22.2           | 26.6           | 31.0           | 35.3           | 39.7           | 44.2            |
| $\text{CsAuCl}_4$ | 0.5            | 0.8            | 1.7            | 3.2            | 5.4            | 8.2            | 12.0           | 16.3           | 21.7           | 27.5            |

The solubilities of the double salts (with exception of the lithium salt) are inversely proportional to the molecular weights of the salts.

N. H. M.

## Mineralogical Chemistry.

**Artificial Breithauptite from the Mechernich Lead Furnaces.** By A. BRAND (*Zeit. Kryst. Min.*, 12, 234—239).—In 1885 the author found a number of peculiar crystals in the clay used for stopping the tap-holes of the lead furnaces in which antimonial lead was smelted. They occur in all the furnaces; the clay being pulverised and used again. It is therefore impossible to determine whether they were originally formed in the smelting of hard lead. The crystals were columnar, hexagonal prisms, 0·1 to 0·5 mm. thick, and 5 to 26 mm. long. They were brittle, had an uneven fracture, adamantine lustre, steel-grey to copper-red colour, and greyish-brown streak. The hardness was 5 to 5·5, and the sp. gr. about 8. Analysis of carefully purified material gave the following results:—

| Sb.   | Ni.   | Co.  | Pb.  | Cu.  | Fe.  | Total. |
|-------|-------|------|------|------|------|--------|
| 65·46 | 29·67 | 1·12 | 1·39 | 0·16 | 1·45 | 99·25  |

The formula of the mineral is thus NiSb.

B. H. B.

**Chemical Composition of Butyrellite.** By W. I. MACADAM (*Min. Mag.*, 6, 175—180; *Zeit. Kryst. Min.*, 12, 182).—In the investigation of ten samples of bog-butter or butyrellite (Dana) from various localities in the peat bogs of Scotland and Ireland, the author found that the portion of the butyrellite soluble in ether corresponded in all respects with the substance obtained under like conditions from ordinary butter. This portion varies in the ten analyses from 91·52 to 98·94 per cent. The portion insoluble in ether, 0·38 to 4·56 per cent., was slightly soluble in water, and gave evidence of the presence of milk-sugar. The portion insoluble in water contained nitrogen, and gave on combustion the peculiar odour of burning cheese. The ash or mineral portion, 0·01 to 0·36 per cent., contained traces of phosphoric acid. These results, and the fact that a number of cow's hairs were found in the samples, show that butyrellite has no claim to be called a mineral. It cannot be discussed how these masses found their way into the positions from which they are now obtained. It is, however, obvious that the material is not of mineral or even of resinous origin, but of undoubted animal derivation, and should therefore be erased from the list of minerals.

B. H. B.

**Minerals from Vesuvius.** By E. SCACCHI (*Zeit. Kryst. Min.*, 12, 202—203).—1. *Hydrogiobertite* is the name given by the author to a new hydrated magnesium carbonate, which occurs in the form of grey, compact masses 2 to 15 mm. in diameter. With the lens, minute magnetite crystals are observed enclosed in the mass. The sp. gr. is 2·149 to 2·174. The loss on ignition amounted to 53·07 per cent. Of the sample, 0·507 gram contained 0·0025 gram of magnetite, and 0·022 gram of ferric oxide which was subtracted as limonite with the magnetite. The results of the analysis were as follows:—

| CO <sub>2</sub> . | MgO.  | H <sub>2</sub> O. | Total. |
|-------------------|-------|-------------------|--------|
| 25.16             | 44.91 | 29.93             | 100.00 |

The formula of the new mineral is  $\text{Mg}_2\text{CO}_4 + 3\text{H}_2\text{O}$ .

The hydrogiobertite was discovered near Pollena in a block of augitophyre very closely resembling lava. In the interior, the structure was crystalline. On this rock was a compact mixture of silicates (plagioclase, augite, and magnetite) with which the hydrogiobertite was associated.

2. *Altered Aragonite*.—In the mother-rock of the hydrogiobertite, described above, hexagonal prisms, 3—4 mm. long and 1—1.5 mm. broad were found. They are white and opaque, and for the most part soluble in acids; the insoluble portion frequently preserving the original form of the crystal, or becoming divided longitudinally into prismatic fragments. On heating at  $170^\circ$ , there was a loss of 6.81 per cent. In hydrochloric acid, 11.78 per cent. was insoluble; this portion was found to contain 58.97 per cent. of silica with ferric oxide, alumina, and lime; whilst the soluble portion consisted essentially of lime. The insoluble substance also occurs in the interior of the crystals.

3. *Fluorspar*.—A number of minute octahedral crystals occurring on a lava from Pollena (1872) were found to be fluorspar. This mineral has hitherto been unknown in the lavas of Vesuvius and other volcanoes. Associated with the fluorspar are minute acicular crystals of apatite.

B. H. B.

**Chemical Constitution of Barytocalcite and Alstonite.** By A. BECKER (*Zeit. Kryst. Min.*, 12, 222—227).—The monoclinic barytocalcite and the rhombic alstonite have hitherto been regarded as having the same chemical composition ( $\text{BaCO}_3 + \text{CaCO}_3$ ). The question now arises whether they should both be considered isomorphous mixtures of  $\text{BaCO}_3$  and  $\text{CaCO}_3$ , or whether one of them is not a molecular compound of the two carbonates with the formula  $\text{BaCaC}_2\text{O}_6$ . Groth regards barytocalcite as a molecular compound of this kind, whilst alstonite, he thinks, is an isomorphous mixture of equal amounts of the two salts. This view is confirmed experimentally by the author, who gives the following results of a series of analyses of the two minerals in question:—

|      | BaO.  | CaO.  | MnO. | CO <sub>2</sub> . | Insol. res. | Total. |
|------|-------|-------|------|-------------------|-------------|--------|
| I.   | 50.09 | 19.77 | 0.35 | 29.52             | —           | 99.73  |
| II.  | 50.36 | 19.22 | 0.25 | 29.44             | 0.30        | 99.57  |
| III. | 51.59 | 18.61 | 0.35 | 29.39             | 0.28        | 100.22 |
| IV.  | 44.69 | 23.40 | 0.29 | 31.71             | —           | 100.09 |
| V.   | 37.41 | 29.06 | 0.30 | 32.21             | —           | 98.98  |
| VI.  | 50.97 | 19.83 | —    | 29.65             | 0.25        | 100.70 |
| VII. | 51.45 | 19.89 | 0.20 | 29.52             | —           | 101.06 |

All the specimens analysed were from Alston Moor.

I. Barytocalcite, purchased from Stürtz of Bonn. II. Barytocalcite, purchased from Pech of Berlin. III. Barytocalcite from the

mineralogical museum of the University of Leipzig. These three analyses correspond with the formula  $\text{BaCO}_3 + \text{CaCO}_3$ .

IV. Alstonite from Pech of Berlin; formula  $3\text{BaCO}_3 + 4\text{CaCO}_3$ .

V. A second specimen of the same, formula  $\text{BaCO}_3 + 2\text{CaCO}_3$ .

VI. Alstonite, purchased from Gregory of London, formula  $\text{BaCO}_3 + \text{CaCO}_3$ .

VII. Alstonite from the mineralogical museum of the University of Leipzig, formula  $\text{BaCO}_3 + \text{CaCO}_3$ .

For the three specimens of barytocalcite analysed, the same formula ( $\text{BaCO}_3 + \text{CaCO}_3$ ) is obtained; so that this mineral must be regarded as a molecular compound; whilst of the four specimens of alstonite analysed, two had the same formula ( $\text{BaCO}_3 + \text{CaCO}_3$ ), and the other two the formulæ  $3\text{BaCO}_3 + 4\text{CaCO}_3$  and  $\text{BaCO}_3 + 2\text{CaCO}_3$ . Alstonite, consequently, is undoubtedly an isomorphous mixture of the two carbonates.

B. H. B.

**Chemical Composition of Herderite.** By A. DES CLOIZEAUX and A. DAMOUR (*Zeit. Kryst. Min.*, 12, 204).—Since Des Cloizeaux (Abstr., 1884, 827) established the optical identity of the herderite crystals from Stoneham, Maine, and from Ehrenfriedersdorf, Saxony, C. Winkler (Abstr., 1884, 1102) has given an analysis of the crystals from both localities, attributing the loss to water, and not to fluorine. Subsequently F. A. Genth (Abstr., 1885, 488) found 8.93 per cent. of fluorine in the Stoneham herderite. These discordant results have induced the authors to make a fresh investigation, and their analysis shows the presence of a considerable amount of fluorine. The sp. gr. of the mineral examined was 2.98 (compare Abstr., 1885, 359).

B. H. B.

**Minerals from Tuscany.** By L. BUSATTI (*Zeit. Kryst. Min.*, 12, 200—202).—At Caprillone, near Montecatini, fine, large crystals of barytes are found in geodes in conglomerate and miocene marl-limestone. The crystals are opaque, porcelain-white at the edges, and reddish-yellow in the middle. In appearance, the crystals resemble those of celestine. Analysis gave the following results:—

| Ba.   | Ca.  | SO <sub>4</sub> . | Total. | Sp. gr. |
|-------|------|-------------------|--------|---------|
| 57.82 | 0.24 | 41.09             | 99.15  | 4.38    |

The author also describes a twin-crystal of hæmatite from Rio in Elba, in the Pisa Museum, exhibiting the planes R,  $\frac{1}{2}\text{R}$ ,  $-\frac{1}{8}\text{R}$ ,  $\frac{2}{3}\text{R}$ ,  $\frac{1}{3}\text{P}$ . The twinning axis is perpendicular to  $\infty\text{R}$ . Descriptions are also given of crystals of chlorite from Bottino in the Apuan Alps; quartz from the Cala dell' Allume ore-bed in the island of Giglio; gypsum from the same locality; pyrolusite from the manganese ore-bed of the Campese in the island of Giglio; and magnetite and epidote from Romito.

B. H. B.

**Rare Copper Minerals from Utah.** By G. S. MACKENZIE (*Min. Mag.*, 6, 181—182; *Zeit. Kryst. Min.*, 12, 182—183).—The author gives analyses of two minerals from the American Eagle Mine, Utah Territory, occurring in intimate association with olivenite and other copper compounds. The results of the analyses were as follows:—

|     | CuO.  | CaO.  | MgO. | ZnO. | Ag.  | Fe <sub>2</sub> O <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | As <sub>2</sub> O <sub>5</sub> . |
|-----|-------|-------|------|------|------|----------------------------------|----------------------------------|----------------------------------|
| I.  | 28.59 | 19.67 | 0.61 | 2.75 | 0.29 | 0.45                             | —                                | 39.80                            |
| II. | 26.88 | 0.55  | 0.23 | —    | —    | 26.94                            | 1.17                             | 34.62                            |

|     | P <sub>2</sub> O <sub>5</sub> . | H <sub>2</sub> O. | CO <sub>2</sub> . | Quartz. | Total. |
|-----|---------------------------------|-------------------|-------------------|---------|--------|
| I.  | 0.20                            | 5.55              | (0.98)            | 1.11    | 100.00 |
| II. | —                               | 9.25              | —                 | 0.71    | 100.35 |

I. *Conichalcite* in emerald-green globules. II. *Chenevixite* scattered in patches throughout such parts of the ore as occur in hard lumps, in a greenish opaque body with no lustre (compare Abstr., 1886, 516). B. H. B.

**Columbite.** By E. S. DANA (*Zeit. Kryst. Min.*, 12, 266—274).—In 1861 Schrauf published his monograph on this mineral, in which the axial ratio is stated to be  $a : b : c = 0.40744 : 1 : 0.33467$ . The author has now made an exhaustive investigation of the recently discovered crystals from Standish in Maine. He gives a list of the 13 planes observed, and finds the axial ratio to be  $a : b : c = 0.40234 : 1 : 0.35798$ . The angles calculated from this ratio, on the whole, agree better with those given by Dana (1837) and Des Cloizeaux (1851) than with those given by Schrauf. The frequently repeated question whether columbite does not belong to the monosymmetric system like wolfram, is answered by the author in the negative. There can be no doubt that columbite crystallises in the rhombic system. B. H. B.

**Plagioclase from California.** By K. VON CHROUSTSCHOFF (*Zeit. Kryst. Min.*, 12, 204—205).—The felspar examined forms large dark tabular crystals in a hypersthenite from San-Diego. The angles made by the directions of extinction with the edge formed by the faces 0P and  $\infty P\infty$ , on cleavage plates taken parallel to 0P is  $+1^\circ$  to  $+2^\circ$ , on plates parallel to  $\infty P\infty$   $+12^\circ$ . Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | CaO. | Fe <sub>2</sub> O <sub>3</sub> . | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. |
|--------------------|----------------------------------|------|----------------------------------|------|-------------------|--------------------|
| 65.17              | 21.04                            | 1.20 | 0.74                             | 0.04 | 1.70              | 9.20               |

Loss on  
ignition.  
0.80

Total.  
99.89

Sp. gr.  
2.659

B. H. B.

**Oligoclase.** By A. DES CLOIZEAUX and F. PISANI (*Zeit. Kryst. Min.*, 12, 204).—A flesh-coloured felspar from Telemarken (Norway) with a cleavage angle  $\infty P\infty : 0P$ , equal to  $86^\circ 30'$ , proves to be an oligoclase of the first class (Abstr., 1886, 776). The extinction on plates parallel to 0P is  $+1^\circ$  to  $2\frac{1}{2}^\circ$ , parallel to  $\infty P\infty$   $+10^\circ$  to  $12^\circ$ . Analysis gave the following results (I):—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | Na <sub>2</sub> O. | K <sub>2</sub> O. | Loss on<br>ignition. | Total. | Sp. gr. |
|-----|--------------------|----------------------------------|----------------------------------|------|--------------------|-------------------|----------------------|--------|---------|
| I.  | 65.30              | 23.00                            | —                                | 2.42 | 9.65               | 0.70              | 0.20                 | 101.27 | 2.610   |
| II. | 62.25              | 24.80                            | 0.25                             | 4.90 | 7.80               | 0.80              | 0.20                 | 101.00 | 2.628   |

For comparison, an analysis (II) of sunstone from Frederiksvärn (*Zeit. Kryst. Min.*, 11, 648) was made. As in the sunstone from Tvedestrand, the percentage of ferric oxide is very small in spite of the large amount of hæmatite particles intermingled. B. H. B.

**Botryogene.** By J. HOCKAUF (*Zeit. Kryst. Min.*, 12, 240—254).—The author gives the results of two analyses of botryogene from the Vienna Museum. The specimen examined formerly belonged to Haidinger, and probably supplied the material for his original investigations. The analytical results were as follows:—

|     | SO <sub>3</sub> . | $\overbrace{\text{Fe}_2\text{O}_3. \text{ MnO.}}$ | FeO. | CaO. | MgO. | H <sub>2</sub> O. | Residue. | Total. |        |
|-----|-------------------|---|------|------|------|-------------------|----------|--------|--------|
| I.  | 37.12             | 18.31   | 2.24 | 0.75 | 7.91 | 34.10             | 0.34     | 100.77 |        |
| II. | 37.00             | 16.69   | 1.93 | 2.24 | 1.06 | 7.40              | 34.10    | 0.30   | 100.72 |

The formula adopted by the author is  $5\text{R}''\text{SO}_4 + 2(\text{Fe}_2\text{S}_2\text{O}_9) + 38\text{H}_2\text{O}$ . A mineral is frequently sold by the dealers as botryogene, which is not identical with it. There is a specimen thus obtained in the Vienna Museum, an analysis of which gave the following results:—

| SO <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | MnO. | CaO. | MgO. | H <sub>2</sub> O. | Total. |
|-------------------|----------------------------------|----------------------------------|------|------|------|------|-------------------|--------|
| 33.53             | 4.52                             | 1.93                             | 2.09 | 2.34 | 0.79 | 5.44 | 48.68             | 99.32  |

**Flexibility of Itacolumite.** By G. SPEZIA (*Zeit. Kryst. Min.*, 12, 202).—The author was induced to test the accuracy of the general theory as to the cause of the flexibility of itacolumite by the fact that the flexible mica-like mineral occurs but sparsely in the itacolumite of North Carolina. His observations show that the rock is flexible when it is composed exclusively of quartz-grains. Under the microscope each separate grain is seen to be distinctly flexible. This may also be observed in the coarsely granular itacolumite from Mariaña in Brazil. The itacolumite examined is also very porous, as is shown by the rapid absorption of liquids. A prism weighing 186.444 grams absorbed 5.825 grams of distilled water, and had a volume of 73.5 c.c., of which 5.825 c.c. were of course taken up by the absorbed water, and thus represent the intergranular space. The tenacity of this itacolumite is also remarkable. The fracture of a prism 6.29 square cm. in section, by tension in the direction of the plane of cleavage and longitudinal axis of the flexible mica-like lamellæ, was effected with a load of 29.66 kilos. (= 67.06 lbs. per square inch). This tenacity is obviously due to the twisting of the quartz-grains, whilst the porosity is due to their power of moving. Consequently, the flexibility of itacolumite may be explained mechanically from the form and relative position of the quartz-grains, without assuming a flexible mineral. This conclusion is in accordance with the author's observations that rectangular prisms cut in different directions exhibit uniform flexibility.

**Volcanic Fragments from the Lake of Bracciano.** By G. STRÜVER (*Zeit. Kryst. Min.*, 12, 197—200).—Numerous volcanic

fragments have recently been discovered in the district between l'Anguillara and the Lake of Martignano, in the midst of an enormous heap of angular fragments of limestones, leucitic and tephritic lavas, leucite phonolites, and trachytes. Similar materials have been found at Monte S. Angelo and near Cesano, in grey tuff. In these volcanic fragments, the following minerals have been found:—Pleonast, magnetite, limonite, wollastonite, pyroxene, hornblende, garnet, idocrase, humboldtilite, merxene, sarkolite, nepheline, hauyn, leucite, anorthite, sanidine, titanite, apatite, and calcite. Of these minerals, *sarkolite* is the most interesting, as it has hitherto only been observed as a rare mineral in the Somma volcanic bombs. The crystals are 10 mm. long, 10 mm. broad, and 5 mm. deep. The combinations observed are  $OP. \infty P\infty. P.$  and  $OP. \infty P\infty. P. P\infty. \frac{1}{3}P. \infty P. 3P3$ . Fracture conchoidal, vitreous lustre, flesh colour or colourless, translucent to transparent, streak white, hardness 6, optically uniaxial, double refraction positive.

B. H. B.

**Cosmical Powder which fell on the Cordilleras, near San Fernando, Chili.** By A. E. NORDENSKIÖLD (*Compt. rend.*, 103, 682—686).—This powder fell for about half an hour on the surface of fresh fallen snow on the Cordilleras, in November, 1883. During this month a peculiar red glow was observed in the sky in the evening, and the atmosphere was highly charged with electricity. The powder was collected by C. Stolp and forwarded to the author. It consists mainly of irregularly rounded reddish-brown grains, frequently agglomerated in somewhat large masses, which showed no signs of fusion, and dissolved, though slowly, in hydrochloric acid. The powder also contained a small quantity of annular scales, probably feldspar and green hexagonal plates, which consisted chiefly of mica. No metallic iron was present. The powder had the following composition:— $Fe_2O_3$ , 74.59;  $NiO$ , with traces of  $CoO$ , 6.01;  $CuO$ , traces;  $P_2O_5$ , 0.63;  $SO_3$ , 0.37;  $SiO_2$ , 7.57;  $Al_2O_3$ , 2.90;  $CaO$ , 0.31;  $MgO$ , 3.88; loss on heating, 2.61 = 98.87. A small quantity of alkali is probably also present.

The composition of the powder shows that it is not a product of the Krakatoa eruption, and is not of terrestrial origin. It is evidently of cosmical origin, but there is no proof that the red glow in the sky was in any way connected with the fall of the powder.

C. H. B.

**Meteorite in a Tertiary Lignite.** By GURLT, with Note by DAUBRÉE (*Compt. rend.*, 103, 702—703).—The meteorite was found in a block of tertiary lignite from Wolfsegg. It formed a rectangular parallelepiped 67 mm. by 62 mm. by 47 mm., and weighed 785 grams. The surface showed cupules similar to those observed on meteorites, and was covered with a thin layer of magnetic oxide of iron. The meteorite is a holosiderite, and contains carbon with a trace of nickel, but no quantitative analysis was made. It showed cubical cleavage, but a polished surface did not show Widmanstätt's figures when treated with acid.

Daubrée considers that the position of the meteorite and other

evidence proves that the "meteorite" was deposited in the lignite during the formation of the latter. C. H. B.

*Note by Abstractor.*—Lawrence Smith has shown (Abstr., 1879, 892) that the native iron found in the miocene lignites of Greenland is really of terrestrial origin. C. H. B.

**Analysis of Mineral Springs in Aegina and Andros.** By A. K. DAMBERGIS (*Ber.*, 19, 2538—2540).—The water from Aegina springs from a calcareous rock, has a salt taste, and a temperature of 26°; sp. gr. at 12° = 1·009635; 10,000 c.c. of the water contain—

|                                      |         |        |
|--------------------------------------|---------|--------|
| Calcium sulphate.....                | 12·3757 | grams. |
| Sodium carbonate.....                | 4·2400  | "      |
| „ chloride .....                     | 84·0915 | "      |
| Potassium chloride .....             | 1·9455  | "      |
| Magnesium bromide.....               | 0·3050  | "      |
| „ chloride.....                      | 15·4679 | "      |
| Calcium carbonate .....              | 0·8501  | "      |
| Magnesium carbonate .....            | 3·4391  | "      |
| Iron carbonate .....                 | 0·0160  | "      |
| Alumina.....                         | 0·0200  | "      |
| Silica .....                         | 0·1600  | "      |
| Carbonic anhydride (half combined) . | 4·1004  | "      |
| Free carbonic anhydride.....         | 1·4150  | "      |

Traces of strontia, fluorine, iodine, nitric and phosphoric acids, ammonia, lithia, and organic substances are also present in the water.

The water of Andros has an agreeable taste, is colourless and without odour; it is used on account of its medicinal properties; 10,000 c.c. of the water contain—

|                                      |         |       |
|--------------------------------------|---------|-------|
| Sodium carbonate.....                | 0·12046 | gram. |
| Calcium „ .....                      | 0·83000 | "     |
| Magnesium carbonate .....            | 0·25140 | "     |
| Calcium sulphate .....               | 0·24010 | "     |
| Sodium chloride .....                | 1·11996 | "     |
| Potassium chloride .....             | 0·09586 | "     |
| Magnesium „ .....                    | 0·18192 | "     |
| Alumina .....                        | 0·06000 | "     |
| Silica .....                         | 0·14400 | "     |
| Carbonic anhydride (half combined).. | 0·54680 | "     |
| „ „ (free) .....                     | 0·15640 | "     |

Traces of iron carbonate, ammonia, nitric and phosphoric acids, and organic substances were also found to be present. N. H. M.

## Organic Chemistry.

**Volatility of Methane-derivatives.** By L. HENRY (*Compt. rend.*, 103, 603—606).—The volatility of methane-derivatives follows the same order as that of the substituted elements when the latter are arranged in natural families in the order of their atomic weights. The boiling point rises as the molecular weight increases, but the differences between the volatility of the methane-derivatives are much less than those between the boiling points of the electronegative elements which they contain.

|                 | B. p. | Diff. |                               | B. p. | Diff. |
|-----------------|-------|-------|-------------------------------|-------|-------|
| Cl, gas .....   | — 33° | 96°   | MeCl, gas ....                | — 23° | 27·5  |
| Br, liquid .... | + 63  |       | MeBr, gas ....                | + 4·5 |       |
| I, solid .....  | + 250 | 187   | MeI, liquid ...               | 44    | 39·5  |
| O, gas.....     | — 181 |       | Me <sub>2</sub> O, gas .....  | — 23  |       |
| S, solid .....  | + 448 | 629   | Me <sub>2</sub> S, liquid ... | + 37  | 60·0  |
| N, gas .....    | — 193 |       | Me <sub>3</sub> N, gas .....  | + 9   |       |
| P, solid .....  | + 287 | 480   | Me <sub>3</sub> P, liquid ... | + 41  | 50·0  |

The differences show that electronegative elements in the same natural family are far from being comparable in the free state, whilst in methane-derivatives they may be regarded as existing under analogous physical conditions.

In each of the groups of methane-derivatives, the rise of the boiling point is not proportional to the increase in the molecular weight; in fact the greater the increase in the molecular weight resulting from substitution, the less proportionally is the rise of the boiling point. The substitution of sulphur causes proportionally less rise in the boiling point than the substitution of oxygen, and the substitution of phosphorus less than the substitution of nitrogen, although sulphur and phosphorus are solids, whilst oxygen and nitrogen are gases.

The atomic weights being nearly equal, the diminution of volatility resulting from substitution is greater the more strongly marked the electronegative character of the substituted element, or, in other words, the more distinctly its properties differ from those of hydrogen. This is well seen in the case of the nitrogen- and boron-derivatives.

Me<sub>3</sub>N, mol. wt. 59, a liquid boiling at 9·3°.

Me<sub>3</sub>B, mol. wt. 56, a gas which liquefies at —10° under a pressure of 3 atmos.

This phenomenon is doubtless connected with the fact that the heat of combination of carbon with electronegative elements diminishes as the atomic weight of the latter increases. C. H. B.

**Sugars.** By BERTHELOT (*Compt. rend.*, 103, 533—537).—A solution of invert sugar which had been kept for nearly 30 years, deposited spheroidal groups of radiating crystals, which when care-

fully dried on filter-paper resembled purified glucose. The crystals have the composition  $C_6H_{12}O_6$  when anhydrous; their reducing power is equal to that of glucose, and they are completely fermentable, but their rotatory power is only  $[\alpha]_D = +32.2$ , or little more than half that of glucose. The crystals are a compound of glucose and levulose, in which one constituent behaves like water of crystallisation. The compound is decomposed by solvents; its rotatory power shows that the ratio of levulose to glucose is 1 : 5. A similar compound prepared by Gélis has the rotatory power of  $+15^\circ$ , which corresponds with a ratio of levulose to glucose of 1 : 3.

The compound formed as an intermediate product in alcoholic fermentation is most probably formed by the union of one molecule of levulose with two of glucose, but it does not seem to have been obtained in crystals.

In the process of extracting raffinose from cotton-seed cake, crystals were obtained which when dried on filter-paper without treatment with any solvent had all the properties of mellitose from the manna of eucalyptus. When the aqueous solution of this substance is treated with yeast, only half the sugar undergoes fermentation, and the liquid contains a non-fermentable sugar with the properties of eucalyne. If the mellitose is treated with boiling alcohol, it splits up into raffinose, which crystallises after some time, and eucalyne, which remains in solution. An alcoholic solution of raffinose and eucalyne when allowed to remain, deposits crystals which seem to be formed by the recombination of the raffinose with the eucalyne.

Mellitose, which is widely diffused in the vegetable kingdom, is the result of the association of raffinose, a true saccharose, with eucalyne, a non-fermentable carbohydrate. This association bears no resemblance to the union of glucoses to form saccharoses, and the constitution of mellitose is analogous to that of hydrates and alcohols rather than to that of ethereal salts.

C. H. B.

**Sugar formed in the Inversion of Lichens.** By P. KLASON (*Ber.*, 19, 2541).—Bauer showed (*Abstr.*, 1886, 869) that dextrose is formed by inverting lichens. The author previously obtained the same results (*Lund's Fysiogr. Sällskops Minneskr.*, 1878, 61). Apparently no other sugar is formed in the inversion.

N. H. M.

**Action of Dilute Acids on Grape-sugar and Fruit-sugar.** By M. CONRAD and M. GUTHZEIT (*Ber.*, 19, 2569—2574).—According to Tollens and v. Grote (*Annalen*, 175, 181, and 206, 207), dextrose as well as levulose when boiled with sulphuric, or better with hydrochloric acid, yields acetopropionic acid in very small quantity.

Quantitative experiments on the decomposition of cane-sugar by hydrochloric acid, made by the authors (*Abstr.*, 1885, 745), pointed to the formation of a small amount of acetopropionic acid from dextrose. Experiments described in the present paper show that this view (the formation of acetopropionic acid chiefly from levulose) only holds good for the decomposition of cane-sugar with dilute sulphuric acid, and not with hydrochloric acid.

Quantities of dextrose and levulose corresponding with 20 grams of

cane-sugar were heated for 17 hours with the same amounts of acid and water as those previously used (*loc. cit.*).

1. Decomposition with dilute sulphuric acid—

|                |         | Humic<br>substances. | Dextrose. | Aceto-<br>propionic<br>acid. | Formic<br>acid. |

N. H. M.

**Decomposition of Milk-sugar by Dilute Hydrochloric Acid.**

By M. CONRAD and M. GUTHZEIT (*Ber.*, 19, 2575—2576).—The following results were obtained from three experiments, in which 21, 21, and 10.5 grams of milk-sugar were heated with 50 c.c. of water and 4.87, 5.0, and 4.87 grams of hydrochloric acid respectively:—

|         | Humic<br>substances. | Milk-sugar<br>(unchanged). | Acetopropionic<br>acid. | Formic<br>acid. |
|---------|----------------------|----------------------------|-------------------------|-----------------|
| 1 ..... | 3.68                 | 5.54                       | 6.29                    | 2.39            |
| 2 ..... | 3.94                 | —                          | 5.80                    | 2.24            |
| 3 ..... | 1.60                 | —                          | 3.32                    | 1.33            |

In 2 and 3, the milk-sugar was not determined.

N. H. M.

**Carbohydrates.** By O. WALLACH (*Annalen*, 234, 364—375).—The rhizome of the water lily, *Iris pseudacorus*, contains a peculiar carbohydrate, called "irisin" by the author. *Irisin*,  $C_6H_{10}O_5 + H_2O$ , closely resembles inulin, but is distinguished from the latter by its more powerful action on polarised light;  $[\alpha]_D = -49^\circ 90$  for a 2 per cent. solution of irisin, and  $[\alpha]_D = -37^\circ 27'$  for a solution of inulin of the same strength. Fehling's solution is not reduced by irisin, but the carbohydrate is easily attacked by dilute acids, yielding levulose as the chief product. Irisin is four times as soluble as inulin in water at  $22^\circ$ . Under the microscope, the globules of irisin resemble the minute globules of inulin in size, but they do not exhibit double refraction.

W. C. W.

**Animal Gum.** By H. A. LANDWEHR (*Pflüger's Archiv*, 39, 193—204).—The animal carbohydrates may be arranged in parallel groups with those occurring in the vegetable kingdom, and animal gum resembles vegetable gum in yielding oxalic acid after treatment with nitric acid. It is obtained readily from mucin. Mucin was prepared

by precipitation with acetic acid from an extract of submaxillary glands, made with a 1 per cent. sodium carbonate solution. The precipitate was washed with weak acetic acid, and then dissolved in weak hydrochloric acid by the aid of heat. On neutralising with soda, a white flocculent precipitate is obtained, which is increased in amount on the addition of sodium sulphate and boiling. The precipitate is collected and freed from salt by dialysis; it consists of an ordinary proteid. The filtrate contains no nitrogen, but contains animal gum. From tendon mucin, the same carbohydrate is obtained, in spite of what Loebisch (Abstr., 1886, 166) says to the contrary; it may also be obtained from synovia, colloid cysts, and from the mucin of the snail's mantle. Mucin and animal gum both yield lævulic acid when treated with hydrochloric acid.

Another source of animal gum is chondrin. By long boiling with water, chondrin splits into gelatin, animal gum, and possibly a third substance not yet further investigated. Pure chondrin is soluble in hot water, and its solutions gelatinise when cold, if not too dilute; this power of gelatinising is lost after prolonged boiling. A dilute solution gives the following reactions:—Dilute mineral acids cause a precipitate soluble in excess; acetic acid gives a precipitate insoluble in excess; acetic acid and potassium ferrocyanide give a precipitate, soluble in excess of the latter reagent. Sodium chloride solution gives no cloud, but hinders the precipitation by acetic acid. Metaphosphoric acid gives a cloudiness disappearing on warmth. Alum gives a cloudiness, disappearing on adding excess. Lead acetate gives a precipitate, soluble in excess. Basic lead acetate gives a precipitate, partially soluble in excess. Lead acetate and ammonia give a flocculent precipitate, insoluble in excess. Tannin and acetic acid give a precipitate, insoluble in excess. Copper sulphate and sodium hydroxide colour the liquid violet, which becomes red on boiling. Boiling the solution for five or six hours with 1 per cent. sulphuric acid gives it the power of reducing copper salts, this being due to the formation of a reducing sugar from animal gum. Animal gum may be separated from chondrin in the same way as from mucin.

Metalbumin and paralbumin may also be used as sources of animal gum. It is also found in small quantities, but constantly in the red blood corpuscles, brain, kidney, spleen, liver, and pancreas. Proteïds proper do not yield it.

W. D. H.

**Derivatives of Thioformaldehyde.** By A. WOHL (*Ber.*, 19, 2344—2347).—*Thiometaformaldehyde*,  $(\text{CH}_2\text{S})_2$ , is obtained when an aqueous or alcoholic solution of hexamethyleneamine saturated with hydrogen sulphide is heated on a water-bath. It separates as a white, amorphous substance, which is washed with water and hydrochloric acid, and extracted with boiling glacial acetic acid and alcohol. It is insoluble in all the usual solvents, and has a peculiar odour; it melts at  $175\text{--}176^\circ$ , and decomposes at a high temperature. It dissolves unchanged in strong sulphuric acid.

*Methylthioformaldine*,  $\text{S}_2(\text{CH}_2)_3\text{NMe}$ , is prepared by diluting 50 c.c. of a 20 per cent. solution of formaldehyde with an equal volume of water, and saturating with hydrogen sulphide; 200 c.c. of water are

then added, the whole filtered and stirred with 20 c.c. of a 30 per cent. solution of methylamine. In 24 hours crystals separate. More hydrogen sulphide is then passed through the solution until it is no longer turbid; the crystals are collected, washed with water, and dissolved in ether. It crystallises in needles melting at  $65^{\circ}$ , and is insoluble in water, soluble in dilute mineral acids, alcohol and glacial acetic acid. It distils with steam, boils at about  $185^{\circ}$ , being at the same time converted into a compound melting at  $130$ – $140^{\circ}$ . The *hydrochloride* forms needles readily soluble in water; it melts at  $188^{\circ}$  with decomposition.

*Dimethylthioformaldinium iodide*,  $S_2(CH_2)_3NMe_2I$ , is formed by treating the compound with methyl iodide. In two to three days the liquid solidifies to a mass of slender, lustrous needles. It melts at  $161$ – $163^{\circ}$ , and dissolves readily in water, sparingly in alcohol. The *platinochloride*,  $[S_2(CH_2)_3NMe]_2Me_2PtCl_6$ , is a bright yellow, crystalline substance. The iodide dissolves in hot aqueous potash and separates unchanged on cooling. When boiled with silver oxide, it yields an ammonium base, which, however, could not be isolated.

N. H. M.

**Chloro-derivatives of Acetals.** By O. MAGNAMINI (*Gazzetta*, 16, 330–333).—*Trichloromethylethylacetal*,  $CCl_3 \cdot CH(OMe) \cdot OEt$ , is obtained by heating tetrachlorether with methyl alcohol in sealed tubes. The reaction is as follows:  $CCl_3 \cdot CHCl \cdot OEt + MeOH = HCl + CCl_3 \cdot CH(OMe) \cdot OEt$ . It is a colourless liquid of camphor-like odour; it boils at  $193.4$ ; sp. gr. =  $1.32$ .

*Trichlorodimethylacetal*,  $CCl_3 \cdot CH(CMe)_2$ , obtained from tetrachlorethyl methyl ether, is a liquid of similar characters. It boils at  $183.2^{\circ}$ ; sp. gr. =  $1.28$ .

The *tetrachlorethyl methyl ether*,  $CCl_3 \cdot CHCl \cdot OMe$ , prepared by the action of phosphoric chloride on chloral methylate, is a colourless liquid boiling at  $178^{\circ}$ ; sp. gr. at  $0^{\circ}$  =  $1.84$ . It does not appear to have been previously isolated.

V. H. V.

**Diisonitrosoacetone.** By H. v. PECHMANN and K. WEHSARG (*Ber.*, 19, 2465–2467).—V. Meyer and Züblin have shown that when acetoacetic acid is treated with nitrous acid, carbonic anhydride is evolved, and isonitrosoacetone formed. The authors find that when, in like manner, acetonedicarboxylic acid is treated with water and sodium nitrite, a rapid evolution of carbonic anhydride takes place, and *diisonitrosoacetone*,  $CO(CH \cdot NOH)_2$ , is produced. This forms glistening prismatic crystals, melting with decomposition at  $143$ – $144^{\circ}$ . It is easily soluble in alcohol and ether, sparingly in cold water, chloroform, and benzene. It is very unstable, and detonates when heated. Its aqueous solution when heated decomposes into hydrocyanic acid, carbonic anhydride, and water. Acids cause a similar decomposition, but hydroxylamine is also among the products. It is more stable in alkaline solutions, and forms *alkali salts*, which crystallise in orange-yellow needles. Its salts, especially the red crystalline *silver salt*, explode when heated. When warmed with phenol and sulphuric acid, the nitroso-compound gives a red coloration, with ferric chloride a brown. The authors are further investigating the subject.

L. T. T.

**Ketines.** By L. CECONOMIDES (*Ber.*, 19, 2524—2527).—When a very dilute solution of diethylketine,  $C_{10}H_{16}N_2$ , is treated with the theoretical amount of potassium permanganate, a ketenedicarboxylic acid is obtained, identical with that prepared by Wleügel by reducing ethyl isonitrosoethylacetate (*Abstr.*, 1882, 949). If the oxidation takes place in a warm solution, other and more unstable acids are formed. When 5 grams of ethyl imidoisonitrosobutyrate are carefully warmed with powdered zinc chloride at  $60-70^\circ$  for a long time, and the product saponified with alcoholic potash, a small quantity of an acid melting at  $190-195^\circ$ , identical with Wleügel's acid (*loc. cit.*), is formed. The above reactions, together with the fact that the ketine-acid does not yield an anhydride, point to the following constitutional formulæ for methylketine and the ketine-dicarboxylic acid:—

N. H. M.

**Pure Butyric Acid.** By A. BANNOW (*Ber.*, 19, 2552—2554).—Pure butyric acid is best prepared by converting the commercial acid into the ethyl salt, which is then fractionally distilled. The fraction boiling at  $120-121^\circ$  is reconverted into acid.

N. H. M.

**Derivatives of Tiglic Acid.** By P. MELIKOFF (*J. Russ. Chem. Soc.*, 1886, 287—297).—Tiglic (methylcrotonic) acid,

was prepared either by the saponification of the oil of Roman chamomile (Kopp, *Abstr.*, 1879, 454), or by heating  $\alpha$ -methyl- $\beta$ -hydroxybutyric acid (Rohrbeck, *Abstr.*, 1878, 136). The acid was treated under water with an aqueous solution of hypochlorous acid, the product of the reaction extracted with ether, and the solvent distilled off. The residue, after remaining for some time over sulphuric acid, solidified to a crystalline mass, which was found to consist of two isomeric chlorhydroxyvaleric acids,  $C_5H_9ClO_3$ . A concentrated aqueous solution of this mixture was neutralised with zinc carbonate: a crystalline zinc salt was precipitated, and the mother-liquor on being evaporated left another salt in the form of an amorphous humoid substance. The two acids obtained by decomposing these salts with sulphuric acid are both easily soluble in water, alcohol and ether; the one forming a crystalline sparingly soluble zinc salt, melts at  $75^\circ$ , and crystallises from ether in thin prisms; the other isomeride melts at  $111.5^\circ$ , and is obtained from its ethereal solution in the form of large, translucent prisms.

When a mixture of these acids, or each of them separately, is treated with alcoholic potash, the potassium salt of an anhydro-acid,

line needles having the odour of butyric acid, easily soluble in water, alcohol, and ether, melting at  $62^\circ$ . The energy with which it enters into direct combination is in the main the same as that shown by  $\beta$ -methylglycidic acid:  $\alpha$ -methylglycidic acid in this respect exhibiting

much greater energy. This circumstance, established by experiments on the hydration of the potassium salt by heating with water, is in accordance with the results obtained by the author in a former work on glycidic and  $\alpha$ - and  $\beta$ -methylglycidic acids (Abstr., 1885, 650). The energy of direct combination is diminished with increasing molecular weight in acids of analogous constitution; at the same time among isomeric acids the greatest energy is exhibited by the one containing tertiarily united carbon in its molecule.  $\alpha$ - $\beta$ -Dimethylglycidic acid contains one  $\text{CH}_2$ -group more than  $\alpha$ - and  $\beta$ -methylglycidic acids, but, on the other hand, one of its carbon-atoms combined with oxygen is in tertiary union.

By the action of hydrochloric acid on  $\alpha$ - $\beta$ -dimethylglycidic acid,  $\alpha$ -methyl- $\beta$ -chlor- $\alpha$ -hydroxybutyric acid,  $\text{OH}\cdot\text{CHMe}\cdot\text{CMeCl}\cdot\text{COOH}$ , is formed; it melts at  $75^\circ$ , and is identical with one of the chlorhydroxyvaleric acids above described, the other isomeride being therefore  $\alpha$ -methyl- $\alpha$ -chloro- $\beta$ -hydroxybutyric acid,  $\text{CHMeCl}\cdot\text{CMe}(\text{OH})\cdot\text{COOH}$ . An aqueous solution of  $\alpha$ - $\beta$ -dimethylglycidic acid, when heated during 8—10 hours at  $99^\circ$ , is converted into  $\alpha$ - $\beta$ -dimethylglycidic acid,  $\text{OH}\cdot\text{CHMe}\cdot\text{CMe}(\text{OH})\cdot\text{COOH}$ , melting at  $107^\circ$ , readily dissolving in water, alcohol, and ether. A. T.

**Constitution of Chlorhydroxybutyric and Dichlorobutyric Acid.** By P. MELIKOFF (*J. Russ. Chem. Soc.*, 1886, 227—303).—Chlorhydroxybutyric acid (formed by the combination of crotonic with hypochlorous acid, Abstr., 1884, 1301, and 1885, 650), when heated with concentrated sulphuric acid, yields monochlorocrotonic acid, crystallising in long, thin prisms, melting at  $98^\circ$ , sparingly soluble in cold, more readily in hot water, easily soluble in alcohol and ether. This acid yields normal crotonic acid (m. p.  $72^\circ$ ) on reduction by zinc and sulphuric acid. The chlorocrotonic acid above mentioned is an  $\alpha$ -chlorinated product, the isomeric  $\beta$ -derivative being obtained, amongst other methods, by the action of phosphorus pentachloride on ethyl acetoacetate; hence, the chlorhydroxybutyric acid in question must be  $\alpha$ -chloro- $\beta$ -hydroxybutyric acid.

This acid was heated with hydrochloric acid, and  $\alpha$ - $\beta$ -dichlorobutyric acid was obtained; it crystallises in long prisms and melts at  $69^\circ$ . An alcoholic solution of the latter compound, when treated with alcoholic potash, gives  $\alpha$ -monochlorocrotonic acid.  $\alpha$ - $\beta$ -Dichlorobutyric acid is formed in like manner when  $\alpha$ -monochlorocrotonic acid is heated with hydrochloric acid. A. T.

**Hydroxystearic Acids of Different Origin.** By A. C. and M. SAYTZEFF (*J. Russ. Chem. Soc.*, 1886, 328—348).—A hydroxystearic acid was prepared by one of the authors some time ago in his work on the oxidation of oleic acid (Abstr., 1886, 140). Another acid of this composition was discovered by Frémy (*Annalen*, 19, 296; 20, 50; 33, 10), who obtained it by the action of concentrated sulphuric acid on oleic acid, and described it under the name of hydro-margaritic acid. Although the main points of the reaction had been satisfactorily explained by Frémy's work, yet subsequent work on this question has mostly led to unsatisfactory results. Sabaneieff

(Abstr., 1886, 442) has at last succeeded in throwing some new light on the processes involved, but the authors do not in all cases obtain results in agreement with his.

Oleic acid was obtained by the saponification of oil of almonds, and purified in the ordinary way by conversion into its lead salt. The action of sulphuric acid was regulated in such a manner as to prevent the temperature rising above  $35^{\circ}$ . The mixture was then allowed to remain 20 hours at a temperature below  $0^{\circ}$ , and decomposed by water. In order to increase the yield of hydroxystearic acid, the fatty layer, separated by the action of water and solidifying at the ordinary temperature to a crystalline mass, was treated with alcoholic potash, whereby the anhydrides of this acid are decomposed. The saponified product was then converted into the acid by boiling with sulphuric acid. When the products of the action of sulphuric acid on oleic acid are left for some time even at low temperatures, the quantity of hydroxystearic acid is diminished, whilst the quantity of its anhydrides increases. Hydroxystearic acid was extracted from the above-mentioned crystalline mass by repeated recrystallisation from ether and alcohol. So obtained, *hydroxystearic acid*,

melts at  $83-85^{\circ}$ , and resolidifies at  $68-65^{\circ}$ . At  $20^{\circ}$  alcohol ( $99\frac{1}{2}^{\circ}$  Tr.) dissolves 8.78 per cent., ether 2.3 per cent. of the acid. Hydroxystearic acid does not absorb bromine. The free acid and the hydroxystearates of sodium, calcium, barium, copper, zinc, and silver, were analysed, and the formula of the acid shown to be  $\text{C}_{18}\text{H}_{36}\text{O}_3$ .

With hydriodic acid, hydroxystearic acid yields iodostearic acid,  $\text{CH}_3 \cdot (\text{CH}_2)_{13} \cdot \text{CH}_2 \cdot \text{CHI} \cdot \text{CH}_2 \cdot \text{COOH}$ ; the latter can be converted into ordinary stearic acid by reducing its alcoholic solution with zinc and hydrochloric acid.

When hydroxystearic acid is heated at  $100^{\circ}$  in sealed tubes with fuming hydrochloric acid, a syrupy liquid is formed, soluble in ether, insoluble in alcohol and water, and having the composition of oleic acid. It does not show acid properties, nor give additive products with bromine or iodine (in Hubl's solution); it is therefore considered to be a complete anhydride of hydroxystearic acid,

formed by elimination of 2 mols. of water from 2 mols. of the acid (analogous to glycolide or lactide). The anhydride is decomposed into hydroxystearic acid by treatment with alcoholic potash at temperatures above  $150^{\circ}$ . Heated with dilute sulphuric acid (in sealed tubes at  $100^{\circ}$ ), hydroxystearic acid yields the same anhydride, but when concentrated sulphuric acid is used at ordinary temperature, two other products of non-saturated character are formed, one combining with 17 per cent., the other with 33 per cent., of iodine, when heated with it on the water-bath. These substances bear a great resemblance to Frémy's metoleic acid, and will be further investigated.

It was shown that the hydroxystearic acid prepared by the action

of moist silver oxide on iodostearic acid was identical with that described above.

Finally, the authors have studied the action of alcoholic potash on iodostearic acid. After heating the mixture in a reflux apparatus, and expelling the alcohol by distillation, the product of the reaction was decomposed by sulphuric acid. An acid was obtained, solidifying at ordinary temperatures to a crystalline mass, and consequently not identical with oleic acid. It was purified by converting it into the sodium salt, recrystallising this salt from alcohol, precipitating with zinc sulphate, recrystallising from boiling alcohol, and decomposing the zinc salt by sulphuric acid. Thus purified, the substance crystallises from ether in translucent, rhombic tables, easily soluble in alcohol, sparingly in ether, and melts at 40–45°. The composition of this acid was found to be the same as that of oleic and elaidic acids. It is a non-saturated compound, taking up two atoms of bromine or iodine. When oxidised by potassium permanganate in alkaline solution, it yields dihydroxystearic acid, melting at 78°. The authors intend to continue the investigation of this *solid oleic acid*. Another acid, melting at 20–25°, simultaneously formed by the action of potash on iodostearic acid, was found to be a mixture of ordinary and solid oleic acids. The constitution of solid oleic acid is  $\text{CH}_3(\text{CH}_2)_{13}\text{CH}:\text{CH}\cdot\text{COOH}$ , ordinary oleic acid being represented by  $\text{CH}_3(\text{CH}_2)_{13}\text{CH}:\text{CH}\cdot\text{CH}_2\cdot\text{COOH}$ .  
A. T.

**Action of Trimethylene Bromide on Ethyl Acetoacetate, Benzoylacetate, and Acetonedicarboxylate.** By W. H. PERKIN, Jun. (*Ber.*, 19, 2557–2561; comp. Abstr., 1886, 689).—When the acid  $\text{C}_7\text{H}_{10}\text{O}_3$  (from trimethylene bromide and ethyl sodacetoacetate) is boiled with water, carbonic anhydride is evolved, and Lipp's acetobutyl alcohol (Abstr., 1886, 218) is formed. When the acid is distilled, the anhydride of acetobutyl alcohol,  $\text{CH}_2\langle\begin{smallmatrix} \text{CH}:\text{CHMe} \\ \text{CH}_2\cdot\text{CH}_2\text{—} \end{smallmatrix}\rangle\text{O}$ , is obtained; it is a mobile oil. The same compound is also formed when acetobutyl is heated. Strong hydrobromic acid dissolves the ethyl salt  $\text{C}_9\text{H}_{14}\text{O}_3$ , and decomposes it into bromobutyl methyl ketone (Lipp, *loc. cit.*) and carbonic anhydride. Benzoyltetramethylenedicarboxylic acid is decomposed by hydrobromic acid in a similar manner, with formation of the compound  $\text{COPh}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\text{Br}$ ; this crystallises in plates melting at 61°. The instability towards hydrobromic acid of the products obtained by the action of trimethylene bromide on ethyl acetoacetate and benzoylacetate respectively, distinguishes them sharply from tetramethylenedicarboxylic acid.

Trimethylene bromide acts on the sodium compound—

(from ethyl acetonedicarboxylate and sodium ethoxide), yielding the compound  $\text{COOEt}\cdot\text{CH}\langle\begin{smallmatrix} \text{C}(\text{CH}_2\cdot\text{COOEt}) \\ \text{CH}_2\text{—CH}_2\text{—CH}_2 \end{smallmatrix}\rangle\text{O}$ . The latter is a colourless oil boiling at 238–240 (under 150 mm. pressure). The *mon-ethyl salt* melts at 114°; the free acid at 185–190° with decom-

position. When the monethyl salt is distilled, a substance is obtained apparently identical with the product of the reaction between trimethylene bromide and ethyl acetoacetate. The dicarboxylic acid is decomposed by boiling water into acetobutyl alcohol and carbonic anhydride.

N. H. M.

**Ethyl Acetotrimethylenecarboxylate.** By W. H. PERKIN, Jun., and P. C. FREER (*Ber.*, 19, 2561—2569).—The fact that trimethylene bromide reacts with ethyl malonate, yielding a tetramethylene-derivative, and with ethyl acetoacetate with formation of an ether, suggested the possibility that the product of the reaction between ethylene bromide and ethyl acetoacetate (*Trans.*, 1885, 801) is not a trimethylene-derivative but an ether. The results of determinations of the magnetic circular polarisation, and the optical properties point, however, to the trimethylene formula first ascribed to the compound.

*Ethyl bromethylacetoacetate*,  $\text{CH}_2\text{Br}\cdot\text{CH}_2\cdot\text{CHAc}\cdot\text{COOEt}$ , is obtained by dissolving ethyl acetyltrimethylenecarboxylate, well cooled, in hydrobromic acid, sp. gr. 1·85 (3 parts); after being left for 10 minutes at the ordinary temperature, it is poured into ice water. It is a yellowish oil, having an odour of camphor; when exposed to air it becomes brown, and gives off hydrobromic acid. When reduced by means of zinc-dust and acetic acid, it is converted into ethyl acetoacetate.

*Acetopropyl alcohol*,  $\text{COMe}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OH}$ , is prepared by boiling 20 grams of the above bromo-compound for two hours with 5 grams of hydrochloric acid and 20 grams of water. The reaction is analogous to that by means of which Lipp obtained acetobutyl alcohol from ethyl bromopropylacetoacetate (*Abstr.*, 1886, 218). It is a colourless oil, very soluble in water; the solution very readily reduces ammoniacal silver solution but not Fehling's solution. It is very unstable. A phenylhydrazine-compound was prepared. When the alcohol is heated, it is converted with evolution of water into a mobile oil, having an ethereal odour; it is probably an *anhydride*,

(comp. *Abstr.*, 1886, 219).

*γ-Pentylene glycol*,  $\text{OH}\cdot\text{CHMe}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OH}$ , is obtained by reducing acetopropyl alcohol with sodium amalgam. It is a very thick, colourless oil, extremely soluble in water. It boils at 210—220° with partial decomposition. When heated above its boiling point, or with 50 to 60 per cent. of sulphuric acid at 100°, it is converted into the *anhydride*,  $\text{CH}_2 \begin{array}{c} \text{CHMe} \text{---} \\ \text{CH}_2 \cdot \text{CH}_2 \end{array} \text{>O}$ , boiling at 78—83°.

Pentylene glycol dissolves in hydrobromic acid (sp. gr. 1·85) with considerable development of heat; when the solution is heated at 80°, the *monobromohydrin* of the glycol,  $\text{C}_5\text{H}_{11}\text{BrO}$ , is formed. This is a colourless oil, which boils (under 150 mm. pressure) at 144—145°.

N. H. M.

**Derivatives of Diazosuccinic Acid.** By T. CURTIUS and F. KOCH (*Ber.*, 19, 2460—2462).—This is a continuation of the authors' previous work on this subject (*Abstr.*, 1885, 885). Aspartic acid was

obtained by the reduction of ethyl diazosuccinate with zinc-dust and acetic acid, thus proving the correctness of the formula formerly ascribed to diazosuccinic acid. *Methyl diazosuccinamate*,

(from the action of ammonia on methyl diazosuccinate), crystallises in long, golden-yellow prisms soluble in ether and alcohol, and melting at  $84^\circ$ . When ethyl diazosuccinate is acted on by cold slightly acidified water, *malamic* and *fumaramic* acids are produced. *Malamic* acid,  $\text{NH}_2 \cdot \text{CO} \cdot \text{CH}(\text{OH}) \cdot \text{CH}_2 \cdot \text{COOH}$ , crystallises in colourless prisms easily soluble in water, alcohol, and ether, and melts at  $146^\circ$ ; its *methyl salt* yields silky scales soluble in alcohol, ether, and water, and melting at  $105^\circ$ . *Methyl fumaramate*,  $\text{NH}_2 \cdot \text{CO} \cdot \text{C}_2\text{H}_2 \cdot \text{COOMe}$ , crystallises in colourless plates, soluble in alcohol, and melts at  $160$ – $162^\circ$ . *Ethyl benzoylmalamate*,  $\text{NH}_2 \cdot \text{CO} \cdot \text{CH}(\text{OBz}) \cdot \text{CH}_2 \cdot \text{COOEt}$ , was obtained by heating together equal molecular proportions of benzoic acid and ethyl diazosuccinamate at  $140$ – $150^\circ$ . It forms colourless clinorhombic crystals soluble in water, alcohol, and ether, and melts at  $96$ – $97^\circ$ . It decomposes easily when heated. The corresponding *methyl salt* forms colourless crystals, melting at  $78$ – $80^\circ$ . By the action of iodine on an ethereal solution of ethyl diazosuccinamate an unsymmetrical *ethyl diiodosuccinamate*,  $\text{NH}_2 \cdot \text{CO} \cdot \text{Cl}_2 \cdot \text{CH}_2 \cdot \text{COOEt}$ , is formed. This crystallises in long, greenish-white needles which darken at  $110^\circ$ , melt at  $132^\circ$ , and decompose at  $150^\circ$ . The *methyl salt* and corresponding *methyl* and *ethyl bromo-salts* are oils. L. T. T.

**Dichloropyromucic Acid.** By A. DENARO (*Gazzetta*, 16, 333–335).—If a current of dry chlorine gas is passed into the ethyl salt of pyromucic acid, a thick oil is at first obtained, probably consisting of the tetrachloride of the acid. This on decomposition with alcoholic potash and subsequent acidification, yields a *dichloropyromucic acid* which crystallises in white needles, melting at  $167^\circ$ . Its *barium salt* crystallises with 3 mols.  $\text{H}_2\text{O}$  in prisms, the *calcium salt* with  $3\frac{1}{2}$  mols.  $\text{H}_2\text{O}$  in scales; both become completely anhydrous when heated to  $110^\circ$ . V. H. V.

**Constitution of Glycoluril.** By O. WIDMANN (*Ber.*, 19, 2477–2482).—As the mode of formation and reactions of this substance

are best explained by the formula  $\text{CO} \begin{array}{c} \text{NH} \cdot \text{CH} \cdot \text{NH} \\ | \\ \text{NH} \cdot \text{CH} \cdot \text{NH} \end{array} \text{CO}$ , which un-

doubtedly belongs to acetylenecarbamide, the author has carefully re-examined these two compounds with the view of determining whether they are isomeric or identical. He finds that the latter is the case, and that the apparent differences in their reactions are due to erroneous observation. When boiled with concentrated baryta-water, acetylenecarbamide does not, as previously asserted, yield carbonic anhydride, but, like glycoluril, is decomposed into hydantoic acid and carbamide. The solubility of acetylenecarbamide is given by Schiff as 1 in 333 parts of water at  $15^\circ$ . The author finds that *pure* acetylenecarbamide requires 1090 parts of water for solution, whilst a similar determination of the solubility of glycoluril showed a

ratio of 1 : 1060. Similar agreement was also found in the silver salts, crystalline form, &c., both compounds crystallising variously in needles, prisms, or octahedra according to the solvent employed. Glycoluril and acetylenecarbamide are therefore identical, and the author proposes the adoption of the latter name as the more suitable.

L. T. T.

**Hydrocarbons from Tar-oils Boiling between 170° and 200°.** By O. JACOBSEN (*Ber.*, 19, 2511—2515).—The author has examined a sample of coal-tar oil free from thiophen, of boiling point 170—200°. By combined fractional distillation, conversion into sulphonic acids, sulphonic salts, and sulphonamides, he succeeded in isolating naphthalene, pseudocumene, hemellithene, and another hydrocarbon, boiling like the last-named at 175—175·5°, but yielding a very soluble *sulphonamide* melting at about 122—123°. On oxidation, the hydrocarbon yields an acid which crystallises in needles melting at 119—121° and volatile in steam, and also small quantities of a second acid melting at 90°. The acid of higher melting point yields isophthalic acid when oxidised with permanganate.

L. T. T.

**Chloropropylbenzene.** By G. ERRERA (*Gazzetta*, 16, 310—325).—In order to determine the constitution of the chloropropylbenzene obtained by the action of chlorine on the boiling hydrocarbon, the three alcohols derivable from propylbenzene have been prepared and converted into the corresponding chloro-derivatives.

*Phenylpropyl alcohol*,  $\text{CH}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\text{OH}$ , obtained from crude storax by Rugheimer's process, is not altered by gaseous hydrogen chloride, but when heated in a sealed tube with saturated hydrochloric acid solution, it yields the chloro-derivative  $\text{CH}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\text{Cl}$ . This compound is a pale-yellow liquid, boiling at 219°, and resembling cymene in odour; when pure, it is very stable, being unaltered by prolonged treatment with fused zinc chloride or silver acetate. Heated with alcoholic potash, it yields phenylpropyl ethyl ether,  $\text{CH}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\text{OEt}$ , a colourless liquid boiling at 220°, insoluble in water.

*Methyl benzyl carbinol*,  $\text{CH}_2\text{Ph}\cdot\text{CHMe}\cdot\text{OH}$ , obtained together with allylbenzene and stilbene by the reduction of methyl benzyl ketone with sodium amalgam, is a liquid boiling at 215°, of a pale-yellow colour and agreeable odour. Heated with hydrochloric acid in sealed tubes, it yields the chloro-derivative,  $\text{CH}_2\text{Ph}\cdot\text{CHClMe}$ , a yellowish liquid, boiling at 204—207° with partial decomposition into allylbenzene and hydrogen chloride. A similar reaction occurs with alcoholic potash, metallic zinc or its chloride.

*Ethyl phenyl carbinol*,  $\text{CHPhEt}\cdot\text{OH}$ , prepared by prolonged reduction of the corresponding ketone with sodium amalgam, as described by Barry, is a liquid boiling at 215—217°. It is converted by gaseous hydrogen chloride, even at ordinary temperatures, into the chloride  $\text{CHPhEtCl}$ , a yellow liquid boiling about 200—205°, but with considerable decomposition into hydrogen chloride and allylbenzene, a change which takes place even on distillation in a vacuum. It is distinguished from the two preceding chloro-derivatives by the readiness with which it reacts with silver acetate, yielding the acetyl-

derivative,  $\text{CHPhEt}\cdot\text{OAc}$ , a liquid boiling at  $227^\circ$ , of fruity odour, and insoluble in water. The chloropropylbenzene obtained by the direct chlorination of the hydrocarbon is identical with the second of the above chloro-compounds, in that it is decomposed by distillation and by alcoholic potash, as also by its stability towards silver acetate. In these properties, the chloro-derivatives of propylbenzene are directly comparable to those of ethylbenzene. V. H. V.

**Reduction of Trinitro- $\psi$ -cumene.** By F. MAYER (*Ber.*, 19, 2312—2314).—In preparing nitrocumidine by passing hydrogen sulphide through a boiling alcoholic solution of trinitro- $\psi$ -cumene, the chief product is a new acid,  $\text{C}_9\text{H}_{12}\text{N}_2\text{SO}_5$ . It is insoluble in alcohol, ether, glacial acetic acid, &c., soluble in hot water, from which it crystallises on the addition of a few drops of hydrochloric acid in splendid, white or yellowish plates. It melts at  $240^\circ$  and carbonises. Salts were prepared. N. H. M.

**Hemellithene.** By O. JACOBSEN (*Ber.*, 19, 2517—2520).—The author has investigated this compound, which he has now isolated from the fraction of coal-tar oils boiling between  $170$ — $200^\circ$  (see p. 35).

Hemellithene,  $\text{C}_6\text{H}_3\text{M}_3$  [1 : 2 : 3], boils at  $175$ — $175.5^\circ$ , and does not solidify at  $-20^\circ$ . Tribromohemellithene,  $\text{C}_6\text{H}_3\text{Br}_3$ , forms long needles melting at  $245^\circ$ , and is very sparingly soluble in alcohol; trinitrohemellithene forms prisms melting at  $209^\circ$ . The monosulphonic acid crystallises in hydrated rhombic or hexagonal plates, and yields crystalline salts; its sulphonamide melts at  $195$ — $196^\circ$ . Hemellithenol,  $\text{C}_9\text{H}_{11}\cdot\text{OH}$  [Me : Me : Me : OH = 1 : 2 : 3 : 5], is obtained by fusing the sulphonic acid with alkali. It is soluble in alcohol and ether, and crystallises in needles melting at  $81^\circ$ . Hemellithylic acid,  $\text{C}_6\text{H}_3\text{Me}_2\cdot\text{COOH}$  [Me : Me : COOH = 1 : 2 : 3], is formed by the oxidation of the hydrocarbon by dilute nitric acid. It is volatile in steam, and crystallises in scales melting at  $144^\circ$ . Its calcium salt is described. Distilled with lime, it yields orthoxylene.  $\alpha$ -Sulphaminehemellithylic acid [Me : Me : COOH :  $\text{SO}_2\text{NH}_2$  = 1 : 2 : 3 : 5], is formed by the oxidation of the above sulphonamide. It melts at  $238^\circ$ , and with hydrochloric acid yields a sulphohemellithylic acid melting at  $180$ — $190^\circ$ .  $\beta$ -Sulphaminehemellithylic acid [Me : Me : COOH :  $\text{SO}_2\text{NH}_2$  = 1 : 3 : 2 : 5], formed at the same time as the  $\alpha$ -acid, is more soluble, and melts at  $174^\circ$ . It yields a very soluble sulphonic acid when heated with hydrochloric acid. Both acids when fused with potash yielded an easily soluble hydroxyhemellithylic acid, which does not give a blue coloration with ferric chloride.

Hemellithene may be readily extracted from the tar oil by means of the sparing solubility of its barium sulphonate. L. T. T.

**Reciprocal Transformations of Cymene and Cumene-derivatives.** By M. FILETI (*Gazzetta*, 16, 300—310).—In this paper are collected the hitherto observed transformations of cumene and cymene-derivatives, the one into the other, and from them is drawn the following generalisation:—A propyl-group in the para-position relatively to a carbon-atom combined with other elements or with non-oxygenated groupings, is transformed into the isopropyl-group, if this

element or grouping is displaced by an oxygenated radicle whose oxygen is directly united to the carbon-atom compound, and conversely an isopropyl, is converted into a propyl-group when these substitutions are reversed. (Compare Widman, *Abstr.*, 1886, 453.)

V. H. V.

**Chlorocymene and Bromocymene from Thymol.** By M. FILETI and F. CROSA (*Gazzetta*, **16**, 287—300).—Chlorocymene (parapropylmetachlorotoluene),  $C_6H_3MePrCl$ , is obtained almost in theoretical proportions by heating in a reflux apparatus 4 mols. of thymol with 1 mol. phosphoric chloride. On oxidation with nitric acid, Gerichten (*Abstr.*, 1879, 238) obtained an acid, believed to be a hydrochlorocinnamic acid,  $C_6H_3MeCl \cdot CH_2 \cdot CH_2 \cdot COOH$ . It is here, however, shown that under these conditions three acids are formed, namely, chlorocumic, orthochloroparatoluic, and chloroterephthalic acids.

Sixty per cent. of the theoretical quantity of bromocymene, calculated according to the equation  $4C_{10}H_{13} \cdot OH + PBr_5 = C_{10}H_{13}Br + PO(OC_{10}H_{13})_3 + 4HBr$ , can be obtained by the gradual addition of 26 grams of bromine to 45 grams of phosphorus tribromide, and heating the resulting perbromide with 100 grams of thymol. On oxidation with nitric acid of sp. gr. 1.2, bromocymene yields bromocumic acid; with acid of sp. gr. 1.29, bromonitrocymene with bromocumic, bromonitrotoluic, and bromoterephthalic acids, whilst nitric acid of sp. gr. 1.39 yields the same acids without the bromonitrocymene. The bromocumic acid is identical with that obtained by the direct bromination of cumic acid; it has, therefore, the constitution  $C_6H_3PrBr \cdot COOH$ . The bromonitrotoluic acid crystallises in laminae, which melt at  $200^\circ$  without decomposition; it is isomeric with the acid obtained by the nitration of bromotoluic acid; its barium salt crystallises in long, yellow needles. The bromoterephthalic acid is identical with that obtained by Fischli by the oxidation of bromoparatoluic acid.

V. H. V.

**Ethylxylenes.** By O. JACOBSEN (*Ber.*, **19**, 2515—2516).—For the purposes of comparison with hydrocarbons obtained from the fraction of coal-tar oils boiling between  $170^\circ$  and  $200^\circ$  (this vol., p. 35), the author prepared the three isomeric ethylxylenes from the three corresponding xylenes, using Fittig's method. *Ethylorthoxylene* yields a crystalline *sulphonic acid*, giving a *sulphonamide* crystallising in needles melting at  $126^\circ$ . *Ethylmetaxylene* boils at  $184$ — $186^\circ$ , and is still liquid at  $-15^\circ$ ; its *sulphonic acid* is crystalline, and yields crystalline *barium* and *sodium salts*; its *sulphonamide* melts at  $148^\circ$ . *Ethylparaxylene* boils at  $185^\circ$ , and is still liquid at  $-20^\circ$ ; its *sulphonic acid* crystallises in rhombic scales, forms crystalline *barium* and *sodium salts*, and yields a crystalline *sulphonamide* which melts at  $117^\circ$ .

L. T. T.

**Ethereal Carbonates.** By G. BENDER (*Ber.*, **19**, 2265—2271; compare *Abstr.*, 1881, 48).—When naphthyl ethyl carbonate,  $OC_{10}H_7 \cdot CO \cdot OEt$ , is boiled for some time, carbonic anhydride and alcohol are given off, and the residue consists of a mixture of  $\alpha$ -naphthol and a compound  $C_{21}H_{12}O_2$  (*loc. cit.*). The formation of

diphenylene ketone oxides from salicylic acid (Perkin, Trans., 1883, 35) and the intermolecular change of sodium phenyl carbonate to sodium salicylate, suggest that the naphthyl ethyl carbonate may have become changed to the ethyl salt,  $\text{OH}\cdot\text{C}_{10}\text{H}_6\cdot\text{COOEt}$ , and that 2 mols. of the latter have condensed with formation of the compound  $\text{C}_{21}\text{H}_{12}\text{O}_2$ ; this would then be dinaphthylene ketone oxide,

The *isomeride* obtained by boiling  $\beta$ -dinaphthyl diethyl orthocarbonate (*loc. cit.*) crystallises from benzene in thin prisms melting at  $194^\circ$ .

When phenyl ethyl carbonate is heated at  $300^\circ$  for 3–4 hours diphenylcarbonate is formed.

*Paraditoyl carbonate* is obtained by heating paratoyl ethyl carbonate at  $300^\circ$ ; it is insoluble in water, moderately soluble in hot alcohol, and melts at  $115^\circ$ .

*Thymyl ethyl carbonate* is a thick liquid boiling at  $260^\circ$ ; at  $300^\circ$  it decomposes into *dithymyl carbonate*, melting at  $60^\circ$ .

*Orthonitrophenyl ethyl carbonate* is prepared by the action of ethyl chlorocarbonate on potassium orthonitrophenoxide. It is a heavy yellow oil which boils with decomposition at  $275$ – $285^\circ$ . The *amidosal*,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\text{O}\cdot\text{CO}\cdot\text{OEt}$ , melts at  $95^\circ$ ; it is soluble in alcohol, moderately soluble in boiling water. When distilled, it gives off alcohol with formation of *anhydro-orthamidophenyl carbonate*,  $\text{C}_7\text{H}_5\text{NO}_2$ ; the latter dissolves in alkalis. The *silver salt*,  $\text{C}_7\text{H}_4\text{AgNO}_2$ , forms an amorphous, colourless precipitate. The *ethyl salt* is obtained by boiling the compound with alcoholic potash and ethyl iodide. When heated with fuming hydrochloric acid, it yields ethyl orthamidophenol and carbonic anhydride; the constitution of the substance is therefore  $\text{C}_6\text{H}_4 < \overset{\text{NEt}}{\underset{\text{O}}{\text{C}}} > \text{CO}$ . The *phenylhydrazine compound* of anhydro-orthamidophenyl carbonate,  $\text{C}_6\text{H}_4 < \overset{\text{NH}}{\underset{\text{O}}{\text{C}}} > \text{C} : \text{N}\cdot\text{NHPh}$ , crystallises in yellow needles, which melt at  $208^\circ$ . The *acetyl-derivative* melts at  $97$ – $98^\circ$ . A *mononitro-compound* was prepared; it forms long yellow needles melting at  $256^\circ$ . Bromine acts on the anhydro-compound with formation of a *monobromo-derivative*; this crystallises from water in plates melting at  $196^\circ$ . When treated with phosphoric chloride, the compound  $\text{C}_7\text{H}_4\text{ClNO}_2$  is formed. N. H. M.

**Parahydroxybenzyl Alcohol.** By J. BIEDERMANN (*Ber.*, 19, 2373–2376).—*Parahydroxybenzyl alcohol*,  $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{OH}$ , is prepared by dissolving parahydroxybenzaldehyde (1 part) in a mixture of water (10 parts) and alcohol (5 parts); it is then acidified with dilute sulphuric acid and gradually treated with 3 per cent. sodium amalgam (40 parts). Grey crystals of diparahydroxyhydrobenzoïn and oily drops of diparahydroxyisohydrobenzoïn separate. When hydrogen is no longer evolved, the solution is made strongly acid and left for 12 hours, it is then filtered, the filtrate extracted with ether, and the ethereal extract treated with hydrogen sodium sulphite. On evaporating the ether, the alcohol separates in needles; these are purified by dissolving them in hot chloroform and precipitating with light petroleum. It forms slender

white needles, readily soluble in water, alcohol, and ether, sparingly in benzene and chloroform; sulphuric acid dissolves it, yielding a splendid red-violet solution. It melts at  $110^{\circ}$ . The alcohol is also formed when parahydroxybenzaldehyde is kept dissolved in alcoholic potash for several weeks, but the reaction is still very incomplete. The *acetyl-derivative*,  $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{OAc}$ , is prepared by heating the alcohol with a mixture of glacial acetic acid and sulphuric acid. It crystallises from water in small yellow needles, melting at  $84^{\circ}$ , and is readily soluble in alcohol and ether, sparingly in water, benzene, chloroform, &c. The *diacetyl-derivative*,  $\text{OAc}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{OAc}$ , is obtained by heating parahydroxybenzyl alcohol with an excess of acetic anhydride at  $160^{\circ}$  for 5–6 hours. It forms yellowish needles melting at  $75^{\circ}$ , readily soluble in alcohol and ether, sparingly in benzene, &c.

*Anisic alcohol*,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{OH}$  [= 1:4], is formed when parahydroxybenzyl alcohol is dissolved in methyl alcohol and digested with potash and methyl iodide for some hours at  $100^{\circ}$ . The product is treated with water, heated to expel methyl alcohol and iodide, and extracted with ether. On evaporating the ether, it is obtained as an oil which gradually solidifies when kept over sulphuric acid. It crystallises from water in needles melting at  $45^{\circ}$  (compare Abstr., 1886, 460).  
N. H. M.

**Synthesis of Betorcinol ( $\beta$ -Orcinol).** By S. v. KOSTANECKI (*Ber.*, 19, 2318–2324; compare Abstr., 1886, 242).—Paraxylorcinol [ $\text{Me}_2 : (\text{OH})_2 = 1 : 4 : 3 : 5$ ] was prepared from metadinitroparaxylylene by replacing the nitro-groups successively by amido- and hydroxyl-groups; it is identical with Stenhouse and Groves's betorcinol (*Trans.*, 1880, 396). The crude product obtained by nitrating paraxylylene is crystallised from alcohol to remove most of the orthodinitroparaxylylene, dissolved in hot alcoholic ammonia, and treated with hydrogen sulphide for about one hour; it is then evaporated to dryness. The paradinitro-compound, being more readily reduced than the meta-compound, is thus converted into paranitroparaxylidine, which is extracted by means of hydrochloric acid. The residue, insoluble in acid, was extracted with boiling alcohol, and yielded crystals of pure metadinitroparaxylylene. This was reduced by dissolving in alcoholic ammonia and treating for two hours with hydrogen sulphide, and the nitroxylidine [ $\text{Me}_2 : \text{NO}_2 : \text{NH}_2 = 1 : 4 : 3 : 5$ ] so obtained was converted into the corresponding nitroxylenol. The latter crystallises in yellow plates melting at  $91^{\circ}$ . It was reduced with tin and hydrochloric acid, and the amidoparaxylenol diazotised; to 1 gram of the hydrochloride 10 grams of sulphuric acid and 100 grams of water were used, and the whole kept cold by means of ice and salt.

Paraxylorcinol so prepared has all the properties ascribed to it by Stenhouse and Groves (*loc. cit.*), except that it yields a green fluorescent solution when treated with dilute soda and chloroform.

Metaxylorcinol (Pfaff, Abstr., 1883, 918) crystallises from chloroform in white monoclinic crystals,  $a : b : c = 1.7237 : 1 : ?$ ;  $\beta = 38^{\circ} 21'$ . It boils at  $276$ – $279^{\circ}$ . When heated with sodium carbonate solution at  $130^{\circ}$ , *metaxylorcinolcarboxylic acid*,  $\text{C}_6\text{HMe}_2(\text{OH})_2\cdot\text{COOH}$ , is formed.

The latter crystallises from dilute alcohol in well-formed prisms which melt with decomposition at  $196^{\circ}$ , and give a deep blue coloration with ferric chloride.

N. H. M.

**Acetalresorcinol.** By — CAUSSE (*J. Pharm.* [5], 13, 354—358).—The author has examined the action of sulphuric acid and heat on a solution containing acetaldehyde and resorcinol. The crystals obtained are insoluble in water, ether, chloroform, and benzene. They are soluble in alcohol, which yields them again partly changed. Anhydrous ether dehydrates them, converting them into a powder, which in time aggregates to yellow, translucent crystals. Thus purified, the compound decomposes on fusing with regeneration of resorcinol. Its composition is indicated by the formula  $C_{14}H_{14}O_4 = C_2H_4O + 2C_6H_6O_2 - H_2O$ . The action of heat on the compound apparently removes the elements of water. Heated at  $120^{\circ}$ , a reddish powder was formed which could be obtained in large brown crystals. These had the composition  $C_{28}H_{16}O_7 = 2C_{14}H_{14}O_4 - H_2O$ .

The diacetyl compound,  $C_{36}H_{18}O_{12}$ , melts at  $282^{\circ}$ . The reactions indicate that the yellow crystals are a molecular combination of aldehyde and resorcinyl ether,  $C_2H_4O, O(C_6H_4 \cdot OH)_2$ .

J. T.

**Benzylamine.** By T. CURTIUS and G. LEDERER (*Ber.*, 19, 2462—2463).—When benzaldehyde and amidoacetic acid are heated together at  $130^{\circ}$ , carbonic anhydride is evolved and benzylamine formed. Similar reactions seem to take place when cinnamaldehyde, salicylaldehyde, or orthonitrobenzaldehyde, are substituted for the benzaldehyde, but the products are not so easily isolated.

L. T. T.

**Citric Acid Derivatives of Paratoluidine.** By J. M. GILL (*Ber.*, 19, 2352—2354).—*Citroparatoluidide*,  $C_6H_5O_4(NH \cdot C_7H_7)_3$ , is obtained by heating citric acid (1 mol.) and paratoluidine (3 mols.) at  $140$ — $145^{\circ}$  for 10 hours. It crystallises from alcohol, in which it is sparingly soluble, in lustrous, microscopic needles, melting at  $189^{\circ}$ .

*Citrodiparatoluide*,  $C_6H_5O_4(NH \cdot C_7H_7) : N \cdot C_7H_7$ , is formed when citric acid (1 mol.) and paratoluidine (2 mols.) are heated at  $160$ — $170^{\circ}$  for three hours. It melts at  $205^{\circ}$ , is insoluble in water, rather readily soluble in ether and alcohol, and separates from the latter solvent in small, yellow, well-formed crystals. When heated with citric acid at  $140$ — $145^{\circ}$ , it is converted into citroparatoluidide. Ammonia acts on it, yielding a salt of *citroparaditoluidic acid*,  $C_6H_5O_4(NHC_7H_7)_2 \cdot OH$ . The latter crystallises from alcohol in groups of needles, melting at  $161^{\circ}$ . It is soluble in water, insoluble in alcohol and ether.

*Citroparatoluidic acid*,  $C_6H_5O_4(OH) : NC_7H_7$ , is prepared by adding paratoluidine (1 mol.) to a hot concentrated alcoholic solution of citric acid (1 mol.). On cooling, the solution yields clear prismatic crystals; these are heated for two hours at  $160$ — $170^{\circ}$ , and crystallised from water. It melts at  $172.5^{\circ}$ , and dissolves readily in alcohol, ether, and hot water.

N. H. M.

**Azo- and Diazo-compounds.** By O. WALLACH (*Annalen*, 234, 350—364).—Paracetometatolulylenediamine, obtained by the action

of acetic anhydride on metatoluylenediamine (Abstr., 1883, 329) can also be prepared by converting nitrotoluidine (m. p.  $77.5^{\circ}$ ) into the aceto-compound (m. p.  $144.5^{\circ}$ ), and reducing this substance with iron filings and acetic acid. By means of the diazo-reaction, the aceto-metatoluylenediamine is converted into acetamidocresol (m. p.  $225^{\circ}$ ), proving that the acetyl-group occupies the para-position.

*Paracetamidotolueneorthazodimethylaniline*,

is formed when a solution of the diazo-compound is poured into an ice-cold alcoholic solution of dimethylaniline. The substance crystallises in golden plates and melts at  $200^{\circ}$ . It unites with acids to form salts, which dissolve in water, yielding deep-red solutions. The acetyl-group can be eliminated by boiling with dilute sulphuric acid.

*Paramidotolueneorthazodimethylaniline* crystallises in golden scales. It melts at  $145^{\circ}$ , and dissolves in hot alcohol, chloroform, and benzene. The diazo-compound unites with phenol, forming *tolueneazodimethylanilineparazophenol*,  $\text{NMe}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_3\text{Me} \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{OH}$ .

This substance dissolves in dilute solutions of the alkalis, and is reprecipitated by carbonic acid. It also dissolves in strong acids, and is reprecipitated by the addition of water. It dissolves freely in alcohol, ether, chloroform, and benzene.

The corresponding  $\beta$ -*naphthol*-compound melts about  $244^{\circ}$ . It is insoluble in water, sparingly soluble in alcohol, but dissolves in strong sulphuric acid, with a red coloration.

*Paracetamidotolueneorthazodiethylaniline* crystallises in needles of a reddish-brown colour. It melts at  $159^{\circ}$ , and dissolves freely in alcohol, ether, chloroform, and in acids. The salts are decomposed by large quantities of water. *Orthacetometatoluylenediamine*,  $\text{NHAc} \cdot \text{C}_6\text{H}_3\text{Me} \cdot \text{NH}_2$  [Me : NHAc :  $\text{NH}_2$  = 1 : 2 : 4], prepared from orthoamidoparanitrotoluene (m. p.  $107^{\circ}$ ), crystallises in white needles, and melts at  $140^{\circ}$ . It is soluble in alcohol, in ether, and in hot water. *Orthacetamidotolueneparazodimethylaniline* melts at  $192^{\circ}$ , and dissolves freely in alcohol, chloroform, benzene, and ether. *Orthamidotoluene-parazodimethylaniline* melts at  $215^{\circ}$ , and is freely soluble in chloroform.

*Acetamidobenzenemetazodimethylaniline*,  $\text{NHAc} \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NMe}_2$ , crystallises in plates, and melts at  $184^{\circ}$ . *Amidobenzeneazodimethylaniline* forms golden scales, soluble in alcohol, which melt at  $165$ — $166^{\circ}$ .  
W. C. W.

**Quinone-oximes.** By J. SUTKOWSKI (*Ber.*, 19, 2314—2317).—When thymoquinone-oxime is dissolved in cold, fuming hydrochloric acid, a yellow precipitate is formed, consisting of dichlorothymoquinone and monochloramidothymol (Andresen, Abstr., 1881, 590). When the precipitate is boiled with glacial acetic acid, a splendid red dye is formed. The reaction is of interest, as it shows the analogy between the reactions of thymoquinone and of thymoquinone-oxime with fuming hydrochloric acid. Andresen also obtained the same products from thymoquinonechlorimide. The oxime is therefore the hydroxyl-derivative corresponding with the quinonechlorimide.

When chloramidothymol hydrochloride and chloranil are heated in glacial acetic acid solution, the red dye above mentioned is formed. Tetrachloroquinol is formed in the reaction; it crystallises in long colourless needles melting at  $232^{\circ}$ . Analyses of the dye point to the formula  $C_{30}H_{35}Cl_3N_2O_3$ .

In a similar manner, a dye was obtained by the action of paramidothymol on chloranil in glacial acetic acid solution. It has the composition expressed by the formula  $C_{30}H_{38}N_2O_3$ . It dissolves in acetic acid, alcohol, ether, and benzene, but not in water. Ammonia dissolves it with formation of a blue solution. Lead acetate gives a blue precipitate.

N. H. M.

**Amidine-derivatives.** By M. LOEB (*Ber.*, 19, 2340—2344).—When the compound  $C_{16}H_{12}N_2Cl_2O_2$ , prepared by the action of carbonyl chloride on ethenyldiphenyldiamine (Abstr., 1885, 1213), is treated with alkalis or acids, it is reconverted into the amidine. Boiling water has no action on it; boiling alcohol converts it into carbanilide, ethyl acetate, and ethyl chloride. The *ethyl salt*,  $OEt \cdot CO \cdot NPh \cdot CMe : N \cdot C_6H_4 \cdot COOEt$ , separates from its ethereal solution in hard, lustrous, rhombic crystals which melt at  $90.5^{\circ}$ . When the chloride is dissolved in benzene and treated with dry ammonia, it is converted into ethenyldiphenyldiamine and ammonium chloride; aniline acts like ammonia.

*Ethenylimidobenzanilide*,  $CMe \begin{smallmatrix} \nwarrow N \cdot C_6H_4 \\ \nearrow NPh \end{smallmatrix} > CO$ , is prepared by the action of carbonyl chloride dissolved in benzene on an excess of ethenyldiphenyldiamine; it crystallises from benzene in large, lustrous plates melting at  $118^{\circ}$ . It is identical with the compound to which the formula  $CO(C_{14}H_{13}N_2)_2$  was previously ascribed (*loc. cit.*). Dilute hydrochloric acid decomposes it with formation of aniline and phenyl cyanate.

When a saturated ethereal solution of ethenyldiphenyldiamine is treated with two or three drops of water and then with cyanogen until it has a wine-red colour, and allowed to remain for 16 hours, a black crust is formed which yields a compound,  $C_{16}H_{16}N_4O$ ; the latter forms a white, crystalline powder very sparingly soluble in ether and benzene, and cannot be recrystallised, as it at once resinifies when heated with solvents. It becomes violet at  $120^{\circ}$ , and melts with decomposition at  $165^{\circ}$ . Its constitution is probably analogous to that of Griess' cyanocarbimidoamidobenzoic acid, as shown in the formula  $NPh : CMe \cdot NPh \cdot C(NH)CN + H_2O$ . Ethyl allophanate is formed when urethane (7 parts) and carbonyl chloride (1 part) are dissolved in benzene and heated at  $75^{\circ}$ .

N. H. M.

**Preparation of Aromatic Amides.** By M. FILETI (*Gazzetta*, 16, 281—284).—The method, proposed by Letts, for the preparation of the nitriles by heating the carboxylic acids with potassium thiocyanate, has been shown to yield the amides, if ammonium thiocyanate be substituted for the potassium salt. The former change is attributed by Kekulé to the greater dehydrating action of the potassium salt, an interpretation confirmed by the observation of

Müller that in the above method benzamide is formed if the process is conducted quickly, but phenyl nitrile if slowly. In the course of the preparation of cumonitrile, a small quantity of *cuminamide* is obtained from the crude product of the reaction, if the aqueous solution, previously rendered alkaline by ammonia, is agitated with benzene. This amide crystallises in glittering laminæ melting at  $153.5^{\circ}$ , insoluble in cold, sparingly soluble in hot water, soluble in alcohol. It is not decomposed by boiling with hydrochloric acid or potash of moderate concentration. With mercuric oxide, it yields a derivative,  $(C_6H_4Pr \cdot CONH)_2Hg + 1\frac{1}{2}H_2O$ ; this crystallises in needles melting at  $190^{\circ}$ , insoluble in water, soluble in alcohol.

V. H. V.

**Action of Alkyl Iodides on Dibenzylthiocarbamide.** By C. REIMARUS (*Ber.*, 19, 2348—2349).—Will has shown (*Abstr.*, 1882, 723) that alkyl iodides react with diphenyl- and dibenzyl-thiocarbamide, with formation of hydriodides of bases in which the alkyl-group is directly combined with sulphur. The author has found that the isomeric dibenzylthiocarbamide behaves analogously.

*Benzylimidobenzylcarbaminothiomethyl*,  $SMe \cdot C(NHC_6H_5) : NC_6H_5$ , is formed when methyl iodide and dibenzylthiocarbamide are heated for 2—3 hours at  $100^{\circ}$ . The product is dissolved in water, treated with sodium carbonate, and extracted with ether. The *sulphate* of the base crystallises in lustrous needles readily soluble in water and alcohol; it melts at  $145^{\circ}$ . The *hydrochloride* forms large rhombic plates melting at  $125^{\circ}$ ; the *hydriodide* crystallises in splendid octahedra melting at  $99^{\circ}$ , readily soluble in hot water.

*Benzylimidobenzylcarbaminothioethyl*,  $SEt \cdot C(NHC_6H_5) : NC_6H_5$ , crystallises in wide prisms, apparently monoclinic, which melt at  $93^{\circ}$ ; it dissolves readily in alcohol, sparingly in water. The *sulphate* forms large rhombic plates readily soluble in water and alcohol; the *platinochloride* crystallises in needles.

Corresponding compounds were also prepared from propyl iodide and amyl iodide.

N. H. M.

**Phenylseleniocarbimide and Diphenylseleniocarbamide.** By H. STOLTE (*Ber.*, 19, 2350—2352).—*Phenylseleniocarbimide*,  $CSe \cdot NPh$ , is prepared by passing hydrogen selenide into aqueous soda, evaporating, and adding isocyanophenyl chloride diluted with ether to prevent the reaction becoming too violent. After a day, the product is filtered, the ether evaporated, and the residue steam-distilled and dried in a vacuum over sulphuric acid. It is a yellowish-red oil, insoluble in water, readily soluble in alcohol and ether, and has only a slight odour. When the ethereal solution of the substance is treated with ammonia, it is converted into monophenylseleniocarbamide (*Abstr.*, 1886, 781).

*Diphenylseleniocarbamide*,  $CSe(NHPh)_2$ , is prepared from phenylseleniocarbimide by treating its ethereal solution with aniline. The product is washed with ether, and crystallised from alcohol. It melts at  $186^{\circ}$  with decomposition.

N. H. M.

**Substituted Nitrogen Chlorides.** By G. BENDER (*Ber.*, 19, 2272—2274).—When the compound  $C_6H_4<\begin{smallmatrix} NH \\ -O- \end{smallmatrix}>CO$  (this vol., p. 38) is treated with bleaching powder and hydrochloric acid the compound  $C_7H_3NO_2Cl_2$  separates in colourless needles. When the latter is brought into contact with quinol, an odour of quinone is given off, and on cooling crystals of quinhydrone separate. The compound is decomposed by alcohol, alkalis, aniline, &c., into the compound  $C_6H_3Cl<\begin{smallmatrix} NH \\ -O- \end{smallmatrix}>CO$  (*loc. cit.*).

Acetanilide, when treated with bleaching powder in presence of acetic acid, yields the compound  $NPhCl \cdot COMe$ . The latter has the properties of the compound described above. It melts at  $91^\circ$ ; when heated to  $172^\circ$ , it becomes yellow, effervesces violently and is converted into its isomeride, parachloroacetanilide, melting at  $172^\circ$ . The same change takes place when the substance is treated with cold hydrochloric acid or when warmed with absolute alcohol; if more than 2 grams be employed, a violent explosion takes place. The compound reacts with paranitraniline, yielding acetanilide and orthochloroparanitraniline.

The compound  $<\begin{smallmatrix} CH_2 \cdot CO \\ CH_2 \cdot CO \end{smallmatrix}>NCl$  was prepared from succinimide: it crystallises from benzene in large colourless crystals melting at  $148^\circ$ .

Benzamide yielded the compound  $COPh \cdot NHCl$ . This crystallises from water in long prisms melting at  $116^\circ$ . N. H. M.

**Condensation of Nitrobenzaldehyde with Hydrocarbons.** By O. TSCHACHER (*Ber.*, 19, 2463—2464).—Baeyer has shown that fatty aldehydes, in the presence of concentrated sulphuric acid, form condensation products with aromatic hydrocarbons, whilst aromatic aldehydes do not. The author finds that the introduction of a nitro-group into the phenyl-ring gives to aromatic aldehydes the power of forming such condensation products.

With benzene, metanitrobenzaldehyde yields *metanitrotriphenylmethane*, forming crystals melting at  $90^\circ$ . With toluene, *metanitrophenylditolylmethane* is formed. L. T. T.

**Compound of Pyruvic Acid with Hippuric Acid.** By A. HOFFMANN (*Ber.*, 19, 2554—2557).—6 grams of pyruvic acid were digested with 11 grams of sodium hippurate and 25 grams of acetic anhydride on a water-bath. In a short time, a vigorous reaction takes place and the temperature of the mixture rises to  $108^\circ$ . The product is dissolved in alcohol, the solution diluted with water, evaporated, and the brownish crystals recrystallised from petroleum. Analyses of the compound point to the formula  $C_{12}H_9NO_4$ ; the substance is therefore formed by the union of its two constituents (equal mols.) with elimination of the elements of water (2 mols.). It forms colourless, flat needles melting at  $157^\circ$ ; it is very readily soluble in alcohol, ether, and acetic acid; insoluble in water. It yields salts corresponding with a bibasic acid,  $C_{12}H_{11}NO_5$ . The *barium salt*,  $C_{12}H_9NO_5Br + 2H_2O$ , was prepared; when treated with acid, it

yields the anhydride,  $C_{12}H_9NO_4$ , the acid not being capable of existing in the free state. When the anhydride is heated with hydrochloric acid at  $140^\circ$ , benzoic acid is formed. N. H. M.

**Phenyliodohydracrylic Acid.** By E. ERLÉNMEYER and J. ROSENHEK (*Ber.*, 19, 2464—2465).—*Phenyliodohydracrylic* ( $\alpha$ -iodo- $\beta$ -phenylhydroxypropionic) acid,  $OH \cdot CHPh \cdot CHI \cdot COOH$ , was obtained by the action of iodine chloride on cinnamic acid. A chloriodophenylpropionic acid is probably first formed, which is then converted into the hydroxy-acid by the action of water. The acid forms large crystals which melt with decomposition at  $137$ — $139^\circ$ , and are soluble in benzene. When treated with hydrochloric acid, this acid yields a compound  $C_{18}H_{16}ClIO_4$ , which the author believes to have the formula  $CHPh : CH \cdot C(OH) < \overset{O}{\underset{\text{O}}{\parallel}} > C(OH) \cdot CHI \cdot CHClPh$ . L. T. T.

**Creosolcarboxylic Acid.** By H. WENDE (*Ber.*, 19, 2324—2327).—*Creosolcarboxylic acid*,  $OH \cdot C_6H_2Me(OMe) \cdot COOH$  [ $= 4 : 1 : 3 : 5$ ], is prepared by gradually adding 4 grams of sodium to 50 grams of creosol through which a current of dry carbonic anhydride is being passed. The reaction takes place slowly with evolution of hydrogen and slight development of heat, and is assisted by gently warming; much heat is then developed, and the reaction becomes rather violent. The product, when cold, is treated with dilute hydrochloric acid, extracted with ether, and the ethereal solution extracted with sodium carbonate solution. It crystallises in needles melting at  $180$ — $182^\circ$ , dissolves sparingly in water, readily in alcohol, ether, and chloroform, and is almost insoluble in benzene and light petroleum. It sublimes unchanged when carefully heated, and acquires a deep blue colour when treated with ferric chloride. The *ammonium salt* crystallises in globular groups of needles; the *potassium salt* forms small, readily soluble needles; the *barium salt* is sparingly soluble; the *copper salt* is a yellow powder; it is very electric when dry. The *methyl salt* forms small, rhombic crystals,  $a : b : c = 0.5285 : 1 : 0.7334$ ; it melts at  $92^\circ$ , and gives a bluish-green coloration with ferric chloride. The *ethyl salt* crystallises in small needles or prisms melting at  $77^\circ$ .

N. H. M.

**Derivatives of Opianic Acid.** By C. LIEBERMANN (*Ber.*, 19, 2275—2287; compare *Abstr.*, 1886, 550).—*Amidohemipinphenylhydrazide* (azopianphenylhydrazide),  $NH < \begin{array}{c} C : N \text{ --- } NPh \\ | \\ C_6H(OMe)_2 \cdot CO \end{array} >$ , is prepared by the action of phenylhydrazine on azopianic acid. It separates from its solution in benzene in small, honey-coloured, tetragonal crystals, having a glassy lustre,  $a : c = 1 : 0.5947$ . It melts at  $222^\circ$ , and dissolves in strong sulphuric acid and in fuming hydrochloric acid.

*Amido-opianphenylhydrazide*,  $NH_2 \cdot C_6H(OMe)_2 < \begin{array}{c} CO \cdot NPh \\ | \\ CH : N \end{array} >$ , is obtained by reducing the nitro-compound (*loc. cit.*) with tin and fuming

hydrochloric acid, care being taken to prevent the reaction from becoming too violent from the heat developed. On adding water to its alcoholic solution, it crystallises in slender needles melting at  $137-143^{\circ}$ .

*Normethylnitro-opianphenylhydrazide*,

is formed when nitro-opianphenylhydrazide is boiled with alcoholic potash, and the potassium salt thus obtained treated with hydrochloric acid. It crystallises in yellow, glittering, rhombic plates melting at  $191^{\circ}$ . The *potassium salt* is a carmine-red powder.

*Opianoxime anhydride (hemipinimide)*,  $\text{C}_{10}\text{H}_9\text{NO}_4$ , is prepared by boiling opianic acid (1 mol.) dissolved in nine times its weight of 80 per cent. alcohol with hydroxylamine hydrochloride ( $1\frac{1}{4}$  mol.) for two to three hours. It crystallises from alcohol in long, very slender needles melting at  $228-230^{\circ}$ . An aqueous or alcoholic solution containing only a trace of the substance has a fine blue fluorescence. It sublimes unchanged, and can be heated with strong sulphuric acid without decomposition. Cold aqueous alkali dissolves it, forming a yellow solution which soon becomes colourless. When heated with alkali, it yields hemipinic acid and ammonia. The compound was also prepared by heating ammonium hemipinate. The *potassium salt*,  $\text{C}_{10}\text{H}_8\text{ONK}$ , is a white compound almost insoluble in cold absolute alcohol. The *silver salt* was also prepared.

*Hemipinethylimide*,  $\text{C}_{10}\text{H}_9\text{O}_4 : \text{NEt}$ , is obtained by heating potassium hemipinimide with ethyl iodide at  $150^{\circ}$ . It crystallises from boiling water in colourless needles resembling hemipinimide; the solution shows the same fluorescence. It dissolves very readily in alcohol, acetone, and benzene, and melts at  $96-98^{\circ}$ .

The formation of hemipinimide is interesting on account of its complete analogy with observations lately made in the phthalic acid series. The author assigns to the compounds phthalimide and hemipinimide the respective constitutional formulæ  $\text{CO} < \overset{\text{O}}{\underset{\text{C}_6\text{H}_4}{\text{C}}} > \text{C} : \text{NH}$  and  $\text{CO} < \overset{\text{O}}{\underset{\text{C}_6\text{H}_2(\text{OMe})_2}{\text{C}}} > \text{C} : \text{NH}$ .

*Anilido-opianic acid*,  $\text{C}_{16}\text{H}_{15}\text{NO}_4$ , is obtained by boiling a solution of equal weights of opianic acid and aniline, dissolved in glacial acetic acid, for 10 minutes. On cooling, the whole solidifies to a white mass, which is washed with water, dissolved in benzene, and precipitated with ether. It melts at  $186-187^{\circ}$ . It dissolves only in strong alkali solution. *Anilidonitropianic acid*,  $\text{C}_{16}\text{H}_{14}\text{N}_2\text{O}_6$ , is prepared from nitropianic acid in a manner similar to the above compound. It crystallises in needles melting at  $183-184^{\circ}$ . When treated with alkali, it yields a sparingly soluble *potassium salt*.

*Nitrohemipinic acid*,  $\text{NO}_2 \cdot \text{C}_6\text{H}(\text{OMe})_2(\text{COOH})_2$ , is very readily prepared by boiling nitropianic acid with fuming nitric acid (4 parts) for one hour. It melts at  $166^{\circ}$  (not  $155^{\circ}$ ), but has all the other properties ascribed to it by Prinz (Abstr., 1882, 402). When heated above its melting point, it gives up water and yields a yellowish compound, probably the anhydride.

*Opianic anhydride*,  $[\text{CHO} \cdot \text{C}_6\text{H}_2(\text{OMe})_2 \cdot \text{CO}]_2\text{O}$ , is formed when opianic acid is heated at  $160^\circ$  in a current of dry air. It crystallises well from acetone and melts at  $234^\circ$ . It is identical with the compound described by Wegscheider (Abstr., 1883, 996) as triopiamide,  $\text{C}_{30}\text{H}_{28}\text{O}_{14}$ . When boiled with alkali, it is gradually transformed into opianic acid. Strong nitric acid converts it into nitropianic acid.

N. H. M.

**Opianic Acid Derivatives.** By C. LIEBERMANN and S. KLEEMANN (Ber., 19, 2287—2299).—*Acetylopianic acid*,

is prepared by heating opianic acid and dry sodium acetate with acetic anhydride. The excess of acetic anhydride is then removed by contact with cold water for 24 hours, and the remaining compound crystallised from boiling water. It melts at  $120\text{--}121^\circ$ . It is insoluble in cold aqueous alkali, and when boiled with it, is decomposed into opianic and acetic acids.

*Acetylnitropianic acid*,  $\left\langle \begin{array}{c} \text{CO} \text{---} \text{O} \\ \text{C}_6\text{H}(\text{NO}_2)(\text{OMe})_2 \end{array} \right\rangle \text{CH} \cdot \text{OAc}$ , is prepared in a manner similar to acetylopianic acid. It is a yellow substance insoluble in cold sodium carbonate solution.

*Propionylopianic acid*,  $\text{C}_{13}\text{H}_{14}\text{O}_6$ , crystallises in needles melting at  $111^\circ$ .

*Anhydracetamidohemipinic acid*,  $\text{C}_{10}\text{H}_8\text{AcNO}_5$ , and the *propionyl-compound*,  $\text{C}_{10}\text{H}_8(\text{C}_3\text{H}_5\text{O})\text{NO}_5$ , melt at  $164^\circ$  and  $139^\circ$  respectively; they are very unstable.

*Meconine-acetic acid*,  $\left\langle \begin{array}{c} \text{CO} \text{---} \text{O} \\ \text{C}_6\text{H}_2(\text{OMe})_2 \end{array} \right\rangle \text{CH} \cdot \text{CH}_2 \cdot \text{COOH}$ , is obtained by heating opianic acid (3 parts), malonic acid ( $1\frac{1}{2}$  part), glacial acetic acid (2 parts), and sodium acetate ( $1\frac{1}{2}$  part) for five hours at  $100^\circ$ ; the colourless, crystalline product is crystallised from water. It forms lustrous needles melting at  $167^\circ$ ; it has an acid reaction and dissolves in ammonia. The *silver, calcium, &c., salts* were prepared. The *ethyl salt* crystallises in plates soluble in alcohol, ether, and hot water; it melts at  $82.5^\circ$ . The reactions of the acid are analogous to those of phthalylacetic acid. When boiled with baryta, and the excess of baryta afterwards removed by means of carbonic anhydride, *barium opianylacetate*\* is obtained; it forms lustrous prisms. The free acid is not capable of existence. When the silver salt is treated with methyl iodide, it yields, not methyl opianylacetate, but *methyl meconine-acetate*; the latter crystallises in lustrous plates melting at  $124^\circ$ .

*Normeconine-acetic acid*,  $\left\langle \begin{array}{c} \text{CO} \text{---} \text{O} \\ \text{C}_6\text{H}_2(\text{OH})_2 \end{array} \right\rangle \text{CH} \cdot \text{CH}_2 \cdot \text{COOH}$ , is prepared by heating meconine-acetic acid with hydriodic acid and phosphorus; the product is diluted with water and filtered. It crystallises from water in long plates melting at  $228^\circ$ . The *calcium* and *barium salts* form white crystalline precipitates. When the acid is

\* The formula and analysis given in the original do not agree.

heated with ferric chloride, it acquires a characteristic blue colour, which changes to green in presence of an excess of ferric chloride. The *ethyl salt* separates from its solution in boiling water as an oil, which then solidifies and melts at 131°. Its solution is fluorescent and reduces silver solution, but to a smaller extent than the free acid. It has an acid reaction and precipitates from baryta solution a yellow barium salt of the ether. This acid property and the power of reducing silver solutions is due to the presence of pyrocatechol-hydroxyl.

*Orthonitromeconine-acetic acid*,

is obtained by dissolving meconine-acetic acid in fuming nitric acid and afterwards precipitating with water. It forms colourless crystals melting at 176°. The *calcium salt* forms yellow needles. The *ethyl salt* crystallises in lustrous needles, readily soluble in alcohol and benzene; it melts at 129°. Nitromeconine-acetic acid dissolves in sulphuric acid, forming a yellow solution; this, when warmed, acquires a cherry-red colour, characteristic of compounds containing a nitro-group in the ortho-position to a long side-chain (Baeyer, Abstr., 1882, 620). When the nitro-compound is reduced with tin and hydrochloric acid, *dimethoxyhydrocarbostyryl-lactone*,

is formed. This crystallises from water in colourless needles, melting with evolution of carbonic anhydride at 256°. It is readily soluble in alcohol and glacial acetic acid, insoluble in ether and benzene. It dissolves in baryta; when the solution is boiled and treated with carbonic anhydride and evaporated down, lustrous needles of barium dimethoxyhydrocarbostyrylcarboxylate are obtained.

*Dimethoxydihydrochloroquinoline lactone*,  $\text{C}_{12}\text{H}_{10}\text{NClO}_4$ , is prepared by heating the lactone just described with phosphorus pentachloride and some phosphorus oxychloride for two hours at 165–170°; the product is poured into iced water, and the precipitate crystallised from alcohol, from which it separates in needles; these melt at 218° with evolution of carbonic anhydride. The *barium salt*, obtained by boiling the lactone with baryta, and the *silver salt* were prepared.

*Dihydroxydihydroquinoline lactone*,  $\text{C}_{10}\text{H}_7\text{NO}_4$ , is obtained by heating the above chloro-derivative dissolved in glacial acetic acid for one hour at 120° with hydriodic acid. It melts at 220° with decomposition.

N. H. M.

**Azo-opianic Acid.** By H. GRÜNE (*Ber.*, 19, 2299–2305).—Azo-opianic acid, prepared from nitroopianic acid, melts at 200° with decomposition (not 184° as given by Prinz, Abstr., 1882, 404). The *potassium salt* is a white crystalline powder. The *ethyl salt* crystallises in needles melting at 98°; the *methyl salt* melts at 127°. The author confirms the statement of Prinz (*loc. cit.*) that azopianic acid, when boiled with baryta in excess, yields barium amidohemipinate

The yield is almost quantitative. *Sodium amidohemipinate* crystallises from alcohol with 3 mols.  $\text{H}_2\text{O}$ , in long, almost white needles; it is very readily soluble in water. The *copper salt* (with 7 mols.  $\text{H}_2\text{O}$ ) crystallises in stellate groups of slender, green needles. The aqueous solution of the free acid has a fine green fluorescence which disappears when alkalis or acids (except acetic acid) are added. It reduces a cold ammoniacal silver solution, and Fehling's solution when warmed.

*Anhydrodiazohemipinic acid*,  $\text{COOH}\cdot\text{C}_6\text{H}(\text{OMe})_2<\overset{\text{N}_2\cdot\text{O}}{\text{CO}}>$ , is obtained when a cooled solution of sodium amido-hemipinate is treated with sodium nitrate and hydrochloric acid. It is a bright yellow, micro-crystalline powder which becomes superficially red when exposed to light, and explodes at  $140\text{--}150^\circ$  or when struck. It dissolves readily in alkalis and acids; when boiled with water, it gives off nitrogen and yields a hydroxy-acid, which gives an intense blue-violet colour with ferric chloride. The *hydrochloride*,  $\text{COOH}\cdot\text{C}_6\text{H}(\text{OMe})_2(\text{COOH})\cdot\text{N}_2\text{Cl} + \text{H}_2\text{O}$ , crystallises in long, colourless needles; in presence of water, it decomposes into hydrochloric acid and free anhydrazohemipinic acid. When the diazohemipinic acid is boiled with alcohol under slight pressure, it is converted, with evolution of nitrogen, into hemipinic acid.

Nitrohemipinic acid was prepared by Liebermann's method (this vol., p. 46). The *potassium salt* crystallises in deep yellow prisms, readily soluble in water and alcohol, the *silver salt* is also yellow.

*Nitrohemipinic anhydride*,  $\text{NO}_2\cdot\text{C}_6\text{H}(\text{OMe})_2<\overset{\text{CO}}{\text{CO}}>\text{O}$ , is prepared by heating the acid at  $160\text{--}165^\circ$  for two hours; it crystallises from benzene in bright yellow prisms melting at  $145^\circ$ . When nitrohemipinic acid is reduced with ferrous sulphate and soda, amidohemipinic acid is formed identical with the acid obtained by boiling azo-opianic acid with baryta.

The results of the experiments above described confirm the view brought forward by Liebermann (*loc cit.*) that Prinz's so-called azo-opianic acid is not an azo-derivative of opianic acid but an internal anhydride of orthamidohemipinic acid.

When nitrohemipinic acid is reduced with tin and hydrochloric acid, the compound  $\text{COOH}\cdot\text{C}_6\text{H}_2(\text{OMe})_2\cdot\text{NH}_2\cdot\text{HCl}$  is formed.

N. H. M.

**Derivatives of Normethylnitropianic Acid.** By K. ELBEL (*Ber.*, 19, 2306—2312).—Normethylnitropianic acid

is best prepared by heating finely powdered nitropianic acid with fuming hydrochloric acid (10 parts) for 15 hours at  $100^\circ$ , with a reflux condenser, hydrogen chloride being passed in all the time. The product is evaporated down, when the normethyl-compound separates; the yield is 80 per cent. of the theoretical.

*Normethylorthanhydramidohemipinic acid* (normethylazo-opianic acid),  $\text{OMe}\cdot\text{C}_6\text{H}(\text{OH})(\text{COOH})<\overset{\text{CO}}{\text{NH}}> [\text{OMe}:\text{OH}:\text{COOH}:\text{CO}:\text{NH} = 4:3:2:1:6]$ , is obtained by treating a boiling saturated aqueous

solution of normethylnitropianic acid with tin and hydrochloric acid. It is dissolved in alcohol and precipitated with water. It crystallises in colourless, lustrous needles which melt at 174—175° with decomposition; it is readily soluble in alcohol, sparingly in benzene, and insoluble in ether. When boiled with baryta, crystals of barium normethylamidohemipinate are formed. The *diacetyl*-derivative,  $\text{OMe} \cdot \text{C}_6\text{H}(\text{OAc})(\text{COOH}) < \begin{smallmatrix} \text{CO} \\ \text{N}^{\text{Ac}} \end{smallmatrix} >$ , is obtained by boiling normethylanhydramidohemipinic acid with sodium acetate and acetic anhydride (10 parts) for one hour. It melts at 205°, dissolves readily in benzene; the alcoholic solution has a fine blue fluorescence. It is very unstable and changes when kept into the *monacetyl* compound,  $\text{OMe} \cdot \text{C}_6\text{H}(\text{OAc})(\text{COOH}) < \begin{smallmatrix} \text{CO} \\ \text{NH} \end{smallmatrix} >$ , melting at 198°.

*Normethylnitropianic acid phenylhydrazine* crystallises in red needles which melt at 178—179° with decomposition. When boiled with glacial acetic acid, it parts with the elements of water and yields *normethylnitropiazide*,  $\text{NO}_2 \cdot \text{C}_6\text{H}(\text{OMe})(\text{OH}) < \begin{smallmatrix} \text{CO} \cdot \text{NPh} \\ \text{CH} : \text{N} \end{smallmatrix} >$ . The latter crystallises in lustrous, lemon-coloured, rhombic plates melting at 191°. It dissolves unchanged in dilute potash solution. The *potassium salt* is very readily soluble in water, almost insoluble in absolute alcohol. *Normethylamido-opiazide* is obtained by boiling the nitro-compound suspended in ammonia with ferrous sulphate. It crystallises from alcohol in short, almost colourless prisms.

*Normethylnitropianoximic acid*,

is formed by mixing a boiling solution of normethylnitropianic acid in water (40 parts) with an aqueous solution of hydroxylamine hydrochloride and sodium acetate. It crystallises from alcohol in lustrous yellow needles which become brown when warmed, and melt at 252°. It has a slight reducing action on Fehling's solution. It dissolves in alkali with a deep-red colour, and the solution gives off ammonia when boiled, with formation of *normethylnitrohemipinic acid*,  $\text{NO}_2 \cdot \text{C}_6\text{H}(\text{OMe})(\text{OH})(\text{COOH})_2 \quad [= 6 : 4 : 3 : 2 : 1]$ . The latter crystallises from alcohol in almost white, silky needles, readily soluble in water and alcohol; it melts at 220°. The *hydrogen potassium salt* forms bright yellow prisms. The same acid is formed when normethylhemipinic acid is nitrated with dilute nitric acid.

*Normethylnitrohemipinimide*,  $\text{NO}_2 \cdot \text{C}_6\text{H}(\text{OMe})(\text{OH}) < \begin{smallmatrix} \text{CO} \cdot \text{O} \\ \text{C}(\text{NH}) \end{smallmatrix} >$ , is obtained by boiling an alcoholic solution of normethylnitropianic acid with hydroxylamine hydrochloride, or better by boiling normethylnitropianoximic acid with glacial acetic acid. It crystallises in bright yellow needles which melt at 252° with decomposition.

N. H. M.

**Homo-orthophthalimide.** By S. GABRIEL (*Ber.*, 19, 2363—2367; compare Abstr., 1886, 812, and this vol., p. 61).—When a solution of homo-orthophthalimide (2 grams) and potash (1 gram) in methyl alcohol (15 c.c.) is digested with methyl iodide (4 grams) at 100°,

*dimethylhomo-orthophthalimide*,  $C_9H_5Me_2NO_2$ , is formed. The latter crystallises from water in flat needles melting at  $119-120^\circ$ ; it is readily soluble in the usual solvents and in alkali. When heated with potash and methyl iodide at  $100^\circ$ , it yields the *trimethyl-derivative*,  $C_9H_4Me_3NO_2$ ; this crystallises in long needles melting at  $102-103^\circ$ ; it is readily soluble. Alkali does not dissolve it.

*Homo-orthophthalmethylimide*,  $C_6H_4<\begin{smallmatrix} CH_2\cdot CO \\ CO\cdot NMe \end{smallmatrix}>$ , is formed by evaporating a mixture of homo-orthophthalic acid and methylamine, and distilling the residue. It forms long, colourless needles, which melt at  $123^\circ$  and boil at  $314-318^\circ$ . It is readily soluble in the usual solvents and dissolves in alkalis. When heated with methyl iodide and potash, it yields trimethylhomophthalimide melting at  $102-103^\circ$ . In the latter compound, therefore, one of the methyl-groups is attached to nitrogen. Trimethylhomophthalimide is hardly attacked by fuming hydrochloric acid at  $100^\circ$ , and so cannot contain methoxyl; when heated with the fuming acid at  $230-240^\circ$ , the *anhydride* of a bibasic acid,  $C_7H_4Me_2<\begin{smallmatrix} CO \\ CO \end{smallmatrix}>O$ , is obtained. This crystallises in flat crystals melting at  $82.5-83^\circ$ ; the *silver salt*,  $C_{11}H_{16}O_4Ag_2$ , was prepared. The anhydride is also formed when dimethylhomophthalide (from homophthalide, potash, and methyl iodide) is heated at  $230^\circ$  with fuming hydrochloric acid; ammonia is formed in the reaction.

Tri- and di-methylhomophthalimide and the anhydride (m. p.  $82.5-83^\circ$ ) have probably the constitution expressed in the formulæ—

N. H. M.

**Action of Amines on Phthalylacetic Acid.** By E. MERTENS (*Ber.*, 19, 2367—2373).—Pure phthalylacetic acid is stirred with water and treated with a 33 per cent. solution of ethylamine until it is dissolved; it is then filtered and saturated with hydrogen chloride, being kept cold the whole time. A white crystalline substance gradually separates with slight evolution of carbonic anhydride. Analyses show the compound to have the formula  $C_{23}H_{24}O_5N_2$ . It melts at  $129^\circ$ , dissolves readily in warm alcohol, ether, and chloroform, more sparingly in benzene; boiling water decomposes it.

*Methylenephthalethimidine*,  $CO<\begin{smallmatrix} C_6H_4 \\ NEt \end{smallmatrix}>C : CH_2$ , is formed when the compound  $C_{23}H_{24}O_5N_2$  is heated above its melting point; carbonic anhydride and water are evolved. It has a carrot-like odour, distils with steam, and is readily soluble in alcohol, ether, and chloroform, &c. It strongly resembles Gabriel's methylenephthalomethimidine (*Abstr.*, 1885, 1228).

*Phthalethimidylacetic acid*,  $CO<\begin{smallmatrix} C_6H_4 \\ NEt \end{smallmatrix}>C : CH\cdot COOH$ , is obtained by keeping a solution of the compound  $C_{23}H_{24}N_2O_5$  in sulphuric acid (10 parts) for 24 hours, and then pouring it into water. The white crystalline precipitate is crystallised from dilute alcohol, from which it

separates in yellow needles melting at  $180^{\circ}$  with effervescence. It is readily soluble in hot water, alcohol, and ether, less soluble in benzene. The *silver salt* forms a flaky crystalline precipitate; the *barium salt* crystallises in yellow lustrous needles. Propylamine and phthalylacetic acid yield the *compound*  $C_{25}H_{28}O_5N_2$ . It forms large well-formed prismatic crystals which melt with effervescence at  $103^{\circ}$ . It behaves similarly to the ethylamine compound.

*Acetophenone-orthocarboxanilide*,  $CO\cdot C_6H_4\cdot CO\cdot NHPh$ , is obtained by warming phthalylacetic acid with aniline. After the evolution of carbonic anhydride has ceased, the whole is left for 24 hours, when the substance separates in white crystals. It crystallises from benzene in large, well-formed cubes which melt at  $189$ — $192^{\circ}$ , and dissolve readily in warm alcohol, ether, or chloroform. When heated at  $204^{\circ}$  and afterwards at  $230^{\circ}$ , it is converted with evolution of aniline and water into *methylenephthalphenimidine*,  $CO\langle\begin{smallmatrix} C_6H_4 \\ NPh \end{smallmatrix}\rangle C:CH_2$ . The latter crystallises in yellowish prisms readily soluble in alcohol, ether, and chloroform; it melts at  $100^{\circ}$ . When acetophenonecarboxanilide is kept dissolved in strong sulphuric acid for 24 hours, it is converted into a *compound*,  $C_{15}H_{11}NO$ , isomeric with the compound just described. It is sparingly soluble in alcohol and ether, readily in benzene, chloroform, and light petroleum; it melts at  $265^{\circ}$ .  
N. H. M.

**Bromoterephthalic Acid.** By M. FILETI (*Gazzetta*, 16, 284—287).—Fischli (Abstr., 1879, 639) states that the monobromoterephthalic acid obtained by the oxidation of bromotoluic acid retains 1 mol.  $H_2O$ , even after drying at  $120^{\circ}$ . As the same acid obtained from bromocymene was found to be anhydrous, the author has repeated Fischli's experiments. The analytical results obtained for the proportion of carbon and bromine show that this acid is also anhydrous. It melts at  $296^{\circ}$ , and at the same time sublimes. Its *silver salt* is precipitated as a white, gelatinous mass, somewhat soluble in water. The *methyl salt*,  $C_6H_3Br(COOMe)_2$ , obtained from the said chloride (Fischli), as also from the acid itself (Fileti), crystallises in acicular prisms, melting at  $52^{\circ}$ ; it presents a well-marked chromatic polarisation.  
V. H. V.

**Cumidic Acids.** By E. SCHNAPPAUFF (*Ber.*, 19, 2508—2511).—The author prepared  *$\alpha$ -cumidic acid*,

by a modification of Wurtz's process, by the action of ethyl chlorocarbonate and sodium amalgam on dibromometaxylene. This acid forms glittering prisms melting much above  $320^{\circ}$ , and subliming with only slight decomposition. It is easily soluble in boiling alcohol, very sparingly in boiling water. Its *barium salt* crystallises with  $1\frac{1}{2}$  mol.  $H_2O$ , and is very soluble in water: the *methyl salt* forms long needles or plates and melts at  $76^{\circ}$ .

Cumidic acid, obtained as described by Jannasch (this Journal, 1871, 240) by the oxidation of durene, was converted into the methyl

salt, and this by crystallisation from alcohol was separated into two parts, the one melting at  $76^{\circ}$  the other crystallising in needles and melting at  $114^{\circ}$ . The former was the methyl salt of the  $\alpha$ -acid just described. The ether melting at  $114^{\circ}$  yielded  $\beta$ -cumidic acid [ $\text{Me} : \text{Me} : \text{COOH} : \text{COOH} = 1 : 4 : 2 : 5$ ] on hydrolysis. This acid is easily soluble in boiling alcohol, very sparingly in boiling water; it crystallises in hexagonal prisms, and sublimes at high temperatures without previous fusion. Its barium salt crystallises with  $2\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ ; its methyl salt melts at  $114^{\circ}$  and boils at about  $297^{\circ}$  (corr.). When the barium salt is distilled with excess of lime, paraxylene is formed, so that the above formula may be regarded as established.

Jannasch's acid is, therefore, a mixture of two isomeric cumidic acids. L. T. T.

**Reaction of Stilbene.** By G. ERRERA (*Gazzetta*, 16, 325).—Kade (Abstr., 1880, 46) states that stilbene in alcoholic solution gives a red coloration when heated with a solution of ferric chloride. It is here shown that this change is in reality due to the presence of water in the alcohol, which causes a partial decomposition of the ferric chloride into hydrochloric acid and some stable form of ferric hydroxide. Stilbene is not even necessary for the reaction; if absolute alcohol is used no colour-change ensues. V. H. V.

**$\beta$ -Naphthaquinone.** By T. ZINCKE (*Ber.*, 19, 2493—2502).—In the hope of elucidating the constitution of the two compounds,  $\text{C}_{22}\text{H}_{18}\text{N}_4\text{O}_6$  and  $\text{C}_{34}\text{H}_{22}\text{N}_4\text{O}_6$  (Abstr., 1882, 736, and 1883, 210), obtained by the action of nitrous acid on  $\beta$ -naphthaquinone-anilide and -toluide respectively, the author has undertaken similar investigations with phenanthraquinone. In the present communication, the author details some preliminary experiments as to the action of alkalis on halogen-derivatives of  $\beta$ -naphthaquinone, which were made to determine whether  $\beta$ -naphthaquinone-derivatives undergo changes similar to the conversion, by the action of alkalis, of phenanthraquinone into diphenyleneglycollic acid.

*Bromo- $\beta$ -naphthaquinone*, [ $\text{O} : \text{O} : \text{Br} = 1 : 2 : 3$ ], obtained by the action of bromine in acetic solution on  $\beta$ -naphthaquinone, and crystallising in red prisms melting at  $177$ — $178^{\circ}$ , dissolves readily in cold dilute alkalis. From these solutions, acids precipitate hydroxybromo- $\beta$ -naphthaquinone, described by Merz and Baltzer. Aniline and ammonia also act on bromo- $\beta$ -naphthaquinone, forming compounds analogous to naphthaquinoneanilide. *Dibromo- $\beta$ -naphthaquinone*, [ $\text{O} : \text{O} : \text{Br} : \text{Br} = 1 : 2 : 3 : 4$ ], could not be obtained directly from naphthaquinone, but was formed by the action of excess of bromine on an acetic solution of the monobromo-derivative. It is best obtained, however, by the action of bromine on  $\alpha$ -amido- $\beta$ -naphthol. It crystallises in red, rhombic scales or tables, sparingly soluble in alcohol and ether, and melts at  $172$ — $174^{\circ}$ . With ammonia and aniline, it yields the same compounds as the monobromo-derivative. It dissolves in cold dilute alkalis, and from these solutions acids precipitate a substance, crystallising in small white needles; this has not been further investigated.

*Chloro-β-naphthaquinone*, [O : O : Cl = 1 : 2 : 3], is formed when chlorine is passed through a solution of β-naphthaquinone in ten times its weight of glacial acetic acid, until a precipitate begins to be formed. It crystallises in red needles, soluble in alcohol, glacial acetic acid, and benzene, and melts at 172°. It gives an additive product with hydrochloric acid which forms white crystals. It dissolves in dilute alkalis, and this solution when acidified yields hydroxychloro-α-naphthaquinone. The unstable β-hydroxy-compound undoubtedly first formed passes into the more stable α-derivative. When chloro-β-naphthaquinone is reduced with sulphurous acid in acetic solution, *chloro-β-naphthaquinol*, C<sub>6</sub>H<sub>5</sub>Cl(OH)<sub>2</sub>, is formed, and crystallises in long, colourless needles melting at 116—117°. The *anilide* and *imide* of chloro-β-naphthaquinone both crystallise in dark-coloured scales having a metallic lustre, the former substance melting at 253°, the latter at 260°.

*Dichloro-β-naphthaquinone*, [O : O : Cl : Cl = 1 : 2 : 3 : 4], may be obtained directly from the quinone, but is best prepared by the action of chlorine on α-amido-β-naphthol. It crystallises in red scales, needles, or tables, easily soluble in chloroform and boiling benzene, sparingly in alcohol, melts at 184°, and sublimes without decomposition. With ammonia or aniline, it forms the imide or anilide respectively. When reduced with sulphurous acid in acetic solution, it yields dichloro-β-naphthaquinone, crystallising in white needles which melt at 125°. It dissolves in cold dilute alkali, and this solution when heated becomes cloudy, and deposits a greyish-white precipitate. If the cold alkaline solution be treated with excess of acid, an acid of the formula C<sub>10</sub>H<sub>6</sub>Cl<sub>2</sub>O<sub>3</sub> is liberated. This acid crystallises with 1 mol. H<sub>2</sub>O in small white needles, melts at 98—100°, and is easily soluble in alcohol, sparingly so in water. Its *methyl salt* forms colourless scales or hexagonal plates melting at 137—138°. The action of the alkali on the dichloroquinone appears to take place according to the equation C<sub>10</sub>H<sub>4</sub>Cl<sub>2</sub>O<sub>2</sub> + H<sub>2</sub>O = C<sub>10</sub>H<sub>6</sub>Cl<sub>2</sub>O<sub>3</sub>. The author considers the action to be similar to the action of alkalis on phenanthraquinone, and the most probable constitution of the acid to be CCl<C<sub>6</sub>H<sub>4</sub>>C(OH)·COOH. The acid forms an *acetyl-derivative*, melting at 75—76°. Boiling baryta-water or alkalis cause a separation of carbonic anhydride. When a solution of the acid in glacial acetic acid is treated with concentrated sulphuric acid at 120°, hydrogen chloride is evolved, and a yellow crystalline compound melting at 224—226° is produced. The acid is decomposed on heating its aqueous solution, a yellow compound of intense odour and volatile in steam being amongst the products of reaction.

The experiments on the bromo-derivatives were carried out in conjunction with Weltner, those on the chloro-derivatives with C. Fröhlich.

L. T. T.

**Benzene- and Toluene-azonaphthols and their Isomeric Hydrazine-derivatives.** By T. ZINCKE and F. RATHGEN (*Ber.*, 19, 2482—2493).—When the two position-isomerides, benzeneazo-β-naphthol and β-naphthaquinonehydrazide (see Zincke and Bindewald,

Abstr., 1885, 391), are reduced by means of stannous chloride, the former yields  $\alpha$ -amido- $\beta$ -naphthol, the latter  $\beta$ -amido- $\alpha$ -naphthol. When  $\alpha$ -amido- $\beta$ -naphthol is oxidised,  $\beta$ -naphthaquinone is formed, but the authors find that  $\beta$ -amido- $\alpha$ -naphthol yields under similar conditions  $\beta$ -dinaphthaquinone ( $\beta$ -dinaphthadiquinone). Both quinones yield with bromine dibromo- $\beta$ -naphthaquinone.

When heated with nitric acid, benzeneazo- $\beta$ -naphthol yields dinitro- $\beta$ -naphthol,  $C_{10}H_5(OH)(NO_2)_2$  [ $NO_2 : OH : NO_2 = 1 : 2 : 4$ ], whilst  $\beta$ -naphthaquinonehydrazide yields dinitro- $\alpha$ -naphthol [ $OH : NO_2 : NO_2 = 1 : 2 : 4$ ]. The  $\beta$ -derivative melts at  $194^\circ$ , the  $\alpha$ - at  $138^\circ$ . When the above isomeric hydrazide and azo-compound are reduced in alkaline solution, they are both decomposed into aniline and amido-naphthol.

The author disputes the correctness of Denaro's assertion (Abstr., 1886, 246) that two isomeric benzeneazonaphthols can be obtained from  $\beta$ -naphthol.

The authors have also investigated the corresponding toluene-derivatives. *Paratolueneazo- $\alpha$ -naphthol*,  $OH \cdot C_{10}H_6 \cdot N_2 \cdot C_7H_7$  [ $OH : N_2 = 1 : 4$ ], was prepared like the similar benzene-compound. It crystallises in dark-red flakes having a metallic lustre, and melts with decomposition at  $208^\circ$ . It is easily soluble in acetone, aniline, and alkalis, sparingly so in alcohol and acetic acid. No bromo-derivative could be obtained. Nitric acid yields dinitro- $\alpha$ -naphthol (b. p.  $139^\circ$ ). The *hydrochloride* and *hydrobromide* form bluish-green scales, which are slowly decomposed by water, rapidly by alcohol. It also forms metallic derivatives. The *ethoxide* crystallises in red needles, which appear yellow by transmitted light, and melt at  $126$ — $127^\circ$ ; the *methoxide* melts at  $103$ — $104^\circ$ ; the *acetyl-derivative* crystallises in yellow needles melting at  $101$ — $102^\circ$ . *Orthotolueneazo- $\alpha$ -naphthol*, [ $OH : N_2 = 1 : 4$ ], forms red needles melting at  $144$ — $146^\circ$ , soluble in alcohol, benzene, and acetic acid. It forms dinitro- $\alpha$ -naphthol with nitric acid, and yields salts resembling those of the para-compound. The *ethoxide* crystallises in red scales melting at  $94^\circ$ , the *methoxide* in reddish-brown needles melting at  $93^\circ$ . Para- and ortho-tolylhydrazides of  $\alpha$ -naphthaquinone are identical with the corresponding azo-compounds.

*Paratoluene- $\beta$ -naphthol*,  $C_{10}H_6O \cdot N_2H \cdot C_7H_7$ , or  $C_{10}H_6(OH) \cdot N_2 \cdot C_7H_7$  [ $O : N_2 :: 2 : 1$ ], forms red crystals with green fluorescence, is soluble in alcohol, benzene, and acetone, and melts at  $134$ — $135^\circ$ . It forms very unstable salts with acids. The *dibromo-derivative* forms intensely red needles melting at  $190^\circ$ . Nitric acid converts the azo-compound into dinitro- $\beta$ -naphthol (m. p.  $194^\circ$ ). *Orthotolueneazo- $\beta$ -naphthol*, [ $O : N_2 = 2 : 1$ ], crystallises in small red needles or scales which melt at  $131^\circ$ . With nitric acid, it yields a dinitro- $\beta$ -naphthol melting at  $167^\circ$ . The tolylhydrazides of  $\beta$ -naphthaquinone are, like the similar phenylhydrazide, isomeric and not identical with the azo-compounds. They resemble them, however, very closely, the chief difference being their greater solubility in alkalis.  *$\beta$ -Naphthaquinone-paratolylhydrazide*,  $C_{10}H_6O \cdot N_2H \cdot C_7H_7$  [ $O : N_2 = 1 : 2$ ], crystallises in small, red, glistening needles which melt at  $145^\circ$ . The *dibromo-derivative*,  $C_{17}H_{12}Br_2O$ , forms red, sparingly soluble needles melting at  $236^\circ$ .  *$\beta$ -Naphthaquinone-orthotolylhydrazide* crystallises in red scales with a

golden-yellow fluorescence. It is easily soluble in the usual solvents and melts at  $156^{\circ}$ . Its *dibromo-derivative* melts at  $254^{\circ}$ . Besides these hydrazides, the product of the action of the tolylhydrazine on the  $\beta$ -naphthaquinone always contained considerable quantities of dinaphthyldiquinol.

L. T. T.

**New Diamidodinaphthyl.** By P. JULIUS (*Ber.*, 19, 2549—2552). — $\alpha\alpha$ -Dinaphthyl is best prepared by distilling  $\beta$ -dinaphthol with zinc-dust (10—15 parts): the distillate is re-distilled in a vacuum and recrystallised from glacial acetic acid.

*Mononitrodinaphthyl*,  $C_{10}H_7 \cdot C_{10}H_6 \cdot NO_2$ , is obtained by adding nitric acid, of sp. gr. 1.3 (20 grams), to a solution of dinaphthyl (10 grams) in 150 c.c. of glacial acetic acid. It crystallises in lustrous, orange-coloured plates melting at  $188^{\circ}$ . It dissolves easily in hot benzene and glacial acetic acid, less readily in alcohol and ether.

*Dinitrodinaphthyl*,  $NO_2 \cdot C_{10}H_6 \cdot C_{10}H_6 \cdot NO_2$ , is prepared by treating a solution of 10 grams of dinaphthyl in 150 c.c. of glacial acetic acid with 80 grams of nitric acid, and then heating at  $60^{\circ}$ . It crystallises in bright yellow, voluminous needles which melt at  $280^{\circ}$ , it dissolves very sparingly in benzene, xylene, and glacial acetic acid, and is practically insoluble in other solvents.

*Diamidodinaphthyl hydrochloride*,  $NH_2 \cdot C_{10}H_6 \cdot C_{10}H_6 \cdot NH_2 \cdot 2HCl$ , is prepared by treating 10 grams of the dinitro-compound, suspended in 200 c.c. of glacial acetic acid, with hydrochloric acid, and 50 grams of zinc-dust. It is readily soluble in water, sparingly in strong hydrochloric acid; when exposed to the air, it quickly becomes green. The free base could not be isolated. The *diacetyl-derivative* crystallises in almost colourless needles which melt above  $300^{\circ}$ ; it is insoluble. When the hydrochloride is treated with ferric chloride, dark-brown, lustrous needles of *diimidodinaphthyl hydrochloride*,  $C_{20}H_{16}N_2Cl_2$ , are obtained; this is reconverted by reducing agents into the diamido-compound.

N. H. M.

**Tetrahydroxyanthraquinones.** By E. NOAH (*Ber.*, 19, 2337—2340).—When metahydroxybenzoic and gallic acids (equal mols.) are heated with sulphuric acid (10 parts) for 20 hours at  $170^{\circ}$ , two *tetrahydroxyanthraquinones*,  $C_{14}H_4(OH)_4O_2$ , are formed, together with hexahydroxyanthraquinone. The product is extracted with alcohol, the solution evaporated to dryness, and the residue extracted with benzene. The solution contains now only one tetrahydroxyanthraquinone. This crystallises in long, slender, red, lustrous needles, which do not melt at  $350^{\circ}$ , and sublime with difficulty, becoming partly carbonised. It is readily soluble in alcohol, acetone, and glacial acetic acid, sparingly in benzene, xylene, &c. The solutions in sulphuric acid and in caustic alkali are violet and emerald coloured respectively. The *tetracetyl-derivative* crystallises in yellow microscopic needles, which melt with decomposition at  $207$ — $209^{\circ}$ . The second tetrahydroxyanthraquinone is extracted by means of dilute alcohol from the residue undissolved by benzene. It crystallises in small, red needles which do not melt at  $380^{\circ}$ ; it sublimes in small, yellow needles, but is mostly decomposed. It dissolves readily in

alcohol, glacial acetic acid, and acetone, sparingly in ether and water. The solution in sulphuric acid is brownish-yellow; that in caustic alkali emerald-coloured. The *tetracetyl-compound* crystallises in lemon-coloured prisms, which are very readily soluble in glacial acetic acid, alcohol, and chloroform; it melts at 189°. N. H. M.

**Methylanthrakgallols.** By E. L. CAHN (*Ber.*, 19, 2333—2336; compare Abstr., 1886, 556).—1-Methylanthrakgallol,

is prepared by heating orthotoluic acid (3 parts) with gallic acid (2 parts) for 12 to 15 hours up to 130—135°. It crystallises from alcohol in gold-coloured flakes consisting of microscopic needles. It sublimes in long, orange-coloured needles, and melts at 297—298° with decomposition. It is readily soluble in hot alcohol and glacial acetic acid, sparingly in benzene; it also dissolves in hot water, yielding a red solution. The *triacetyl-derivative* crystallises in sulphur-coloured microscopic plates melting at 208—210°, readily soluble in chloroform, acetone, hot alcohol, &c. When methylanthrakgallol is distilled with zinc-dust, a hydrocarbon, crystallising in white plates and melting at 197°, is formed. When oxidised, it is converted into a quinone melting at 278—279°.

3-Methylanthrakgallol is prepared in a manner similar to the above compound from paratoluylic acid. It melts at 275°, and sublimes in orange-coloured needles. It resembles its isomeride. The *triacetyl-derivative* crystallises in well-formed, lustrous, golden prisms melting at 203—208° with decomposition.

2-Methyl- and 4-methyl-anthrakgallol are formed simultaneously from metatoluylic and gallic acids. The separation of the isomerides is difficult, and is best performed by converting the mixed product into the acetyl-derivative and recrystallising repeatedly from glacial acetic acid. The one methylanthrakgallol has a slight golden lustre, and melts at 312—313°; the other crystallises in small, well-formed prisms melting at 235—240°. The *acetyl-derivatives* melt at 188—190° and at 217—218° respectively.

The four methylanthrakgallols closely resemble one another and anthrakgallol. They are readily soluble in alcohol, and dissolve in strong and in dilute alkalis, yielding green and violet solutions respectively. The solution in hot ammonia has a fine blue colour, in sulphuric acid it is red; the latter changes to green on addition of a trace of nitric acid. The absorption-spectra of the red solutions of anthrakgallol and of the methylanthrakgallols in sulphuric acid are almost the same. N. H. M.

**Acid from Santonin: Isophotosantononic Acid.** By S. CANNIZARO and G. FABRIS (*Ber.*, 19, 2260—2265).—*Isophotosantononic acid*,  $\text{C}_{16}\text{H}_{22}\text{O}_5$ , is obtained by exposing 1 kilo. of santonin dissolved in 52 litres of acetic acid to the action of light for several months; one-ninth of the acetic acid is then boiled off under diminished pressure, and the

residue filtered from the photosantonio acid which separates on cooling. A further quantity of photosantonio acid is precipitated by adding water. The solution is then nearly free from photosantonio acid and still contains almost the whole of the isomeride. It is treated with sodium carbonate (which dissolves the photosantonio acid alone) and extracted with ether. It separates from its alcoholic solution in thick, triclinic crystals, rather soluble in ether, and sparingly in water. When heated at  $100^{\circ}$ , it is converted into the lactone,  $C_{15}H_{20}O_4$ . It is dextrorotatory,  $[\alpha]_D = +124^{\circ} 17'$ . Photosantonio acid has nearly the same specific rotatory power, but is levorotatory. Isophotosantonio acid dissolves in alkalis and in warm solutions of alkaline carbonates; the solutions are orange-red. The *barium salt*,  $(C_{15}H_{21}O_5)_2Ba + H_2O$ , is an amorphous powder, readily soluble in alcohol and in water. The *monacetyl-compound* crystallises from alcohol in transparent needles which melt at  $183^{\circ}$ ; it is dextrorotatory,  $[\alpha]_D = +58^{\circ} 16'$ . The *diacetyl-compound* is very sparingly soluble; it melts at  $163$ — $166^{\circ}$ . It is very unstable, and when often recrystallised changes to the monacetyl-derivative.

The results above described point to the following constitutional formulæ for the lactones of isophotosantonio and photosantonio acids respectively:—

N. H. M.

**Cinchol.** By O. HESSE (*Annalen*, **234**, 375—379).—A further comparison of the properties of cinchol and Liebermann's oxyquinoterpene or cholestole (*Abstr.*, 1885, 1075) confirms the author's previously expressed opinion (*Abstr.*, 1885, 1076) that these two substances are identical. They both melt at  $115^{\circ}$ , and are identical in crystalline form. The acetates melt at  $124^{\circ}$ , and also exhibit identical crystalline forms.

W. C. W.

**Alkaloids.** By O. DE CONINCK (*Compt. rend.*, **103**, 640—641).—Piperidine methiodide gives no colour reaction with potassium hydroxide (*Abstr.*, 1886, 897), and this difference furnishes a means of distinguishing between a pyridic base and its hexhydride.

Cicutine methiodide also gives no colour reaction, but the solution acquires an amber tint. The reaction is always obtained with collidines, and therefore will most probably be given by conyryne, the collidine of which cicutine is the hexhydride.

No similar colour reaction is obtained with the methiodides of aniline, orthotoluidine, or metaxylydine. When methiodides of pyridic bases are mixed with a fragment of solid potassium hydroxide

and sufficient water to form a paste, and then heated, a peculiar odour is developed owing to the formation of pyridic dihydrides.

No similar reaction is given by methiodides of pyridic hexhydrides, nor by the methiodides of aniline and its homologues. C. H. B.

**Extraction of Pyrroline from Animal Oil.** By G. L. CIAMICIAN and M. DENNSTEDT (*Gazzetta*, **16**, 336).—Pyrroline may be extracted as the potassium-derivative by using caustic potash instead of the metal as heretofore practised. The reaction is probably  $C_4H_5NH + KOH = C_4H_5NK + H_2O$ ; the excess of potash serving as a dehydrating agent. The fraction of the oil, freed previously from nitriles, which passes over at  $125-140^\circ$ , is heated in an oil-bath with an excess of fused potash, using a reflux apparatus. At the conclusion of the reaction, the liquid separates into three layers, the heaviest of which is the excess of potash, the next the potassium compound, and the lightest the unaltered hydrocarbons. On cooling, the potassium compound solidifies, and is washed with anhydrous ether. The substance thus obtained, distilled in a current of steam, yields pyrroline of boiling point  $130-138^\circ$ ; with chloroform, it yields chloropyridine (Abstr., 1881, 820). V. H. V.

**Pyridine Bases.** By A. LADENBURG (*Compt. rend.*, **103**, 692—695; see also Abstr., 1884 and 1885).— $\alpha$ -Methylpyridine (picoline),  $C_6NH_7$ , is obtained in the form of hydriodide by heating pyridine methiodide at  $300^\circ$ . The base boils at  $128-129^\circ$ , and is miscible with alcohol and water; sp. gr. at  $0^\circ = 0.9656$ . It forms a characteristic mercuriochloride,  $C_6NH_7, HCl, HgCl_2$ , by means of which it can be isolated in a state of purity; this compound is very soluble in hot water, but only slightly soluble in cold water.  $\beta$ -Methylpyridine is best prepared by Zanoni's method of heating glycerol and acetamide with phosphoric anhydride. It boils at  $142^\circ$ ; sp. gr. at  $0^\circ = 0.9771$ . The platinochloride crystallises with 1 mol.  $H_2O$  and melts at  $214^\circ$ ; the aurochloride is anhydrous and melts at  $183^\circ$ ; the mercuriochloride is also anhydrous, melts at  $143^\circ$ , and forms slender needles which can be crystallised from water.  $\gamma$ -Methylpyridine is formed only in small quantity by the action of heat on pyridine methiodide; it boils at  $144-145^\circ$ ; sp. gr. at  $0^\circ = 0.9708$ . The platinochloride is anhydrous, melts at  $225^\circ$ , and is only slightly soluble in water.  $\alpha\alpha'$ -Dimethylpyridine is isolated from the fraction of animal oil boiling at  $138-145^\circ$  by means of the mercuriochloride,  $C_7NH_9, HCl, HgCl_2$ , which can be crystallised from water, and melts at  $183^\circ$ . When decomposed, it yields lutidine boiling at  $142-143^\circ$ ; sp. gr. at  $0^\circ = 0.9424$ . The aurochloride forms yellow needles which melt at  $124^\circ$ ; the platinochloride crystallises in large monoclinic crystals isomorphous with  $\beta$ -picoline platinochloride, although the former is anhydrous, whilst the latter contains 1 mol.  $H_2O$ . The picrate is only slightly soluble in water and melts at  $159^\circ$ . When the base is oxidised, it yields a bibasic acid,  $C_5NH_3(COOH)_2$ , crystallising in beautiful needles which melt at  $226^\circ$ , and at the same time decompose into pyridine and carbonic anhydride.  $\alpha\gamma$ -Dimethylpyridine exists in large quantity in Dippel's

oil, and can be isolated from the fraction which boils at 155—160° by acidifying with hydrochloric acid and adding mercuric chloride. The precipitated mercuriochloride,  $2(C_7NH_9, HCl, 2HgCl_2) + H_2O$ , is repeatedly recrystallised, and forms beautiful needles which melt at 129°. When decomposed, it yields the base; this boils at 157°, and is only slightly soluble in cold water, still less soluble in hot water. The platinochloride is somewhat soluble, crystallises readily, and melts at 219—220°. The aurochloride,  $C_7H_9N, HAuCl_4$ , is less soluble and does not crystallise so well. The picrate melts at 180°. This lutidine is identical with the lutidine prepared synthetically by Hantzsch. When oxidised, it yields lutidinic acid, which crystallises in plates which melt at 235°.

*α-Ethylpyridine* is the principal product of the action of a high temperature on pyridine ethiodide; it boils at 150°, is miscible with alcohol, but is only slightly soluble in water. The platinochloride is somewhat soluble in water, and melts at 168—170°; the aurochloride melts at 120° and crystallises readily from hot water; the picrate melts at 110°. When the base is oxidised, it yields picolinic acid only.

*γ-Ethylpyridine* is also formed in smaller quantity by the action of heat on pyridine ethiodide, and is separated from its isomeride by taking advantage of the comparative insolubility of its salts, especially the platinochloride or ferrocyanide. The base boils at 165°; sp. gr. at 0° = 0.9522. The platinochloride melts at 208°, the picrate at 163°, the aurochloride at 138°. The ferrocyanide is precipitated even from very dilute solutions. When the base is oxidised, it yields isonicotinic acid. *α-γ-Diethylpyridine* is also obtained in small quantity by the action of heat on pyridine ethiodide; it boils at 187—188°, has a disagreeable odour, and is only slightly soluble in water. When carefully oxidised, it yields lutidinic acid which melts at 235°.

*α-Isopropylpyridine*, obtained by heating pyridine with propyl or isopropyl iodide at 300°, boils at 158—159°, is slightly soluble in water, and has a very disagreeable odour; sp. gr. at 0° = 0.9342. The platinochloride,  $(C_8H_{11}N)_2, H_2PtCl_6$ , is somewhat soluble and melts at 168°; the aurochloride crystallises from dilute solutions in yellow plates which melt at 91° and are only slightly soluble in water; the picrate forms yellow needles which melt at 116°. When the base is oxidised by potassium permanganate, it yields picolinic acid. *γ-Isopropylpyridine* is obtained in smaller quantity by the same reaction, and is separated by means of the platinochloride, which is only slightly soluble in water, and melts at 203°. The base boils at 177—178°; sp. gr. at 0° = 0.9439. When oxidised, it yields isonicotinic acid.

C. H. B.

**Quinoline.** By A. CLAUS and F. COLLISCHONN (*Ber.*, 19, 2502—2508).—The authors describe a number of halogen additive products of the propio-haloid compounds of quinoline. Quinoline propio-bromide is easily formed when its constituents are heated alone, or better, with alcohol, at 90—100°. It is easily soluble in alcohol and water, and crystallises from water in colourless plates containing 2 mols.  $H_2O$ , and melting at 66°; from absolute alcohol, it separates in anhydrous crystals melting at 148°. It is easily soluble in chloroform, and from this solution crystallises with 1 mol.  $CHCl_3$  in quadratic

prisms which gradually lose chloroform and become opaque, soften at 65°, and melt with evolution of chloroform at 128—129°. *Quinoline propiodide* forms yellow anhydrous crystals melting at 145°, and becoming rapidly discoloured in the light. This also crystallises with 1 mol.  $\text{CHCl}_3$  in quadratic prisms which begin to evolve chloroform at 92°. *Quinoline propiochloride* cannot be easily prepared directly from its constituents, but is best obtained by acting on the corresponding bromide with silver chloride. It is very soluble in water, and crystallises in colourless prisms or plates containing 1 mol.  $\text{H}_2\text{O}$  and melting at 95°. The hygroscopic anhydrous salt melts at 135°; it also crystallises with 1 mol.  $\text{CHCl}_3$  in quadratic prisms melting at 79°.

The additive products were obtained by treating a chloroform solution of the propiohaloid salt with the halogen.

*Quinoline propiobromide dibromide*,  $\text{C}_9\text{NH}_7 \cdot \text{PrBr}_3$ , forms glistening, red, triclinic crystals melting at 93°. The *di-iodide* forms brown metallic needles melting at 60°. The *dichloride* forms yellow scales melting at 60°. The *tetridide*,  $\text{C}_9\text{H}_7\text{N} \cdot \text{PrBrI}_4$ , yields small, almost black needles having a green fluorescence and melting at 49°.

*Quinoline propiodide dibromide* forms orange triclinic crystals melting at 77°. The *di-iodide* forms thin, bronze-coloured scales melting at 62°. The *dichloride* forms yellow needles melting at 87°. The *tetrabromide*,  $\text{C}_9\text{NH}_7 \cdot \text{PrIBr}_4$ , is a very unstable orange-red powder which evolves bromine at the ordinary temperature, and gave no constant melting point (48—58°). The *tetridide* forms iodine-coloured plates melting at 50°. The *tetrachloride* crystallises in needles which show the high melting point 144—145°. It is also formed when quinoline propiochloride is treated with iodine trichloride, and may therefore really be quinoline propiochloride iodide trichloride. When boiled with water, it is gradually decomposed into quinoline propiochloride. Similar migration of the halogen-atoms may also very likely take place in others of the mixed haloïd compounds.

*Quinoline propiochloride dibromide* forms orange crystals melting at 84—85°. The *di-iodide* melts at 61—62°. The *dichloride* is very unstable and could not be obtained in a pure state. A tetridide is easily formed, but could not be obtained in a pure state.

All these additive compounds decompose when heated at 150—200°, propyl haloïd salts, quinoline haloïd salts, and halogenised and alkylated quinolines being amongst the products of decomposition. These decompositions are being studied. All the above temperatures are uncorrected.

L. T. T.

**Isoquinoline and its Derivatives.** By S. GABRIEL (*Ber.*, 19, 2354—2363; compare *Abstr.*, 1886, 812).—*Dichlorisoquinoline*,

is prepared by heating homo-orthophthalimide (8 grams) with phosphorus oxychloride (24 grams) for three hours at 150—170°. The product is poured into alcohol (5 vols.), the mass of crystals so obtained treated with soda until alkaline, filtered, and recrystallised from alcohol. It is readily soluble in hot alcohol, cold chloroform,

ether, and benzene; it boils at 305—307°. The alkaline mother-liquor obtained in the preparation of this compound, when treated with hydrochloric acid, yielded the *chloro-derivative*  $C_6H_4<\begin{smallmatrix} CH_2\cdot CO \\ CCl:N \end{smallmatrix}>$ , or  $C_6H_4<\begin{smallmatrix} CH\cdot C(OH) \\ CCl:N \end{smallmatrix}>$ ; this crystallises from boiling alcohol in long needles melting at 195—197° with evolution of gas. It is rather soluble in hot alcohol, sparingly in hot benzene and in chloroform; it dissolves in alcohol, but not in ammonia. The *methyl-compound*,  $C_9H_5MeClNO$ , is obtained by dissolving half a gram of the substance in methyl alcohol (10 c.c.), adding methyl iodide (2 grams), and heating at 100°. It forms slender, white crystals, readily soluble in alcohol, ether, benzene, &c., insoluble in alkali. It melts at 66—67°, and has an odour of fruit.

*Chlorisoquinoline*,  $C_6H_4<\begin{smallmatrix} CH\cdot CCl \\ CH\cdot N \end{smallmatrix}>$ , is obtained by reducing the dichloro-compound with phosphorus and hydriodic acid at 150—170°, or with tin and hydrochloric acid. It melts at 47—48°, and boils at 280—281° under 753 mm. pressure, and is readily soluble.

*Methoxyphenylchlorisoquinoline*,  $C_6H_4<\begin{smallmatrix} CCl\cdot CPh \\ C(OMe)\cdot N \end{smallmatrix}>$ , is formed when phenyldichlorisoquinoline (1 gram) and sodium methoxide are heated for three hours at 100°. It crystallises from alcohol in needles melting at 76°, readily soluble in ether, benzene, &c. It dissolves also in strong hydrochloric acid, but is precipitated by water. When heated with fuming hydrochloric acid at 100°, it is converted, with evolution of methyl chloride, into the compound  $C_{15}H_{10}ClNO$ , probably *chlorisobenzal phthalimidine*,  $C_6H_4<\begin{smallmatrix} CCl\cdot CPh \\ CO\cdot NH \end{smallmatrix}>$ . It crystallises from alcohol in slender, lustrous needles, melting at 211—212°, moderately soluble in ether and cold alcohol, readily in glacial acetic acid, benzene, &c. The formation of this compound is analogous to that of isobenzal phthalimidine from phenylethoxyisoquinoline (Abstr., 1886, 631).

*Ethoxychlorisoquinoline*,  $C_6H_4<\begin{smallmatrix} CH=CCl \\ C(OEt)\cdot N \end{smallmatrix}>$ , is prepared by heating dichloroisoquinoline with alcoholic soda at 100°. It forms readily soluble needles melting at 37—37.5°.

The *methoxy-derivative*,  $C_{10}H_8NOCl$ , is prepared in a similar manner. It melts at 73—74°, and is isomeric with the methyl-compound obtained from chloroxyquinoline. When heated at 150° in a current of dry hydrogen chloride, it is converted into *oxychlorisoquinoline*,  $C_6H_4<\begin{smallmatrix} CH\cdot CCl \\ CO\cdot NH \end{smallmatrix}>$ . This crystallises from dilute alcohol in slender needles melting at 218—220°; it dissolves rather readily in ether, easily in alcohol and chloroform; it is also readily soluble in dilute aqueous soda. The *methyl-derivative*,  $C_6H_4<\begin{smallmatrix} CH\cdot CCl \\ CO\cdot NMe \end{smallmatrix}>$ , crystallises in long, broad needles which melt at 111—112°; it is readily soluble. Oxychlorisoquinoline is formed in small quantities in the preparation of ethoxychlorisoquinoline.

Isoquinoline is conveniently prepared by heating dichlorisoquinoline (3 grams), and hydriodic acid, sp. gr. 1.96 (18 c.c.) for five hours at 230°. The product is treated with alkali, and steam distilled; the distillate being treated with hydrochloric acid and again steam distilled to remove the unchanged chloro-base. Isoquinoline melts at 20—22°, and boils at 236—236.5°. The *ethiodide* crystallises in gold-coloured plates melting at 147—148°, readily soluble in water and in warm alcohol. N. H. M.

**Synthesis of Hydroxyquinolinecarboxylic Acid.** By E. LIPPMANN and F. FLEISSNER (*Ber.*, 19, 2467—2471).—Unlike ordinary phenol-derivatives, the potassium compound of orthohydroxyquinoline is not acted on by carbonic anhydride even at 300°. When, however, nascent carbonic anhydride (obtained by the action of potash on carbon tetrachloride) is employed, action takes place. Orthohydroxyquinoline, carbon tetrachloride, and caustic potash are mixed in alcoholic solution in the proportions necessary for the equation  $C_9NH_7O + CCl_4 + 6KHO = 4KCl + C_9NH_5(OK) \cdot COOK + 4H_2O$ , and the whole boiled for 12 hours. The product contains *hydroxyquinolinecarboxylic acid*,  $OH \cdot C_9NH_5 \cdot COOH$ , which when purified crystallises in yellow prisms melting at 280°. This acid agrees in its salts and in all its properties, save melting point and oxidation products, with the  $\alpha$ -hydroxycinchonic acid (m. p. 254—256°) obtained by Weidel and Cobenzl from sulphocinchonic acid (*Abstr.*, 1881, 742). The acid is sparingly soluble in the ordinary solvents. It dissolves in dilute hydrochloric acid to form a *hydrochloride*, which is precipitated on the addition of concentrated hydrochloric acid in the form of glistening needles. The *platinochloride* forms unstable, bright yellow needles. The acid forms a *normal barium* salt, the pale yellow solution of which, on the addition of baryta-water, yields white needles of the *basic barium* salt  $C_{10}NH_5BaO_3 + H_2O$ ; these only part with their water of crystallisation at 140—150°. The *silver* salt is precipitated in the form of pale lemon-yellow flocks, which soon change to microscopic needles. The aqueous solution of the acid gives a green coloration with ferric chloride, but none with ferrous sulphate. When subjected to dry distillation, the acid yields orthohydroxyquinoline.

When oxidised by potassium permanganate in alkaline solution, the acid yields a *pyridinedicarboxylic acid*,  $C_7NH_5O_4$ , forming bright yellow crystals melting at 234—235°. With ferrous sulphate, it gives a blood-red coloration, and forms a silver salt which is gelatinous when first precipitated, but soon becomes crystalline. This acid is probably identical with Böttinger's pyridinedicarboxylic acid, and isomeric with Weidel's isocinchomeronic acid.

Weidel and Cobenzl's  $\alpha$ -hydroxycinchonic acid, when similarly oxidised, yields  $\alpha$ -pyridinetricarboxylic acid. The authors are further investigating this subject. L. T. T.

**Peculiar Formation of  $\beta$ -Diquinoline.** By O. FISCHER and H. VAN LOO (*Ber.*, 19, 2471—2476).—This is a continuation of the authors' previous work (*Abstr.*, 1884, 1372). When  $\beta$ -diquinoline is heated with ethyl iodide in closed tubes at 90—100°,  $\beta$ -diquinoline

*ethiodide*,  $C_{18}N_2H_{12}EtI$ , is formed in long, ruby-red crystals. It is very unstable, and is decomposed by water and by boiling alcohol. No diethiodide could be obtained. When bromine is allowed to act on  $\beta$ -diquinoline in chloroform solution, a *tetrabromo-additive product*,  $C_{18}N_2H_{12}Br_4$ , is produced. This crystallises in pale yellow needles melting at  $192^\circ$ , and is decomposed at once by sulphurous acid, diquinoline sulphate being formed.  $\beta$ -Diquinolinedisulphonic acid,  $C_{18}N_2H_{10}(SO_3H)_2$ , is produced when  $\beta$ -diquinoline is heated with a large excess of fuming sulphuric acid. It is very soluble in water, and is precipitated from this solution by a mixture of alcohol and ether in yellowish flocks. Its *potassium salt* crystallises from 50 per cent. alcohol in glistening white prisms containing 3 mols.  $H_2O$ . The anaquinolinecarboxylic acid described in the former paper (*loc. cit.*), as obtained by the oxidation of the base by chromic acid in acetic solution, is undoubtedly identical with that lately obtained by Skraup and Brunner (m. p.  $247^\circ$ ). The melting point previously given by the authors was obtained from a sample crystallised from benzene; when crystallised from water, it melts at  $248$ — $249^\circ$ . The author considers this acid to be *metaquinolinecarboxylic acid*, and that the name anaquinolinecarboxylic acid should be transferred to the acid melting at  $357^\circ$ , and hitherto designated *metaquinolinecarboxylic acid*.

If chromic acid is dissolved in sulphuric acid in place of acetic acid, the oxidation takes place in quite a different way. Under these circumstances *pyridylquinolinecarboxylic acid*,  $C_9NH_6 \cdot C_5NH_3 \cdot COOH$ , is formed. This crystallises in glistening needles, which melt with decomposition at  $271$ — $273^\circ$ . It is sparingly soluble in water, easily in alcohol, and forms salts both with acids and bases. The silver salt, when heated, yields a *pyridylquinoline*,  $C_{14}N_2H_{10}$ , which crystallises in white needles melting at  $104^\circ$ , and gives a reddish-yellow crystalline *platinochloride*.

L. T. T.

**Piperidine Bases.** By A. LADENBURG (*Compt. rend.*, **103**, 747—749).—The bases are obtained by treating boiling alcoholic solutions of the corresponding pyridine bases with a large excess of sodium.

*Piperidine* obtained in this way is identical with the base prepared from piperine.  $\alpha$ -Methylpiperidine or  $\alpha$ -pipecoline boils at  $118$ — $119^\circ$ , has the same odour as piperidine, and dissolves readily in water; sp. gr. at  $0^\circ = 0.860$ . The hydrochloride is very soluble, but not deliquescent, and melts at  $189^\circ$ . The hydrobromide is less soluble, and forms confused needles which melt at  $182^\circ$ ; the platinochloride is very soluble. With carbon bisulphide, the base yields a thiocarbamate,  $CS_2 \cdot 2C_6H_{13}N$ , which crystallises readily, melts at  $118^\circ$ , and is analogous to that formed from piperidine.  $\beta$ -Methylpiperidine or  $\beta$ -pipecoline boils at  $125^\circ$ , and dissolves readily in water; sp. gr. at  $0^\circ = 0.8684$ . The hydriodide crystallises in beautiful, non-deliquescent needles, which melt at  $131^\circ$ . It combines with cadmium iodide, forming the compound  $CdI_2 \cdot 2C_6H_{13}NHI$ , a white precipitate soluble in warm water, from which it crystallises in white tables melting at  $145^\circ$ . The platinochloride is somewhat soluble, and forms orange prisms melting at  $192^\circ$ ; the aurochloride is very soluble, and melts at  $131^\circ$ ; the picrate melts at  $136^\circ$ .  $\alpha\alpha'$ -Dimethylpiperidine or  $\alpha\alpha'$ -lupetidine boils at  $128$ —

130°, and is very soluble in water and alcohol; sp. gr. at 0° = 0.8492. The hydrochloride and hydrobromide crystallise in non-deliquescent needles; the platinochloride forms large orange crystals which melt at 212°. *αγ-Dimethylpiperidine* boils at 141°, has an odour of piperidine, and dissolves readily in water, though not in all proportions; sp. gr. at 0° = 0.8615. The hydrochloride crystallises in beautiful needles which melt at 235°; the hydrobromide is even more soluble; the platinochloride is not very soluble, and crystallises in nodules; the aurochloride is an oil. *α-Ethylpiperidine* boils at 143°, and dissolves slightly in water, but separates from the solution on heating, and has an odour resembling that of piperidine and conicine; sp. gr. at 0° = 0.8674. The hydrochloride forms non-deliquescent crystals; the platinochloride crystallises in large tables which melt at 178°. The methyl-derivative boils at 149—152°; sp. gr. at 0° = 0.8495. *γ-Ethylpiperidine* boils at 157°, has a disagreeable odour, is only slightly soluble in cold water, and still less soluble in warm water; sp. gr. at 0° = 0.8795. The hydrochloride is deliquescent; the platinochloride forms yellow tables which melt at 170—173°; the aurochloride crystallises from warm water in lamellæ which melt at 105°. *α-Isopropylpiperidine* boils at 160—162°, and is slightly soluble in water, but separates from the solution when gently heated; sp. gr. at 0° = 0.8676. Its odour and its properties generally resemble those of its isomeride, conicine, but it is much less poisonous. The platinochloride is much less soluble in water, and is not soluble in alcohol or ether; it melts at 193°; the hydrochloride melts at 240°, the hydrobromide at 230°, the hydriodide at 242°. All these derivatives crystallise readily. The iodide combines with cadmium iodide, forming a slightly soluble double salt, which crystallises readily and melts at 132°. The picrate and aurochloride crystallise readily, and are only slightly soluble. With carbon bisulphide, the base yields a crystalline compound,  $\text{CS}(\text{C}_8\text{H}_{16}\text{N})\text{SH}$ ,  $\text{C}_8\text{H}_{17}\text{N}$ , which melts at 105°, dissolves readily in alcohol, but is only slightly soluble in water. The methyl-derivative of *α-isopropylpiperidine* boils at 166°; sp. gr. at 0° = 0.8593. Its hydrochloride is extremely soluble in water; the aurochloride forms shining lamellæ, and is also very soluble in water; the platinochloride is somewhat soluble, and melts at 100°; the picrate crystallises readily, and melts at 149°. *γ-Isopropylpiperidine* boils at 168—171°, dissolves slightly in water, and has a very disagreeable odour. The hydrochloride crystallises, but is not stable in moist air; the platinochloride is crystalline, and is only slightly soluble in water, but dissolves in alcohol and ether, and melts at 172°; the aurochloride is also crystalline, and only slightly soluble.

C. H. B.

**Method of Preparing Extracts of Pepsin.** By W. PODWYSSOZKI (*Pflüger's Archiv*, 39, 62—74).—If the gastric mucous membrane of carnivora and herbivora be placed in glycerol almost immediately after death, very little pepsin is extracted.

Ebstein and Grützner state that glycerol dissolves pepsin only, but the author finds that a certain amount of pepsin precursor, or as he terms it "propepsin," is dissolved also.

Mucous membrane exhausted with glycerol still yields an important

amount of pepsin when treated with hydrochloric acid or hydrochloric acid and glycerol. It appears, therefore, that gastric mucous membrane contains two propepsins, one soluble in glycerol, the other insoluble.

If the mucous membrane is kept in a warm place for 24 hours before it is extracted, a much larger yield of pepsin is obtained, provided no putrefaction has set in.

Hydrogen and carbonic anhydride have no influence on the formation of pepsin, but oxygen, on the other hand, appears to favour its development; more pepsin is formed when the mucous membrane is allowed to remain in contact with oxygen than when it is in contact with air.

Chlorine gas passed through any extract entirely destroys the ferment. J. P. L.

**Comparative Estimation of Preparations of Pepsin.** By A. A. LIPSKI (*Russkaya Meditsina*, 35, 583—584).—The powdered pepsins were examined by digesting 0.2 gram of the preparation with 10 grams of white of egg and 100 c.c. of hydrochloric acid (0.25 per cent.) for four hours at 40°. The undissolved albumin being then determined, the weight of this in grams was:—Perret acidifié 8.756, Marquart 8.577, Lamatch 8.557, Merck 7.213, Boudault neutre (No. 4) 2.62, Witte 2.195, Boudault acidifié 1.2, Russicum soluble (of the Russian Ph.) 0.721, do. do. recent 0.47, do. do. without the sugar contained in the official preparation 0.157. The Russian pepsin is, therefore, far more active than any of the German or French preparations tested. The same holds good for the pepsin wines.

## Physiological Chemistry.

---

**Sugar in the Blood with Reference to Nutrition.** By J. SEEGEN (*Pflüger's Archiv*, 39, 121—131).—Experiments on dogs have shown (Abstr., 1886, 382 and 411) that the percentage of sugar is always approximately twice as great in the blood of the hepatic as in the blood of the portal vein during various carbohydrate diets and during long periods of inanition, also that peptone is probably the chief constituent from which the liver forms sugar under normal conditions. The sugar formed in one day during starvation is far in excess of the total glycogen present in the body.

Further experiments have been made on dogs fed with a diet of meat only, of fat with a minimal quantity of meat, and in some instances with fat only.

The general result is the same as in previous experiments, namely, that the percentage of sugar in the blood leaving the liver is double that of the blood on entering. The total amount of sugar in the blood as well as the difference between the percentages in the blood

on entering and leaving the liver is greater with a meat diet than any other.

The most striking result is the continued formation of sugar during an almost exclusively fat diet. It might be supposed that this is due to proteid decomposition, but a determination of the nitrogen excreted during the feeding was quite insufficient to account for the increase.

The amount of blood passing through the liver of dogs of 10 to 12 kilos. is not less than 200 litres in the 24 hours. The mean difference in the percentage of sugar of the blood on entering and leaving the liver is 0.1 per cent., consequently about 200 grams of sugar would be formed in 24 hours. During the fat diet, the amount of nitrogen excreted daily was on an average 15 grams, corresponding to 100 grams of proteid, a quantity quite insufficient to furnish 200 grams of sugar, even supposing that none of the carbon of the proteid be utilised for the formation of urea.

The conclusion drawn from these experiments is that the liver has the power of forming sugar from fat. This would satisfactorily explain the constant formation of sugar during starvation, for Voit has shown that an animal during starvation loses 97 per cent. of its fat, and only 30 per cent. of its muscular substance.

The chief results of the author's experiments may be thus summed up:—

1st. The blood of the hepatic vein is without exception richer in sugar than the blood of the portal vein.

2nd. The new formed sugar does not depend on the sugar and carbohydrates ingested with the food.

3rd. The glycogen of the liver is not concerned in the formation of sugar.

4th. Albumin and fat are the materials from which the liver forms sugar.

J. P. L.

**Power of the Liver to Form Sugar from Fat.** By J. SEEGEN (*Pflüger's Archiv*, 39, 132—142).—It has been previously shown that small pieces of freshly excised liver in the presence of defibrinated blood have the power of converting peptone into sugar (Abstr., 1886, 382). By a similar series of experiments, the author has proved that the liver cells can under the same conditions convert fat into sugar, thus confirming the conclusion he arrived at from his experiments on feeding dogs on a diet consisting exclusively of fat (preceding Abstract).

For each experiment, 50 grams of finely cut liver excised from a recently killed dog was mixed with 60 to 80 c.c. of freshly defibrinated blood and placed in a large flask; to this mixture various emulsions of vegetable oils were added. The flask and contents were maintained for 5 or 6 hours at 35° to 40°, and a constant stream of air was drawn through the mixture of blood by means of an aspirator.

The average increase in the percentage of sugar was found to be 50 per cent. Control experiments were made in every instance.

A further series of experiments proved that both constituents of a fat, that is both glycerol and the fatty acid, are alike capable of being converted into sugar by the liver.

J. P. L.

**Importance of Ammonia for the Formation of Glycogen in the Liver of the Rabbit.** By F. RÖHMANN (*Pflüger's Archiv*, 39, 21—53).—Asparagine and glycocine given with a carbohydrate diet increase the amount of glycogen formed in the liver to a marked extent; this increase is more pronounced with asparagine than with glycocine. On account of its slight solubility, asparagine is probably not absorbed unchanged, but undergoes decomposition with formation of ammonia.

Ammonium carbonate given with the same diet increases the glycogen in a still more marked manner, but ammonia in the form of lactate seems to be inert.

As sodium carbonate and hydrogen carbonate have no effect, ammonium carbonate does not exert its influence by reason of its alkalinity.

As a possible explanation, the author suggests that the ammonia and a carbohydrate entering the liver cells together may form a new compound which will split into glycogen on the one hand and a nitrogenised product on the other, for instance, urea. J. P. L.

**Feeding and Development of Silkworms.** By O. KELLNER (*Landw. Versuchs-Stat.*, 1886, 381—392).—This article contains an account of experiments which are a continuation of those previously detailed (*Abstr.*, 1884, 1202). The research was commenced with the view of determining what quantity of food was necessary for the full and healthy development of the worm, with the largest subsequent supply of silk. Without entering into the details of feeding, &c., all of which are fully given in tables, it will be sufficient to give the final results. Every increase of growth requires an increase in the food, but this increase in food is not commensurate with the growth, being very much higher; the weaker the insect is before envelopment, the greater will be the loss during metamorphosis, by respiration, &c.

A poorly fed and developed caterpillar produces a lower yield of valuable silk than those which are well and largely fed, and will contain more nitrogenous and mineral matter, whilst the well-fed insect will be richer in fat and other non-nitrogenous matter. E. W. P.

**Isethionic Acid in the Body, and Thiosulphuric Acid in the Urine.** By E. SALKOWSKI (*Pflüger's Archiv*, 39, 209—222).—In a former paper (*Virchow's Archiv*, 66, 315), the author stated that in the dog the administration of sodium isethionate produced an increase of sulphuric acid in the urine, but that thiosulphuric acid was under all circumstances absent. Heffter (*Pflüger's Archiv*, 38, 476) states however, that sulphuric acid is not formed from isethionic acid, but that the greater part (78 per cent.) of the latter acid leaves the body as thiosulphuric acid, and a smaller portion (22 per cent.) in some undiscovered manner. Heffter himself explains the discrepancy by supposing it to be due to the difference in diet during the investigation, Heffter using meat, not bread and milk as in Salkowski's earlier experiments.

The present research is a reinvestigation of the subject: a dog was

fed on a fixed meat diet, and for three days 3 grams of sodium isethionate was given *per diem*. The results are shown in the following table:—

| Day. | Diet.               | Nitrogen<br>in urine. | Sulphuric acid<br>in urine. |
|------|---------------------|-----------------------|-----------------------------|
| 1    | Meat                | 12·22                 | 3·20                        |
| 2    | Do.                 | 12·49                 | 3·15                        |
| 3    | Do.                 | 12·49                 | 2·97                        |
| 4    | 3 gr. of drug added | 12·49                 | 3·83                        |
| 5    | Do.                 | 12·23                 | 4·65                        |
| 6    | Do.                 | 12·25                 | 4·99                        |
| 7    | Meat                | 12·04                 | 3·40                        |
| 8    | Do.                 | 11·63                 | 2·89                        |
| 9    | Do.                 | 11·49                 | 3·16                        |

This table shows that whereas the nitrogen output remains constant, the amount of sulphates is increased; the increase could therefore not have been due to increased metabolism of proteids; it is therefore all due to the isethionic acid, and it is found from the foregoing numbers, that 30 per cent. of the isethionic acid must have become oxidised into sulphuric acid. By comparing the intensity of the sulphuretted hydrogen reaction, it was found also that the amount of thiosulphuric acid in the urine was slightly increased. The amount of this acid in the urine was estimated also by its reducing action on potassium permanganate; the increase during the days when the drug was given, show theoretically that 13·4 per cent. of the sulphur of the isethionic acid pass out of the body in the form of thiosulphuric acid, a figure which is shown by control experiments to be too high, as the urine contains other easily oxidisable substances. The question as to what becomes of the remainder of the sulphur is not entered into. There seems also to be no way of reconciling the present results with those obtained by Heffter.

The aromatic sulphonie acids pass out unchanged in the urine, no thiosulphates being formed; this also is contradictory to the statements of Heffter.

W. D. H.

**Trypsin in Urine.** By H. LEO (*Pflüger's Archiv*, **39**, 246—264).—Since the publication of the author's paper (*Abstr.*, 1886, 381) in which he showed that trypsin did not exist in the urine, Gehrig (*Pflüger's Archiv*, **38**, 35) states he has found trypsin in the urine; pieces of fibrin stained with magdala-red, soaked in urine, and transferred to 1 per cent. soda solution undergo digestion in a few hours; this cannot be due to putrefaction as it is so rapid; it is however prevented by the admixture of thymol with the digesting mixture; this is explained by saying that thymol hinders pancreatic digestion. The present research is a reinvestigation of the subject, the urine of healthy men and dogs being employed. It is found that thymol does not hinder pancreatic digestion. A very weak solution of the tryptic ferment was prepared by adding a drop of glycerol extract of pancreas to a litre of water. This excited no digestive action on fibrin. After pieces of fibrin had been soaked in it for

24 hours, however, and then transferred to a 1 per cent. soda solution they underwent digestion, as they had absorbed the ferment. With the urine, however, no such result ever occurred; that is, urine, if it contains trypsin at all, contains a less amount than the weak solution of it obtained by adding a drop of extract of pancreas to a litre of water.

## Chemistry of Vegetable Physiology and Agriculture.

---

**The Bacillus of Panary Fermentation.** By E. LAURENT (*Bied. Centr.*, 1886, 648).—The author says that the surface of wheat, rye, and other food grains contains spores of bacilli which in grinding pass into the flour, and when made into dough they germinate, evolve carbonic anhydride, and raise the bread. When cultivated on gelatin, it develops characteristic cultures different from other bacilli, and has been given the name of *Bacillus panificans*; it exists with or without oxygen, and renders albumin and gluten soluble; it also grows in saccharose and in a weak solution of boiled starch; it withstands the heat of boiling water, if at a depth of 7 or 8 mm. in the bread; it is abundant in bread which has been eaten, and is found freely in the fæces. It can attack starch after baking, if the medium is not sufficiently acid, and causes a disease in bread which the author has often observed, and calls viscid or clammy bread; the addition of a sufficient quantity of an organic acid prevents this.

J. F.

**Decomposition of Silicic Acid by Leaves.** By A. DENARO (*Gazzetta*, 16, 328—330).—A few years ago Grimaldi stated in a pamphlet that silica is decomposed by leaves exposed to sunlight, precisely as carbonic anhydride is, into the element and oxygen. It is probable, however, that sufficient care was not taken to exclude carbonic anhydride derived from the potassium carbonate, as an impurity in the silica. Accordingly the author has repeated the experiments with a sample of silicic acid obtained from a sodium silicate produced by the direct fusion of sodium oxide with silica. Comparative experiments were made with leaves of which some were previously deprived of air, whilst others were introduced directly into the solution of silicic acid. In the former case, no oxygen was evolved, in the latter only a small quantity. Further, it is shown that no silica is absorbed by the leaves; the proportion of silica in them was found to be the same, whether or not they had been treated by the silicic acid solution.

**Formation of Albuminoïds in Plants.** By C. O. MÜLLER (*Landw. Versuchs-Stat.*, 1886, 326—335).—From the experiments which have been made on many plants, it would appear that under normal conditions, plants contain asparagine, and this amide appears

if the growing parts are placed in darkness; but in fully grown portions, asparagine is only exceptionally found, and then only in traces.

If a portion of a plant is placed in darkness, by enveloping it in black paper, whereby it still remains connected with the parent, and the older portions are left undisturbed, then an accumulation of asparagine is formed, which when the light is admitted, is absorbed; This does not occur in the fully grown parts, save exceptionally. This result seems to show that the formation of asparagine is independent of carbohydrates, and also that the amide formed is not a bye-product of the interchange of matter within the plant. It has also been found that even when a plant is growing under abnormal conditions, when all carbonic anhydride has been removed from the air, asparagine is formed in the young parts, but not in the matured portions. Consequently it appears as if light played as inconspicuous a part in the formation of asparagine as carbohydrates. The author considers that asparagine is formed by the union of inorganic nitrogen compounds and malic acid within the plant, the acid being derived from the carbohydrates.

**Observations on the Growth of Potatoes.** By U. KREUSLER (*Bied. Centr.*, 1886, 618—624).—The author has examined potatoes at different stages of their growth. At the time of sowing, large and small tubers were of the same specific gravity and composition; taken up shortly after the sowing, there was but little change observable, there was more moisture, due to partial exhaustion of their substance. Glucose was not found before planting, but was present in the germinating tubers; nitrogenous combinations diminished considerably in the growing roots.

The young tubers gradually developed dry matter, principally starch, in proportion as they grew. Glucose was present at the beginning, but gradually decreased as they ripened, when it disappeared. Substances which reduced copper were absent from the very young plants, but appeared at a later stage to disappear when fully ripe; the amount of carbohydrates in the sap was twice as much in the young as in the ripe tubers.

In the stalks and leaves, cellulose and non-nitrogenous extract increased, raw protein and fat decreased; the fruit is tolerably rich in fat; the whole young foliage of the potato belongs to those vegetables which are richest in nitrogen, the proportion of the dry substance amounting to 7.5 per cent. = 47 per cent. crude protein; the amount of nitrates in the non-protein portions is also very considerable, in the whole plant 3.5 per cent., in the stalks 5 per cent., calculated as  $N_2O_5$ .

This large quantity of nitrates leads the author to agree with André, Berthelot, and Schulze, that it is not altogether supplied from external sources, but that a part is formed in the plant itself.

J. F.

**Ammonia in Beetroots.** By L. BATTUT (*Bied. Centr.*, 1886, 604—607).—The opinions of persons who interest themselves in this matter are divided, some asserting the presence of ammonia in the roots, others the contrary. Owing to the rapid decomposition of the organic constituents of beet-juice when heated with alkalis, the deter-

minations were made in the cold by Schlösing's method—in each of four dishes 100 c.c. of distilled water was poured, in one normal beet-juice with 10 c.c. milk of lime, in two others milk of lime with two kinds of ammonium salts, the fourth milk of lime only—the dishes covered with glass plates to which were fixed moistened test-papers; the three gave an immediate alkaline reaction. Attempts at quantitative estimations were made without much success, but the author concludes from their results that an ammoniacal salt exists in the roots which is readily decomposed by caustic magnesia, and that there are two nitrogenous organic substances present, one, probably asparagine, quickly decomposed by lime, the other by caustic potash solution.

J. F.

**Milky Juice of Certain Euphorbiaceæ.** By G. HENKE (*Arch. Pharm.* [3], 24, 729—759).—Hitherto euphorbone had not been obtained in a pure state, even Flückiger, who proposed the name, was unsuccessful. The author treated finely powdered euphorbium in the cold with light petroleum of 60—70° boiling point; this treatment being repeated as long as anything was dissolved. The solutions obtained were mixed, filtered, and allowed to evaporate spontaneously. The sides of the evaporating vessel became coated with beautiful, transparent, crystalline needles of euphorbone, whilst the remainder of the residue consisted of a yellowish, crystalline, warty mass. Repeated treatment with light petroleum gives a pure product finally, but is wasteful; it is better to dissolve the yellow mass in ether after removing the petroleum by heating on the water-bath; on adding alcohol until a faint turbidity appears, filtering and allowing to remain, a yellow, resinous mass separates. The liquid on evaporation leaves a snow-white, butter-like mass which gives brilliant needles on crystallising from a sufficiently dilute solution of light petroleum. *Euphorbone* thus prepared melts at 67—68°, its composition was found to be  $C_{20}H_{36}O$ . Its rotatory power dissolved in chloroform was  $[\alpha]_D = +15.85^\circ$ . Its crystals are persistent in the air, tasteless, and are neutral in solution. It is very soluble in light petroleum, chloroform, ether, alcohol, benzene, acetone, and 90° vol. per cent. alcohol, less soluble in more dilute alcohol. It is unaffected by dilute acids, sodium carbonate, ammonia, potash, and soda, and by alcoholic zinc chloride solution. It is soluble in 10,000 parts of hot water. Cold anhydrous acetic acid does not affect it; when heated at 150—200° a solution is obtained from which a yellowish precipitate is thrown down on diluting with much water, this precipitate has the properties of unchanged euphorbone. Bromine acts violently on the compound, producing a yellow, resin-like, non-crystallisable mass. Hot nitric acid dissolves euphorbone, and from the solution an amorphous, nitrogenous compound can be obtained. A granular oxidation product was obtained by long boiling with potassium dichromate and sulphuric acid. On heating euphorbone with phosphoric anhydride, heptane, octane, xylene and small quantities of other aromatic hydrocarbons were obtained. The residue from the preparation of euphorbone, when extracted with alcohol, yielded two resins, one soluble and the other insoluble in ether; their reactions are detailed. The detection of malic acid, gum, and other substances in the residue and the extrac-

tion therefrom are described. The pure euphorbium was found to contain:—Euphorbone, 34·60; resin soluble in ether, 26·95; resin insoluble in ether, 14·25; caoutchene, 1·10; malic acid, 1·50; gum and salts precipitated by alcohol, 8·10; gum and salts not precipitated by alcohol, 12·30; salts and organic substances soluble in ammonia, 1·20 per cent. Somewhat similar results were obtained in the case of juices of other plants of the euphorbia class. J. T.

**Composition of Barley and Pease.** By KLIEN (*Bied. Centr.*, 1886, 644—645).—The author's experiments show that in soils containing but little lime, large quantities of superphosphate diminish the proteïds contained in the grain, whilst soils rich in lime bear very heavy manuring with those substances without damage to the crop; precipitated phosphate, a neutral combination of phosphoric acid, was applied in considerable excess without reducing the proteïds; even in a soil composed of phosphorite containing 20 per cent. of phosphoric acid, the proteïd was not lower in the case of pease than in normally manured soils. Wagner has found that an increase in proteïd by heavy manuring with phosphates can only be obtained in straw and green crops, not in grain and seeds, the percentage being diminished in the latter by large applications of phosphatic manures; the author thinks Wagner's conclusions are true only when the soil is poor in lime and has traces of mineral acids present, in such cases he recommends the application of neutral, that is, precipitated phosphate.

J. F.

**Composition of Tea-leaves.** By O. KELLNER (*Landw. Versuchs-Stat.*, 1886, 370—380).—The chief interest in this research lies in the fact that it is almost the only case in which an evergreen plant has been systematically examined throughout the year. The leaves were dried at 60—80°, and the "total nitrogen" estimated by soda-lime, whilst the albuminoid nitrogen was determined by a modification of Stutzer's process, because theïne-tannate is only decomposed with difficulty and at 100°; also the filtration of the solution is attended with great difficulty. The method employed was to boil 2 grams of the substance with 100 c.c. water, to add 20 c.c. of a 10 per cent. copper sulphate solution, and then to precipitate the copper by a titrated solution of sodium hydroxide, still leaving a small quantity of copper in solution; after washing with hot water, the precipitate was washed with 95 per cent. alcohol. The filtrate ran rapidly through the paper and was free from albuminoids, which were found to be rather lower than the original process showed. The total soluble matter was estimated indirectly, in that 3 grams were repeatedly boiled with water, the residue being dried and weighed. Theïne was estimated in 5 to 7 grams which were boiled in water, the solution evaporated, and *magnesia usta* added; after gently drying, the residue was extracted with ether, and the alkaloid obtained by evaporation. To obtain the tannic acid, which by reason of the presence of pectin could not be filtered in the usual way, the leaves were extracted with alcohol acidified with a few drops of acetic acid, the solution thus obtained evaporated and the residue dissolved in water, and filtered through asbestos: in calculating the results, 63 parts of oxalic acid were taken

to be equivalent to 34·25 gallotannic acid; the tannin in tea being identical with that acid. The composition of the leaves is shown in the accompanying tables.

The fluctuation in the percentage of water is less than that observed in leaves of deciduous trees; the percentage of ash lies between that found in the needles of pines and in ordinary leaves. It will be noticed that the non-albuminoid nitrogen is almost wholly absent during the later stages of growth, being found as theine. Connecting this with the fact that albumin has increased, and that no theine is found in the seeds, the author believes that positive proof is afforded that the alkaloid, like glutamine and asparagine, is a decomposition product of albumin, and is capable of again forming albumin.

As regards the ash, we have here a regular increase, whilst in deciduous trees is found both diminution and increase. E. W. P.

**China bicolor.** By O. HESSE (*Annalen*, 234, 380—384).—The author is of opinion that the small quantities of quinine and other alkaloids which Hodgkin (*Pharm. Jour.*, 15, 217) found in the bark of *China bicolor*, are probably due to the presence of a small quantity of the bark of *Remijia pedunculata* in the *China bicolor* bark.

W. C. W.

**Chlorosis in Plants.** By J. v. SACHS (*Bied. Centr.*, 1886, 602—604).—When attacked by this disease, the leaves pale and turn perfectly white; weak plants succumb quickly. Stronger ones are attacked year after year until their reserve material is exhausted; they then die. The touching of a diseased leaf with a dilute solution of an iron salt often causes the production of chlorophyll and cures the disease. However, from extended observations the author does not think that it is altogether the absence of iron that causes the disease, as plants growing on the same soil are irregularly attacked, some escaping altogether. His experience leads him to think that the roots or leading vessels suffer some alteration which prevents the minute quantities of iron contained in the sap from reaching the leaves. A too rapid and luxuriant growth favours the disease. In the winters of certain years, thousands of trees and shrubs were heavily pruned; the energy divided between numerous growths was concentrated on a much less number; they grew rapidly and luxuriantly; the first leaves were green, but the later were quite white. Trenches 20 to 30 cm. deep and wide were dug round the diseased trees at a distance of 80 to 100 cm.; in these trenches ferrous sulphate in lumps was placed, in quantities varying from 1 to 5 kilos., according to the size of the tree. Water was then freely admitted and the trenches filled up with earth. Within three to six days the smaller bushes commenced to green, within 14 days no sign of chlorosis was visible, and in the following spring all the growths were normal.

An experiment of the author's has, he considers, an important bearing on vegetable physiology. Certain acacia trees showed symptoms of chlorosis, in particular the thick branches of a 20 year old tree. The author caused holes to be bored in the main stem, just beneath the bifurcation of the branch with the core of the tree. In these holes he placed corks fitted with funnels, charged afterwards with ferrous sulphate or ferric chloride in dilute solution. In dry weather the tree absorbed the solutions so readily that the funnels had to be frequently refilled. The leaves in line of each funnel became quite green in 10 to 14 days, but those not in the line remained white. This the author thinks a proof that each branch and twig has its own sap-ducts.

J. F.

**Absorption by Soils.** By O. KELLNER (*Landw. Versuchs-Stat.*, 1886, 349—358).—After a detailed description of the modification of Pillitz's method, which was employed to estimate the absorption of various solutions by soils, the author shows that the absorption of bases by the soils he employed is but slightly dependent on the composition of those soils; that soils rich in zeolites and humus have not of necessity a higher absorptive capacity; nor does absor-

tion wholly depend on the quantity of the absorbing medium, but largely on the character of the surfaces with which the absorbable substances come in contact. It would appear also, that potash and ammonia are absorbed according to the ratio of their equivalents.  
E. W. P.

**Estimation of Absorbed Bases in Soils, &c.** By O. KELLNER (*Landw. Versuchs-Stat.*, 1886, 359—369).—From the analytical details given, it is concluded that the potash held in a soil by absorption only may be readily estimated by digestion of the soil in a concentrated solution of ammonium chloride. As regards the estimation of lime, the author has failed, as the soils he employed would not retain added lime. He attempted to saturate with calcium chloride and then remove with ammonium chloride, but found more lime present in the solution than should have been, showing that other forms of lime (carbonate) had been attacked. In a second series of experiments, he found that peas, when growing, only assimilated the potash and lime held in solution in the soil, and that the insoluble compounds (anhydrous silicates, &c.) were in no wise taken up by the roots.  
E. W. P.

**Chili Saltpetre as Manure.** By A. STUTZER (*Bied. Centr.*, 1886, 585—597).—The author was awarded the first prize offered by the union of nitrate firms on the western coasts of South America, for his essay on the value of Chili saltpetre as a manure. Wagner has condensed the contents of this essay and that of Damseaux, which obtained the second prize, into a compact form of questions and answers, which are of value in agricultural science. Some of the answers follow:—Plants cannot grow under normal conditions unless a supply of nitrogen is available for their roots, and a satisfactory crop cannot be obtained without the use of nitrogenous manures. Stable manure, in the quantities produced on a farm, does not provide sufficient nitrogen to produce good results; high farming requires that nitrogen be procured as artificial manure. Manures containing nitrogen in the form of animal matter take a long time to alter into nitrates, whilst the Chili saltpetre is at once available.

The increase in weight of various crops tried was greater when the saltpetre was used than when ammonium sulphate was the manure. The application of phosphates and potassium salts increase materially the activity of the saltpetre. This manure does not unduly exhaust the soil; it renders the mineral plant foods more assimilable, but no more of them is removed than is accounted for in the increase of the crop. The crops which are most benefited by Chili saltpetre are all straw-growing plants; next rape, mustard, &c.; fodder, sugar-beets and potatoes come in the second rank; meadow grasses in the third; the least effect is produced on pease, vetches, lupines, clover, and linseed. Chili saltpetre should be applied as top-dressing only on sandy or porous soils, just before vegetation begins; the time of application should be in early spring.  
J. F.

**Comparative Manurial Values of Chili Saltpetre and Ammonium Sulphate.** By V. MAGERSTEIN (*Bied. Centr.*, 1886, 583—585).

—The experiments were made on a sandy soil, with barley and oats. 200 kilos. of Chili saltpetre and 300 kilos. of ammonium sulphate were used to the hectare; the plots manured with the former salt showed a better result in grain, but a smaller yield of straw. Compared with unmanured plots, the increase obtained by manuring was—

|                           | Barley.           | Oats.              |
|---------------------------|-------------------|--------------------|
| Chili saltpetre . . . . . | 8.13 hect. grain. | 10.25 hect. grain. |
| Ammonium sulphate. . . .  | 5.46        „     | 6.94        „      |

Calculating the cost of the manures and the market prices of barley, oats, and straw, the author considers the Chili saltpetre the more paying of the two. J. F.

**Experiments with Chili Saltpetre.** By v. MAGERSTEIN (*Bied. Centr.*, 1886, 581—583).—In order to compare the effects of this manure when used as top-dressing and when dug in, the author prepared plots of 7 to 8 square metres all cultivated in the same way, except as regards the application of the manure. In the cases of potatoes and oats, the top-dressing gave the better results, but the contrary was the case with barley; the difference is attributed to the dryness of the season. The solution of the salt was slow and concentrated; therefore unfavourable to growth. The roots of barley came first in contact with it, whilst the deeper roots of potatoes and oats received a more dilute solution and were stronger when it reached them. J. F.

## Analytical Chemistry.

**Kjeldahl's Method of Estimating Nitrogen.** By C. ARNOLD (*Arch. Pharm.* [3], 24, 785—794).—The author shows that this method (*Abstr.*, 1884, 364; 1885, 930) is also applicable to nitrates, nitro- and cyanogen-compounds, in the presence of benzoic acid, sugar, mercury, and copper sulphate; further, in the case of alkaloids and other compounds that can be treated by this method, oxidation by potassium permanganate is unnecessary if the boiling be continued until the warm liquid acquires a bluish-green tint, becoming colourless on cooling; this takes place tolerably quickly in the presence of mercury and copper. That the oxidation has been completed can readily be ascertained by adding a crystal of potassium permanganate, which should give a persistent violet or green coloration. A description of the apparatus used by the author is given. J. T.

**Separation of Arsenic and Antimony.** By ZAMBELLI and LUZZATO (*Arch. Pharm.* [3], 24, 772).—These elements can be separated, even in forensic cases, by treating the still moist sulphides with hydrogen peroxide at 40° for some hours, then heating to near 100°

and filtering. The arsenic acid formed goes into the filtrate, whilst the insoluble antimony oxide remains on the filter. The method is said to be very delicate. J. T.

**Detection of Thiosulphate in Hydrogen Sodium Carbonate.** By BRENSTEIN and T. SALZER (*Arch. Pharm.* [3], 24, 761).—According to Brenstein, the reaction given for thiosulphate by Mylius is not characteristic, as other oxygen-compounds of sulphur, such as sulphites, give rise to the formation of hydrogen sulphide. A better test for thiosulphate is to add to a 5 per cent. solution of hydrogen sodium carbonate a few drops of silver nitrate solution, then excess of nitric acid, and heat to boiling; even minute traces of thiosulphate give an immediate dark precipitate of silver sulphide.

According to Salzer, the absence of thiosulphate is easily ascertained by adding a few drops of iodine solution to about 20 c.c. of a saturated solution of hydrogen sodium carbonate; the solution must have a yellowish tint. Decolorisation of the iodine solution does not necessarily imply the presence of thiosulphate, since normal carbonate, the most commonly occurring impurity, produces this effect. Both authors found thiosulphate to be a constant impurity of ordinary qualities of hydrogen sodium carbonate, whilst the better qualities were mostly free from it. J. T.

**Estimation of Small Quantities of Silver in Burnt Pyrites.** By E. THILO (*Chem. Zeit.*, 10, 822; 1065—1067).—The amount of silver in burnt pyrites is ordinarily 0.003—0.008 per cent., and to obtain trustworthy results material containing 0.01 gram of silver should be taken for analysis, or about 300 to 500 grams of pyrites. Many difficulties have been encountered in endeavouring to deal with these large quantities of material so as to get all the silver. Experiments show that the decomposition of the whole mass is out of the question, therefore methods for extracting the silver, &c., were tried; treatment with nitric acid or with gaseous chlorine, and subsequent extraction of the silver chloride proved unsuitable. Digestion with chlorine-water was somewhat better; but bromine or bromine-water gives the best results. The powdered burnt pyrites is passed through a 0.25-mm. mesh sieve, and about 300—500 grams of it is placed in an acid-proof iron basin; it is well covered with water, and while vigorously stirred, bromine is added until present in excess. After 24 hours it is heated on a water-bath for one hour with frequent stirring, treated with excess of ammonia, then with 500 grams of ammonium chloride, and 1 litre of water. The mass is boiled for an hour, and filtered. The residue is dried, ignited at a low red heat, and again treated with ammoniacal ammonium chloride, by which means all the silver is extracted. Inasmuch as copper is quite as difficult as silver to extract by means of bromine, and as the amount of copper in the pyrites is reduced from 5 per cent. to a trace (0.01 per cent.) by the above treatment, this may be used as an indicator of the progress of the desilvering, and in practice when the copper is reduced to this amount it may be safely inferred that all the silver is removed. The solution, about 4 litres, is made acid with hydrochloric acid; it is not

affected by daylight either before or after acidifying. The silver, copper, and lead are then precipitated by means of chemically pure zinc. When the precipitation is complete, the solution is colourless (or rose-red if cobalt is present), and is not turned blue by ammonia. As the precipitate contains, most likely, silver chloride and bromide, and some iron oxide, it is fused with potassium cyanide, and subsequently with anhydrous borax, the temperature being raised to melt the copper. The regulus is dissolved in nitric acid, and the silver either precipitated by means of hydrochloric acid or determined electrolytically. Silver determinations may also be made in ordinary pyrites, which is first roasted carefully, and then treated in the above manner. Good results have been obtained by this method, with roasted copper schist, with spathic iron ore containing argentiferous tetrahedrite and pyrites, and with other ores. A determination can be completed in three days.

D. A. L.

**Comparative Gasometric Assaying with Especial Reference to the Valuation of Zinc Powder and the Testing of Carbonates.** By J. BARNES (*J. Soc. Chem. Ind.*, 5, 145—147).—In a previous communication (*Trans.*, 1881, 462), the author described a method for the valuation of zinc powder, consisting in measuring the amount of hydrogen liberated on treatment with an acid. The author has since devised a method and constructed an apparatus for gasometric assaying, contrived originally for the valuation of zinc powder, but applicable also to the estimation of other substances, which may be made to cause or control the evolution of gases. The method, which is described in detail in the paper, is a comparative one, and requires at least two graduated instruments, each provided with a suitable gas evolving arrangement. A substance of known value, taken as the standard, is placed in one, and the sample to be examined in the other instrument. The value of the sample is then calculated by the following formula:  $\frac{v}{V} \cdot \frac{W}{w} \cdot R = x$ ; where  $V$  equals the volume of gas from standard,  $v$  the volume of gas from sample,  $W$  the weight of standard, and  $w$  the weight of sample.  $R$  is the amount of pure substance or its equivalent in unit of standard, and  $x$  the amount of pure substance in unit of sample.

**Determination and Valuation of Copper in Ores and Products for Commercial Purposes, with some Remarks on the Assay of Gold in Bar Copper.** By J. W. WESTMORELAND (*J. Soc. Chem. Ind.*, 5, 48—64).—*Estimation of Moisture.*—This, although apparently a simple process, is conducted very differently by various assayers, and the author proposes that the temperature and manner in which the moisture is to be taken should be more clearly defined than it is at the present time.

*Wet Assay of Copper.*—Having examined a large number of samples of all kinds of copper ores and products by several wet processes, the author has given the iodide process as modified by Brown the preference—being more trustworthy and accurate than the electrolytic process. For cupreous pyrites, burnt ores, &c., the following method

may be used. From 50 to 150 grains of the sample is dissolved in acids, evaporated to dryness with excess of sulphuric acid, diluted with water and filtered. From this solution, the copper is separated with sodium thiosulphate, the precipitate dried, ignited, dissolved in nitric acid, evaporated with sulphuric acid to separate traces of lead, diluted with water and filtered, sodium carbonate added in excess, and then acetic acid to acid reaction. The solution is then titrated with potassium iodide. As an alternative method, the ore may be calcined, dissolved in hydrochloric acid, the ferric salt reduced by boiling with a solution of sodium sulphite, and hydrogen sulphide passed through the cold solution; the precipitated sulphides are then washed, and the process conducted as before. Richer copper ores, mattes, precipitates, &c., are dissolved in acids, and the solution precipitated either with sodium thiosulphate or hydrogen sulphide, the sulphides being dissolved in acids, and treated as before. The accuracy of this process was tested by numerous experiments, in which known weights of pure electrolytic copper, silver, arsenic, antimony, lead, cadmium, bismuth, tin, manganese, zinc, and iron salts were used. The solutions were made to represent cupreous burnt ores, mattes, cupriferous lead regulus, second quality and rich precipitates, &c. Experiments were also made in many cases with the metals separately. The electro-deposition method may be employed in cases where it is desirable to have results of two separate and distinct processes, it being noted that with pure solutions of copper, accurate results are obtained, whilst when silver or bismuth are present they are precipitated, and in one experiment tin was also deposited with the copper. In the presence of ferric salts, the deposition is retarded. It was found that whilst the results with refined or bar coppers and rich precipitates agree with those obtained by the iodide process, those obtained by electrolysing sulphuric acid solutions of mattes, copper ores, &c., are generally slightly below the true percentage. With burnt ores, cupreous pyrites, and ores containing but little copper, the author first precipitates with hydrogen sulphide, dissolving the sulphide in nitric acid, and evaporating this solution with excess of sulphuric acid, the sulphates dissolved in water give a solution from which copper (and bismuth) is readily deposited. The results by the battery process are generally from 0.01 to 0.04 per cent. higher than by the iodide process, this being caused by a slight deposit of bismuth.

*The Cornish Process of Dry Assay.*—This process is considered to be inaccurate and misleading, and is also liable to serious variation even in the hands of experienced operators.

The author is of opinion that in cases where the sulphur contents of pyrites are sold to alkali works, the burnt ores being returned to the vendors, an accurate wet assay forms the best check on the copper contents of the ore delivered to and received from the alkali works.

In the remaining part of the paper, the methods in vogue for fixing the prices payable for copper in pyrites, copper ores, &c., are discussed. Reference is also made to the assay of gold in bar copper, and the opinion is expressed that these assays are not conducted as carefully as they should be, taking the value of the metal into consideration.

D. B.

**Estimation of Ammoniacal Nitrogen in Soils, and the Amount of Assimilable Nitrogen in Uncultivated Land.** By A. BAUMANN (*Landw. Versuchs-Stat.*, 1886, 247—303).—The methods employed to estimate the ammonia in soils are unsatisfactory. Schlösing's method, whereby the ammonia is freed by means of milk of lime or sodium hydroxide, gives results too high, probably owing to the formation of ammonia from other compounds during the period (2—3 days) required for the process. In Boussingault's process as modified by Schlösing, a hydrochloric acid extract of the soil is treated with magnesia usta, but the ammonia collected in acid must not be estimated by titration, but must be azotometrically determined; nor must cork nor caoutchouc be employed in the formation of the apparatus. The liquid in the evolution flask must be boiled for at least an hour, and the magnesia usta must be fresh. With these two processes, it is found that humous soils, when treated with sodium hydroxide, continuously yield ammonia; if the soil, after treatment with magnesia, be further treated with sodium hydroxide, another supply of ammonia is obtained, but only in the case of soils rich in humus. Knop's process, in which the ammonia is decomposed by brominated sodium hydroxide solution, is vitiated by the fact, noticed by Knop and others, that in the presence of the soil itself a contraction of the volume of gas enclosed in the apparatus occurs; this contraction was stated by some to be due to absorption by the organic matter, whilst others considered the oxides of iron in the clay to be the real cause; also it had been stated that the presence of borax prevented this contraction. To ascertain the cause of the contraction, a sample of stiff soil poor in humus, was taken from uncultivated land at a depth of 15—20 cm.; this sample seemed free from humus, although root-fibres were visible; at a distance of 40 m. from this spot another sample was drawn from a depth of 2—10 cm., this was close to a pine 50 years old. The sample showed humus, and when dry was grey. At another spot, close to a 100 year old pine, a third sample was taken, and this when dry was dark-brown. These last two samples overlaid a soil similar to the first sample. Employing these samples, the author argued that if the contraction was due to the clay and the iron, and not to the humus, then identical contractions would be observed when equal quantities of all samples were subjected to like conditions. On the other hand, if the phenomenon is caused by the humus, then that sample richest in humus would produce the greatest effect on the volume of the gas, and when borax was employed no contraction should occur. It appears that the ferruginous soil poor in humus produced no contraction, but rather an increase of volume after the first  $\frac{1}{4}$  hour; this is explained by the probable presence of nitrogenous matter decomposable by the brominated alkali. The presence of borax assisted the evolution of gas.

Experimenting with humous samples, it was found that the volume of gas evolved by Knop's method stands in no ratio to the percentage of ammonia present; this remarkable result was most manifest in the case of the third sample, which contained most humus, for then the contraction was evident when only 5 grams were used,

and in spite of borax the contraction amounted to 71 per cent. when 100 grams was employed. This contraction is clearly due to oxidation of the organic matter of the soil, and consequent removal of part of the gaseous contents of the azotometer.

Working with sandy and chalky soils, the author found that the results obtained by Knop's method are quite as untrustworthy as in the case of humous samples.

The following method is recommended for the estimation of ammonia in soils:—200 grams of the soil is mixed with 100 c.c. of hydrochloric acid (1:4), then diluted with 300 c.c. of distilled water and allowed to remain for two hours, with frequent shaking. Should much chalk be present, then more than 100 c.c. acid must be added, and the whole amount of *liquid* made up to 400 c.c.; all heating must be avoided. Of the filtrate, 200 c.c. (= 100 grams soil) is placed in the evolution vessel of the azotometer together with 5 grams of freshly ignited magnesia usta, and the vessel closed by a doubly bored india-rubber stopper; through one of the borings a glass tube passes to the bottom of the flask, whilst the other opens immediately below the stopper, and is connected with an aspirator, whilst the other tube supplies air ozonised by passing through potassium permanganate and concentrated sulphuric acid. The passage of this gas for 10 minutes oxidises organic matter, so that no subsequent contraction occurs. The rest of the process is conducted in the ordinary way.

*Percentage of Ammonia in Soils.*—Soils of various characters were examined, and the percentages as found by Schlösing's and the other methods are given: there appears to be a wide difference between the first and the other two methods. The percentages at different periods in summer and at different depths are recorded. The conclusions drawn are that the percentage of ammonia in uncultivated soils varies with the character of the soil, loams containing most, the quantity increasing with the increase of clay; chalks and sands are poor in ammonia, but in sands rich in humus there is a large supply of organic compounds which readily decompose and yield ammonia, although generally speaking, the percentage of organic matter is no indication of the amount of ammonia present, and the percentage of ammonia in a soil does not seem to vary with the weather, but does decrease with depth from the surface.

*Percentage of Nitrates in Unmanured Soils.*—Baumann employs Schlösing's method of estimating nitrates if the solution of 1000 grams soil in water made up to 2000 c.c. shows the brucine reaction, even if the reaction is only obtained after evaporating the solution to one-half of its original volume. If this test should fail, then diphenylamine is to be employed; this should indicate 1 in 1,500,000 or 0.6—1 mgrm. per litre; should this fail, so also will Schlösing's method, and it will be necessary to evaporate 1 litre of extract with some alkali to dryness, add alcohol, boil, filter, and then evaporate the alcohol and dissolve in 40 c.c. water. The solution must be again tested by brucine and diphenylamine, and if indications of the presence of nitrates are visible, the Marx-Trommsdorf's method (*Zeit. anal. Chem.*, 1868, 412, and 1870, 171) is to be employed for the quantitative

estimation; this will indicate 0.00001 per 300—400 grams soil. Examination of many soils shows that when the soil is uncultivated the percentage of nitrates is very small, especially in forests, where it only appears as traces.

The author then reviews the work of Warington, Schlösing, and Müntz on nitrification, and considers that the absence of nitrates in such soils as he refers to, is due to the normal temperature ( $5^{\circ}$ ) being so close to that at which nitrification first occurs; also water is necessary for nitrification, and in forest soils, therefore little nitrification takes place, because of the great dryness of that soil in summer, due especially to the enormous transpiration continually occurring, which renders the soil almost "air-dry;" a further cause for the absence of nitrification may be found in the want of animal nutriment for the growth of the ferment.

E. W. P.

**Analysis of Gas Coal.** By L. T. WRIGHT (*J. Soc. Chem. Ind.*, **4**, 656—667).—*Proximate analysis.*—The first determination is that of moisture. Various temperatures have been recommended at which the sample of coal shall be dried. Since  $100^{\circ}$  is a temperature easily secured and maintained constant by means of a water-bath, the author has adopted it as the standard. The estimation of moisture by loss of weight in drying at  $100^{\circ}$  until the weight of the substance becomes constant is not, however, free from error; as it has been noticed by different observers, that after a time the coal not only ceases to lose weight but actually gains. Hinrichs attributes this increase to the slow oxidation of pyrites and other substances in the coal; the author, however, considers it to be due to the absorption of gases into the pores of the coals left vacant by the expelled moisture. He has also found that the increase of weight, which only exhibits itself when the coal has been nearly dried, has been going on during the whole period of the drying process, so that where accuracy is required it is preferable to weigh the water as such. According to Hinrichs the total volatile matter of coal is determined with accuracy by taking 1 to 2 grams of undried pulverised coal, heating for three and a half minutes over a Bunsen burner, and then immediately igniting without cooling, for the same period over a blast gas lamp (white heat). The greatest difference which Hinrichs obtained amounted to 0.29 per cent. The author has repeated this method and obtained very fair results, although not quite so accurate as the above. The author adopts the following method:—Take about 2 grams of finely pulverised coal and let it form an even layer on the bottom of a thin platinum crucible. Weigh without cover, place the crucible (with cover on) in an upright position, then apply a powerful gas flame. Note when the gases cease issuing from under the lid; allow one minute further heating, remove the gas flame, place the crucible and cover in a desiccator for about five minutes to cool, and then weigh without cover as soon as possible. For the determination of ash in refractory cokes and such substances as gas carbon, heat to redness 2 grams of the coal or coke placed on a piece of platinum foil, in a combustion tube through which a gentle current of air is drawn. The ash should be saved for the determination of sulphuric acid.

For the determination of the total sulphur, the best and simplest method is that suggested by Nakamura, which consists in heating the coal below a red heat in contact with alkaline carbonates, when the coal whether bituminous or not rapidly undergoes complete oxidation. For the purpose of distinction between the sulphur which goes over into the volatile matter, the sulphur left in the coke and that which is finally left in the ash combined as sulphate, three determinations are required:—(1) Total sulphur by Nakamura's method. (2) Sulphur which is converted into sulphurous anhydride by combustion of the coke in air, obtained by roasting a quantity of coke representing a known quantity of the coal, and aspirating the gaseous products of combustion through a solution of iodine or bromine. (3) Sulphur in ash. This can be done either by boiling the ash with hydrochloric acid, filtering and determining the sulphuric acid in the filtrate, or by fusion with alkaline carbonates.

*Proximate Analysis of Australian Shale.*

|                                | 100·00 |                        |

The practical method of examining coal for gas-making purposes partakes of two forms: (1) a partial imitation of the process of gas manufacture on a small scale; (2) analysis of coal by conducting a gas manufacture in a setting of clay retorts with large plant for exhausting, condensing, scrubbing, purifying, measuring the gas, and so on, as is in actual use.

The laboratory practical analysis is undoubtedly of great value; it will, however, be necessary in interpreting the results, to recollect that the method of heating the coal is different to that used in practice with clay retorts. As far as quality and volume of gas are concerned, the best results are obtained with the small iron retort. The difference varies with the kind of coal employed. With the very finest coking coals the difference is very small, and as the coking quality of the coal increases so the difference between the two methods of testing increases. With coals (not cannels) which scarcely intumesce at all, the difference becomes very high. Cannels also vary in the same manner, the difference in the results being always connected with differences in the qualities of the cokes. Since the gas from the iron retort is not scrubbed, a deduction of about 3 per cent. should be made from the results of the small apparatus to compensate for the small loss of illuminating power suffered by the gas

of the large experimental works in the washing process. When this allowance is made there is but little difference between the two methods of testing in the case of coking coals.

*Estimation of Hydrogen Sulphide and Carbonic Anhydride in Crude Coal-gas.*—The author prefers the use of a method admitting of the employment of a tolerably large quantity of gas collected regularly during an interval of time sufficiently long to afford an idea of the average composition of the gas supply to be tested. The reagent used for absorbing the hydrogen sulphide is cupric phosphate. Absorption tubes charged with cupric phosphate gain in weight under the action of pure coal-gas; the increase of weight, however, soon reaches a limit, and the phosphate may be saturated by passing 3 cubic feet of pure dry-coal gas slowly through the tubes. The carbonic anhydride is absorbed in soda-lime tubes, one half full of soda-lime and one half of calcium chloride. To increase its absorptive power for carbonic anhydride the soda-lime is used in a moist condition. In cases where ammonia exists in the gas its removal is best effected by passing the crude gas before it is dried through a 12-inch U-tube filled with broken pumice saturated with syrupy phosphoric acid.

*Cyanogen.*—This substance is estimated by passing a measured quantity of crude gas freed from ammonia through a U-tube filled with soda-lime, and then making a combustion of the residue as in an ordinary nitrogen determination. D. B.

**Analysis of Explosives.** By G. LUNGE (*Chem. Ind.*, 9, 273—274).—To render the author's nitrometer suitable for the determination of nitrogen by Crum's method in substances like dynamite and gun-cotton, which cannot be introduced into the decomposition tube in the liquid form, and at the same time to avoid the error due to the evolution of carbonic anhydride to which Hempel's modification (this Journal, 40, 472) is liable, a small funnel-tube bent into a swan-neck is fitted by a rubber stopper to the cup in which the weighed substance has been placed. Through this the sulphuric acid required to dissolve the substance is poured. Any carbonic anhydride evolved can escape, but loss of nitrous fumes is prevented by the acid which remains in the bend of the swan-neck. When the substance has dissolved (which in the case of gun-cotton may take three-quarters to one hour) the solution is drawn into the graduated tube. The acid in the funnel tube follows and rinses the cup. The stopper can now be removed and further rinsings given. The siliceous earth suspended in the acid has not been found to cause any inconvenience. Three analyses of gun-cotton reported agree very closely. M. J. S.

**Estimation of Glycerol in Wine.** By SAMUELSON (*Chem. Zeit.*, 10, 933—934).—Great discrepancies are observed in the estimation of glycerol by different chemists; this is probably due to want of uniformity in working, therefore the following mode of procedure is recommended. After adding milk of lime, evaporate only as far as to leave the mass just moist, then add somewhat more than 50 c.c. of 96 per cent. alcohol, and evaporate the alcoholic extract to 5 c.c.;

extract with absolute alcohol and ether, evaporate the extract until free from alcohol, then dry the residue for at least an hour.

D. A. L.

**Estimation of Solid Matter in Wines.** By E. BOUILHON (*Compt. rend.*, 103, 498).—When the total residue in wine is estimated by evaporation in a vacuum, the weight of the residue obtained is lower the greater the surface of the evaporating dish, owing to the loss of part of the glycerol. Three dishes each containing 10 c.c. of wine were placed under the same receiver and kept in a dry vacuum for 8–24 hours. The results are given in grams of solid matter per litre of wine.

|                                 | Bordeaux. | Girs. | Rousil-<br>lon. | Coupage. | Dilute alcohol<br>with 10 p. c.<br>glycerol. |

| 28 sq. c.c. surface..           | 22.4      | 30.8  | 34.2            | 25.6     | 34.8   |
| 70   "           "   ..         | 22.0      | 30.3  | 33.0            | 25.1     | 33.2   |
| 70   "           "   ..         | 21.2      | 29.1  | 30.4            | 23.8     | 31.7   |
| with sand 5 mm. }<br>deep ..... |           |       |                 |          |  |

In order to obtain comparable results, flat dishes of the same diameter should be used, and these should contain equal quantities of wine and be placed in the same position in the receiver of the air-pump.

C. H. B.

**Estimation of Acidity of Malt.** By E. PRIOR (*Bied. Centr.*, 1886, 647).—The usual way to estimate the acidity of malt is to digest a weighed quantity of ground malt in water for two hours, with frequent agitation, to filter quickly, estimate acidity in an aliquot part, and calculate as lactic acid; the author found that half an hour's digestion with water sufficed to show acidity; he recommends a 20 per cent. dilution by volume of neutral alcohol as the fluid for extraction, the percentage of acidity when this is employed remaining constant for 24 hours.

His method is to dilute ordinary commercial absolute alcohol with four volumes of water, 500 c.c. of this is used to 100 grams of ground malt, digested in the cold for four hours with frequent agitation, filtered, and 100 c.c. titrated with baryta-water.

J. F.

**Presence of Nitrites and Nitrates in Milk an Evidence of Adulteration.** By M. SCHRODT (*Bied. Centr.*, 1886, 629).—Nitrous or nitric acids are not normally found in milk, and when found in a suspected sample should be taken as evidence of dilution, spring water which is often added to dilute it, generally containing either nitrites or nitrates. The objection may possibly be made that the cow's fodder contained nitrates or nitrites; to put this to the proof, the author fed two cows for five days on beets, to which he added 10 grams daily per head of potassium nitrate, notwithstanding which no trace of nitrates, &c., was found in the milk; he therefore thinks the evidence afforded by their presence is conclusive. The method used was that introduced by Soxhlet, the reagent being diphenylamine.

J. F.

**Further Notes on the Methods of Examining and Chemistry of Fixed Oils.** By A. H. ALLEN (*J. Soc. Chem. Ind.*, 5, 65—72, and 282—283).—*Specific Gravity of Oils.*—A convenient instrument for ascertaining the density of fixed oils is Westphal's hydrostatic balance. A counterpoised thermometer suspended from a piece of thin platinum wire is attached to one end of a graduated lever. On immersing the thermometer in a liquid, it loses a certain weight. The equilibrium is restored by hanging on the lever a series of riders, which are adjusted in weight so as to make the reading very simple. As the employment of a thermometer as a plummet renders the instrument unsuited for determinations of density at 100°, or other high temperature, the author substitutes in such cases a plummet of thick glass rod. For the determination of the density of fats the author some time ago recommended the use of a Sprengel tube, and urged that the density should be taken at the boiling point of water. In all cases, however, where there is sufficient substance at disposal, the Sprengel tube has been abandoned in favour of the plummet.

*Coefficients of Expansion of Oils.*—A series of tables illustrating the rates of expansion of fats and oils are given, showing (1) that the rates of expansion of the fluid fixed oils are not sufficiently different to be of any value for their recognition; (2) that of the fluid fixed oils examined (sperm oil, bottle-nose oil, whale oil, porpoise oil, seal oil, menhaden oil, neats-foot oil, lard oil, olive oil, arachis oil, rape oil, sesamé oil, cotton-seed oil, niger-seed oil, linseed oil, and castor oil) all with the exception of whale oil expand sensibly equally for the same increase of temperature; and (3) that with the exception of whale oil the correction in density for the fluid fixed oils examined may safely be taken at 0.64 for 1° C. (water at 15.5° = 1000).

*Viscosity of Oils.*—The author is of opinion that Redwood's new form of viscosimeter bids fair to become the recognised standard instrument of the future. For many purposes, however, and especially as a convenient test by oil merchants, the following instrument is likely to grow in favour. It consists of a simple arrangement by which a small paddle-wheel (actuated by a falling weight) is caused to revolve in the sample of oil maintained at a definite temperature by an outer vessel of water. The manipulation is very simple, and the results expressed by the number of seconds required by the weight to fall through a given space are very constant.

*Bromine and Iodine Absorptions of Oils.*—In order to facilitate the comparison between the results of Mills (*ibid.*, 2, 435, and 3, 366) and Hübl (Abstr., 1884, 1435), the author has multiplied the bromine absorptions obtained by Mills by  $\frac{127}{80}$ , so as to obtain the equivalent

iodine absorptions, and has compared the results with the experimental numbers for iodine absorptions obtained by Hübl. The figures which are tabulated in the original paper indicate that the drying oils (containing linoleic acid) assimilate the largest proportions of the haloïds, and their capacity in this respect might probably be employed as a measure of their drying properties. The fish liver oils, however, fully equal the vegetable oils in their assimilating power for haloïds. Hübl's results in the main confirm those of Mills.

*Valenta's Acetic Acid Test.*—The author has tried this method (Abstr., 1884, 1078) on a number of oils and finds that a slight variation in the strength or proportion of the acid employed is not of importance, and that the temperature at which turbidity occurs with any particular specimen is readily observed and fairly constant. Concordant results have also been obtained from several samples of butter, and it appears probable that further experience may prove the method to afford a simple means of distinguishing butter from butterine.

*Determination of Glycerol.*—The difficulties attending the determination of the glycerol produced by the saponification of fixed oils have recently been overcome by a method originally suggested by Wanklyn and Fox (Abstr., 1886, 395), and perfected by Benedikt and Zsigmondy. It depends on the saponification of the oil, and oxidation of the glycerol thus formed by potassium permanganate in alkaline solution, with formation of oxalic acid, carbonic anhydride, and water. The excess of permanganate is then destroyed by a sulphite, the solution filtered, the filtrate acidified with acetic acid, and precipitated with a calcium salt. As the precipitate contains calcium sulphate and silicic acid in addition to calcium oxalate, the amount of oxalic acid is determined either by titration of the precipitate with permanganate in acid solution, or by estimating the alkalinity of the ignited precipitate. For the determination of glycerol in fats, the author recommends modifying the method in the following manner:—5 grams of the sample of fixed oil is placed in a six-ounce bottle, together with a solution of 2 grams of caustic potash in 12 c.c. of water. The bottle is securely closed and heated in a water-oven or in boiling water for 8 or 10 hours, the contents being frequently agitated. When the product is perfectly homogeneous and all oily globules have disappeared, the bottle is opened, and the soap diluted with hot water, when a perfectly clear solution should be obtained, except in cases of sperm oil, wax, and other substances yielding insoluble alcohols on saponification. The soap solution is then treated with a moderate excess of acid in the usual way, and the liberated fatty acids are separated from the aqueous liquid containing the glycerol, which latter is then ready for oxidation with alkaline permanganate as above described. D. B.

*Maumené's Test for Oils.* By C. J. ELLIS (*J. Soc. Chem. Ind.*, 5, 150—152 and 361—362).—The author has made some experiments with the view of extending the application of Maumené's test to drying oils and fish oils, to which it cannot be directly applied without some slight modification, owing to the violent action which ensues when these oils are mixed with concentrated sulphuric acid. To overcome this difficulty it was found necessary to mix with a drying or fish oil some liquid which will moderate the action of the acid on the oil. The author employed a mineral lubricating oil of 0.915 sp. gr. for this purpose, and as on mixing sulphuric acid with such an oil a certain increase of temperature takes place, it is necessary to determine the rise due to each gram of the mineral oil. To accelerate the action of sulphuric acid on the mineral oil, a certain proportion of

colza oil was added, for which the standard number, when not mixed, was accurately determined and found to be  $55.8^{\circ}$ . Contrary to expectation, it was found that the smaller the quantity of mineral oil in the mixture the greater is the value representing the rise due to each gram of the mineral oil, providing the rise due to each gram of the vegetable oil remains constant whatever the mixture. To calculate the rise in temperature due to each gram of the mineral oil the following formula is employed:— $y = a + bx$ , in which  $y$  represents the rise in temperature due to each gram of mineral oil,  $x$  is the fraction of the mixture consisting of mineral oil, and  $a$  and  $b$  are constants depending on the conditions of the experiment and the particular mineral oil employed.

In order to obtain the most concordant and trustworthy results, the maximum temperature attained should not exceed  $60^{\circ}$ , and it is for this reason that the author prefers the use of a mineral oil as the retarding reagent.

D. B.

**Employment of Congo-red in Titrating Aniline.** By P. JULIUS (*Chem. Ind.*, 9, 109—110).—Congo-red, the compound of tetrazodiphenyl with naphtholsulphonic acids, is turned blue by acids, and recovers its red colour with an excess of alkali. When used as an indicator in titrating aniline or its homologues with a mineral acid, the point is taken at which a bluish-violet, not changed by small further additions of acid, is produced. A much larger excess is required to produce a pure blue. The results do not vary more than 0.2 per cent. from the theoretical numbers.

M. J. S.

**Hüfner's Method of Estimating Urea.** By E. PFLÜGER and K. BOHLAND (*Pflüger's Archiv*, 39, 1—17).—Pflüger and Schenk previously proved (*ibid.*, 38, 325) that Hüfner's method of estimating the nitrogen in urine gave results which were too low and variable to found a calculation of the total nitrogen on. Owing to the improvement made in Bunsen's method, the authors have been able to ascertain whether Hüfner's method was sufficiently accurate for the determination of urea only. They find that the results are always too high and also very variable. The variation ranges from 1 per cent. to 10 per cent., and does not therefore admit of compensation.

J. P. L.

**Estimation of Urea in Human Urine with Sodium Hypobromite.** By E. PFLÜGER and K. BOHLAND (*Pflüger's Archiv*, 39, 143—158).—Pflüger's new method of estimating urea by hypobromite (*Pflüger's Archiv*, 38, 503) can be applied to the estimation of urea in human urine provided the nitrogenous extractives are first removed. For this purpose, a given volume of urine acidified with hydrochloric acid (1 of acid to 10 of urine) is precipitated with sufficient phosphotungstic acid to ensure the separation of all the extractives, the mixture made up to a known volume, and allowed to remain 24 hours at least previous to filtration. The acid filtrate is carefully neutralised with powdered lime, and again filtered through a dry filter.

Great stress is laid on the use of pure soda and bromine for the

preparation of the hypobromite. The mean error of several analyses of urine by this process was + 1.3 per cent. J. P. L.

**Qualitative Tests for the Dyes Found in Commerce.** By O. N. WITT (*Chem. Ind.*, 9, 1—7).—A table of reactions for the identification of about 80 artificial colouring matters taken singly. Many commercial dyes are mixtures: in this case, the powder strewn upon wet filter-paper or colourless sulphuric acid will generally give streaks of more than one colour. Where the mixture is more intimate a solution must be made, and the colouring matters withdrawn fractionally by dyeing small pellets of wool or silk in it. The principal adulterant for azo-dyes is sodium sulphate. It is best detected after precipitating the colour by pure sodium chloride. M. J. S.

**Detection of Artificially Coloured Red Wine (Claret).** By J. HERZ (*Chem. Zeit.*, 10, 968—969; 998).—To 30—50 c.c. of the wine, or if the quantity of colouring matter in the wine is small, 100 c.c. concentrated to 30 c.c., 20—30 c.c. of a saturated solution of magnesium sulphate, and 10—20 c.c. of soda solution are added, stirring well; if necessary the treatment is repeated until the liquid is colourless, or nearly so. The filtrate is made acid with dilute sulphuric acid (1:3), and if sulphonic acid colours are present the red colour reappears. The most commonly used member of this group, *acid-magenta* (rosanilinesulphonic acid), yields a violet-red solution, and can be estimated by comparing the tint with magenta solutions of known strength. One mgm. of magenta per litre can be distinctly detected in 30 c.c. of wine without previous concentration. When *archil* (*orseille*) colours are present, the filtrate is bluish, and when made acid turns a litmus-red colour. To test for magenta under such circumstances, Blarez' method of shaking with lead dioxide is used; this destroys the orseille and natural colour. Cazeneuve's method is not recommended. To test for other colours in the magnesium hydroxide precipitate, the gelatinous mass is stirred up with hot water, allowed to settle, and the liquid decanted off. If only the natural colour of the wine is present, or *bilberry* has been used, this liquid is yellow-brown; if *archil* has been used, dark-violet; if *ponceau*, onion or ponceau red; if *cassissine*, pale-red or dark-yellow; if *vinicoline bordelaise*, a yellow-red to yellow-brown liquid, which when poured on sulphuric acid gives a violet ring. By shaking the coloured liquid with amyl alcohol, *ponceau* yields an onion-red residue; *vinicoline*, a dark-brown one; *cassissine*, a dirty-green, violet at the edge, turned yellow by strong hydrochloric acid. The precipitate is a dark-grey or brownish-grey colour when the natural or vegetable colours only are present; with *archil*, it is violet; with *magenta* (acid or ordinary), dirty white; with *cassissine*, dirty yellow-brown; with *vinicoline*, crimson-red. The precipitate is mixed with sand, dried, and extracted with ether; the extract contains any ordinary magenta which can be identified in the usual manner by dyeing wool, or *cassissine* which dyes wool red-brown and leaves a yellow-brown residue in the dish. The dyed wool becomes yellow when treated with strong hydrochloric acid and colourless with ammonia. When

wine is shaken with amyl alcohol, and the coloured extract evaporated, the residue, if it contains the substances named, behaves in the manner described below :—

|                     |               | With concentrated                |              |         |
|---------------------|---------------|----------------------------------|--------------|---------|
|                     |               | H <sub>2</sub> SO <sub>4</sub> . | HCl.         | NaHO.   |
| Archil . . . . .    | violet-red    | blue                             | red          | blue    |
| Bordeaux, B. . . .  | carmine       | carmine                          | carmine      | carmine |
| Ponceau, RRR. . .   | dark-red      | crimson                          | crimson      | brown   |
| Cassissine. . . . . | violet-purple | yellow                           | yellow-brown | red     |
| Vinicoline Bor-     |               |                                  |              |         |
| delaise . . . . .   | cherry-red    | brown                            | red          | brown   |

whilst the wine after extraction is cherry-red with ordinary *magenta*, violet-red with *acid-magenta*, dark-cherry with *Bordeaux*, yellow-red with *ponceau*. Wine coloured with *magenta* produces a violet froth. The detection of vegetable colouring matters in presence of the natural colour of wine or otherwise is a matter of great difficulty, and most of the known methods are ineffectual; it is, however, effected by the author with comparative facility in the following manner:—10 to 15 c.c. of wine is shaken with 5 c.c. of a saturated solution of tartar emetic, and then examined by reflected and transmitted light either at once or, if no immediate change has taken place, after some time. This treatment produces with genuine red wine always a cherry-red colour, and with other substances as follows:—*Red-poppy* (*Papaver rhæus*), dark cherry-red; *cherry*, violet; commercial *elder* colouring matter, red-violet; *bilberry* (*Vaccin. myrtill*), blue-violet; *privet-berry*, pure violet. White wines artificially coloured, and red wines mixed with artificial colours have been successfully examined in this manner; in the latter case the wine some time after treatment is compared with a genuine red wine to distinguish more readily the change of colour. Old solutions of privet do not give the colour change. Sodium hydrogen carbonate produces with pure wine, brown-red; with wine coloured with pure *elderberry*, grey-violet; and with *bilberry*, brown-green. Tartar emetic appears to form an antimony lake with the colouring matters. With practice, all the above-mentioned colours can be detected in 30—50 c.c. of wine. In the subsequent communication (*loc. cit.*, 998), the author acknowledges the priority of Ambühl and Elsner's recommendation of the use of tartar emetic for the purpose in question. They, however, recommend hot solutions; the author finds cold better. Fermented bilberries give the violet colour even better than unfermented berries, especially when fresh, inasmuch as oxidation interferes with the delicacy after a time. The distinctness of this colour is increased by diluting the wine.

## General and Physical Chemistry.

---

**Chemical Changes produced by Sunlight.** By E. DUCLAUX (*Compt. rend.*, 103, 881—882).—Many organic compounds are affected by solar radiation in the same way as by microbes, the products of the change being water and carbonic anhydride, with other substances which are relatively stable in the conditions under which they are produced, and are identical with the products of the action of microbes.

Cane-sugar in neutral or alkaline solution is not affected by prolonged exposure to sunlight, but if slightly acidified even with an organic acid it is readily inverted by solar radiation. The solution of invert sugar undergoes no further change so long as it remains acid, but if made alkaline the glucose is rapidly decomposed with formation of water, carbonic anhydride, oxalic, formic, and acetic acids, and about 3 per cent. of alcohol. A similar change takes place, although less rapidly, out of contact with the air, and hence it is evident that the decomposition is due to internal combustion.

Lactose and lactates also yield alcohol under similar conditions. The exact nature of the change in any case is modified by the nature of the source from which oxygen is absorbed (air, salts of platinum, gold, mercury); but the chief products are practically the same from all substances. These products are alcohol, oxalic acid, acids of the acetic series, leucine, carbamide, carbonic anhydride, water, &c. Certain differences are, however, observed. Tartaric acid gives aldehyde in place of alcohol, and the alcohols, if oxidation is regular, tend to produce the corresponding acid of the acetic series. C. H. B.

**Practical Methods of Photographing the Spectrum.** By J. M. EDER (*Monatsh. Chem.*, 7, 429—454).—This paper contains a description of some practical methods of photographing the various parts of the spectrum by silver bromide gelatin plates sensitised by different dyes. The preparation of the plates and the processes used for the development are described in full, and accompanied by copies of photographs taken.

For spectra from the ultra-violet to the yellow, about D, the best dyes are erythrosin, benzopurpurin 4B, and quinoline-red; from the ultra-violet to the red cyanin, is the best; from the orange to the red, cerulein with red glass, and "sensitive green," a dye from parahydroxybenzaldehyde and dimethylaniline, are recommended. These plates, sensitive to the green, yellow, or red part of the spectrum, are suitable for photography by petroleum and gas light, and for taking photographs of gilded documents and papyri, of microscopic preparations, and of clouds on a blue sky, interposing yellow glass to subdue the blue. Excellent photographs of stars have been taken with the aid of these plates. V. H. V.

**Electrolysis of Carbon Compounds.** By J. HABERMANN (*Monatsh. Chem.*, **7**, 529—551).—In continuation of former experiments on the electrolysis of carbon compounds (Abstr., 1881, 215), the author describes the results which are obtained under various conditions with alcohol acidified with sulphuric acid, or rendered alkaline by soda, and with potassium acetate dissolved in methyl alcohol or its homologues. The sources of electrical energy used were a thermobattery of 120 elements, a Smee's battery of 16 elements, and a dynamo-machine of one horse-power.

On electrolysis, alcohol acidified with sulphuric acid yields hydrogen evolved as gas at the negative pole, aldehyde, and after prolonged action aldehyde-resin together with ethyl hydrogen sulphate. The main reaction is therefore  $C_2H_6O = C_2H_4O + H_2$ . If the alcohol is rendered alkaline, or is in the form of sodium ethoxide, the products of decomposition are hydrogen, carbonic anhydride as sodium carbonate, an aldehyde-resin insoluble in ether and alcohol, together with a soluble modification, and a substance allied to cinnamaldehyde.

A concentrated solution of potassium acetate in ethyl alcohol yields a mixture of hydrogen and ethane together with potassium ethyl carbonate, by the mutual decomposition of the salt and acid. In fact, the process serves as a convenient method for the preparation of potassium ethyl carbonate in large quantities, as the salt separates in fine crystalline aggregates. It is quickly decomposed by water, but dissolves in absolute alcohol without change.

The results obtained with solutions of potassium acetate in methyl and butyl alcohols were unsatisfactory. V. H. V.

**Phosphates.** By BERTHELOT (*Compt. rend.*, **103**, 911—917).—When ammonium chloride is added to a solution of trisodium phosphate there is an absorption of heat which varies with the proportion of ammonium chloride, being 5.96, 5.63, 4.84, and 2.62 cal. for 3, 2, 1 and  $\frac{1}{2}$  mols. of ammonium chloride respectively. Complete decomposition of the sodium phosphate would correspond with an absorption of heat equal to -6.4 cal., and hence it is evident that the action of the ammonium chloride is almost complete, although the water exerts a greater dissociating effect on the ammonium phosphate than on the sodium salt.

If trisodium phosphate is added to a solution of a magnesium, barium, strontium, calcium, or manganese salt, a colloidal precipitate of the insoluble phosphate is at first formed, and there is considerable absorption of heat, but after some minutes the precipitate becomes crystalline and a large quantity of heat is developed. The heats of formation of the colloidal and crystallised phosphates are given in the following table:—

|                                | Colloidal. | Crystallised. |
|--------------------------------|------------|---------------|
| Magnesium phosphate . . . . .  | 57.8 cal.  | 83.0 cal.     |
| Magnesium hydrogen phosphate.. | 50.6 „     | 54.2 „        |
| Barium phosphate . . . . .     | 68.4 „     | 100.8 „       |
| Strontium phosphate . . . . .  | 65.4 „     | 97.4 „        |
| Calcium phosphate . . . . .    | 64.0 „     | — „           |
| Manganese phosphate . . . . .  | 45.8 „     | 52.5 „        |

In the case of barium phosphate, the sodium phosphate must be added to the barium chloride, and not *vice versâ*, otherwise the change to the crystalline state is too rapid. The phenomena now described explain the discordant results obtained by Louguinine and the author for the heat of neutralisation of phosphoric acid by baryta, and also the differences observed by Blarez (this vol., p. 7) between the heats of formation of barium phosphate and barium arsenate. In the case of strontium also, the change to the crystalline condition is extremely rapid, if the strontium solution is poured into that of the trisodium phosphate. Calcium phosphate was obtained only in the colloidal form.

The heats of formation of the colloidal insoluble phosphates do not differ to any great extent from the heat of formation of an equivalent quantity of trisodium phosphate,  $33.6 \times 2$  cal. In other words, the precipitate in its initial condition corresponds closely with the soluble salt from which it has been derived, a further example of the tendency of systems which are undergoing transformation to preserve their molecular type. On the other hand, the new phosphates may be dissociated by water to a greater extent than the soluble phosphate from which they have been formed; and this dissociation will be accompanied by an absorption of heat. This absorption is practically *nil* with barium phosphate, which approximates closely to the alkaline phosphates, but it is very distinct with magnesium phosphate, which is more readily dissociated.

In dissolved trisodium phosphate, the third and even the second equivalents of the base are less intimately combined with the acid than the first atom, and are partially separated from it by the dissociating action of the solvent. There can be little doubt that this imperfect state of combination also exists in the colloidal insoluble phosphates, the formation of which is due to a polyalcoholic rather than an acid function of the phosphoric acid. The combination, however, soon becomes more intimate, and the alcoholic function changes to an acidic function comparable with that of ordinary tribasic acids, the change being accompanied by development of heat and crystallisation of the phosphates. The actual development of heat is much greater than can be supposed to be due to the mere physical change from the colloidal to the crystalline condition, even if the change were accompanied by combination with water. As a matter of fact, the crystallised phosphate contains less water than the colloidal phosphate. In their new condition, the heats of formation of the insoluble phosphates become practically treble that of the ordinary monophosphates, or in other words, the three acid functions become equivalent to one another, and to this change is due the greater proportion of the heat developed in the passage from the colloidal to the crystalline form.

C. H. B.

**Heats of Neutralisation of Homologous and Isomeric Acids.**  
By H. GAL and E. WERNER (*Compt. rend.*, 103, 806—809).—The author has determined the heats of neutralisation of isobutyric, isopropylacetic, trimethylacetic (pivalic), caproic, isobutylacetic, and sorbic acids, and his results, together with the heats of neutralisation of the lower acids of the acetic series, as determined by Berthelot,

Louguinine, and others, are given in the following table. Heat of solution of isobutyric acid, directly + 0·973 cal., indirectly + 1·012 cal.; isopropylacetic acid, directly + 1·167, indirectly + 1·030.

| Acid.   | Heat of neutralisation. |
|---|-------------------------|
| Formic acid, $\text{H}\cdot\text{COOH}$ .....   | 13·3                    |
| Acetic acid, $\text{Me}\cdot\text{COOH}$ .....  | 13·4                    |
| Propionic acid, $\text{CH}_2\text{Me}\cdot\text{COOH}$ .....  | 14·3                    |
| { Normal butyric acid, $\text{CH}_2\text{Me}\cdot\text{CH}_2\cdot\text{COOH}$ .....                                 | 14·4                    |
| { Isobutyric acid, $\text{CHMe}_2\cdot\text{COOH}$ .....  | 13·9                    |
| { Normal valeric acid, $\text{CH}_2\text{Me}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$ .....                 | 14·4                    |
| { Isopropylacetic acid, $\text{CHMe}_2\cdot\text{CH}_2\cdot\text{COOH}$ .....                                       | 14·4                    |
| { Trimethylacetic acid, $\text{CMe}_3\cdot\text{COOH}$ .....  | 13·674                  |
| { Normal caproic acid, $\text{CH}_2\text{Me}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$ ..... | 14·689                  |
| { Isobutylacetic acid, $\text{CHMe}_2\cdot\text{CH}_2\cdot\text{COOH}$ .....  | 14·5                    |

Omitting formic and acetic acids, the heat of neutralisation of the other acids, with the exception of isobutyric and trimethylacetic acids, is practically constant, and varies between 14·3 and 14·6. Isobutyric acid is a secondary acid, and trimethylacetic acid is a tertiary acid, and it would seem therefore that the heat of neutralisation of primary acids is greater than that of secondary acids, whilst that of tertiary acids is somewhat smaller still. The heat of neutralisation of sorbic acid, which is regarded by Menschutkin as a tertiary acid, is 12·945.

C. H. B.

**Heats of Neutralisation of Malonic, Tartronic, and Malic Acids.** By H. GAL and E. WERNER (*Compt. rend.*, 103, 871—873).—*Malonic Acid*.—Heat of solution at  $10^\circ = -4\cdot573$  cal. Heat of neutralisation by soda: 1st equivalent, 13·342 cal.; 2nd equivalent, 13·778 cal.; total, 27·120 cal.

*Tartronic Acid*.—Heat of solution at  $12^\circ = -4\cdot331$  cal. Heat of neutralisation by soda: 1st equivalent, 13·711 cal.; 2nd equivalent, 11·856 cal.; 3rd equivalent, 0·0 cal.; total, 25·567.

*Malic Acid*.—Heat of solution at  $20^\circ = -3\cdot148$  cal. Heat of neutralisation by soda: 1st equivalent, 12·730 cal.; 2nd equivalent, 12·189 cal.; 3rd equivalent, 0·0 cal.; total, 24·919.

The heat of neutralisation of oxalic acid is 28·1 cal. (Berthelot and Thomsen); of succinic acid, 26·4 cal. (Chroutschoff); and tartaric acid, 25·3 cal. (Berthelot).

It is evident from these values that the heat of neutralisation diminishes as the molecular weight increases. The introduction of the OH group into oxalic, malonic, and succinic acids lowers the heat of neutralisation by about 2 cal. A similar difference has previously been observed between propionic and lactic acids, and between benzoic and the hydroxybenzoic acids.

C. H. B.

**Thermochemistry of Reactions between Magnesium Salts and Ammonia.** By BERTHELOT (*Compt. rend.*, 103, 844—848).—When magnesium sulphate solution is mixed with an equivalent quantity of sodium hydroxide solution, there is an immediate develop-

ment of  $+0.18$  cal., but the development of heat gradually slackens, and at the end of 10 minutes is  $+1.14$  cal. The successive developments of heat are due to the fact that a basic salt is first formed, which is afterwards decomposed by the soda, and also to the hydration, contraction, &c., of the precipitate. Magnesium chloride and sodium hydroxide behave in like manner. At first there is an absorption of  $-0.32$  cal., and afterwards a development of  $+0.32$  cal., the final result being *nil*.

It is evident, as the researches of Thomsen, Favre and Silbermann, Ditte, and others have already indicated, that the heat developed by the action of acids on magnesium hydroxide approximates closely to that developed by their action on potash and soda.

The action of ammonia on magnesium sulphate is accompanied by an absorption of  $-0.24$  cal., whereas if the magnesium were completely displaced,  $3.0$  cal. should be absorbed. The difference is due to the formation of double salts or oxides, the production of which is accompanied by a development of  $+2.8$  cal. With magnesium chloride, the difference between the calculated and observed values is  $+2.2$  cal.

If magnesium sulphate is mixed with 2 mols. of ammonium chloride,  $+0.32$  cal. is developed, and if an equivalent quantity of ammonia is now added, there is a further development of  $+0.26$  cal., the total development of  $+0.58$  cal. being due to the formation of a complex oxide, the heat of neutralisation of which is  $0.58$  cal. higher than the sum of the heats of neutralisation of magnesium oxide and ammonia separately. When magnesium chloride is mixed with ammonia, there is an absorption of  $-0.48$  cal., and if ammonium chloride is then added there is a development of  $+0.56$  cal., the sum being  $0.08$  cal., from which it follows that the heat of neutralisation of the complex oxide by hydrochloric acid is practically identical with that of magnesium oxide.

If magnesium sulphate or chloride solution is mixed with sodium hydroxide, and ammonia then added, the greater part of the precipitate redissolves, but there is no sensible thermal disturbance, a result which indicates that the heat of solution of the precipitate is identical with its heat of combination with the solvent. If, on the other hand, magnesium sulphate is first mixed with ammonia, and the sodium hydroxide added afterwards, there is a development of  $+1.90$  cal., probably due to the fact that, the order of admixture being reversed, the liquid requires a much longer time to attain the same condition. The difference between the observed thermal disturbance and the development of heat resulting from the action of soda or magnesium sulphate alone is a further proof of the formation of complex compounds.

If magnesium sulphate is mixed with 2 mols. of ammonium chloride and sodium hydroxide then added,  $+3.64$  cal. are developed, and some permanent precipitate is formed. The thermal disturbance is greater than that which would correspond with the displacement of ammonium by sodium, and the difference indicates the combination of magnesia and ammonia with formation of ammonio-magnesium sulphate. If 4 mols. of ammonium chloride are added at the begin-

ning, no precipitate is formed, and the heat developed is +3.90 cal. With magnesium sulphate, the excess of heat developed above that corresponding with the decomposition of the ammonium salt is +1.2 cal., with the chloride it is +1.0 cal.

From these results it follows that the complex ammonio-magnesium bases in uniting with sulphuric or hydrochloric acid, develop about +1.8 cal. more than pure ammonia, and +0.3 cal. more than magnesium oxide. The association of ammonia with a metallic oxide such as magnesia would seem to result in the production of a complex alkali analogous to tetramethylammonium oxide, with an energy greater than that of metallic oxides, and approaching that of the strongest alkalis.

**Heats of Combustion and Formation of Homologous Phenols.** By F. STOHMANN, P. RODATZ, and H. HERZBERG (*J. pr. Chem.* [2], **34**, 311—327).—In this paper a series of determinations of the heats of combustion and formation of the homologous series of phenols are given in detail, as also their heats of liquefaction. The principal values obtained are given in the following table:—

|   | Heat of combustion<br>per gram-molecule. | Heat of<br>formation. |
|---|--|-----------------------|
| Phenol (solid), $C_6H_5 \cdot OH$ .....       | 723659                                   | —                     |
| „ (liquid) .....                              | 726002                                   | —                     |
| Orthocresol (liquid), $C_6H_4Me \cdot OH$ ..  | 883008                                   | 50992                 |
| „ (solid).....                                | 879788                                   | —                     |
| Metacresol (liquid) .....                     | 880956                                   | 53044                 |
| Paracresol „ .....                            | 882900                                   | 51100                 |
| „ (solid) .....                               | 880441                                   | —                     |
| Orcinol, $C_6H_3Me(OH)_2$ (solid).....        | 824724                                   | 109276                |
| Orthoxylenol, $C_6H_3Me_2 \cdot OH$ (solid).. | 1035434                                  | 61566                 |
| Metaxylenol (liquid).....                     | 1037499                                  | 59501                 |
| Paraxylenol (solid) .....                     | 1035638                                  | 61362                 |
| Pseudocumenol, $C_8H_2Me_3 \cdot OH$ (solid)  | 1191451                                  | 68549                 |
| Carvacrol, $C_8H_3MePr \cdot OH$ (liquid)..   | 1354819                                  | 68181                 |
| Thymol (liquid).....                          | 1353750                                  | 69250                 |
| „ (solid) .....                               | 1349982                                  | —                     |

On a comparison of these numbers, it will be seen that every displacement of hydrogen by a methyl-group corresponds with an increment of 156356 cal. in the heat of combustion, a value practically equal to that obtained for the homologues of methyl alcohol. Thus it follows that the displacement of hydrogen by methyl, either in the so-called side-chain or in the nucleus, corresponds with the same value for the heat-increment. Thus the value for ethylphenol will be equal to that of xylenol. Similarly also, as the values for carvacrol and thymol are approximately equal to that of pseudocumenol, namely, the introduction of the isopropyl-group produces the same effect as that of three single methyl-groups, then the heat values of the iso-are equal to those of normal-compounds.

**Some Laws of Chemical Combination.** By DE LANDERO and R. PRIETO (*Compt. rend.*, **103**, 934—935).—If chemical combination is taken as the clashing together of the particles of the elements, and if each particle is regarded as possessing a constant velocity which is characteristic of the particular element, the loss of energy resulting from the union of the non-elastic particles may be regarded as the equivalent of the quantity of heat developed by the combination. These considerations lead to the formula—

$$f = \frac{ee'}{2(e + e')} (V + V')^2,$$

in which  $f$  = the heat of combination expressed in calories,  $e, e'$  = the weights of the combining elements *equivalent* to 1 gram of hydrogen, whilst  $V$  and  $V'$  are quantities which are constant for each element and are proportional to the velocities of their particles. These quantities may be termed *thermodynamic constants*, or *thermodynamic equivalents*, and their value is obtained by the formula—

$$V \pm V' = \sqrt{2f \frac{e + e'}{ee'}}.$$

Take the case of the two copper bromides—

*Cuprous bromide*:  $e + e' = 143.4$ ;  $f = 25900$  cal.;  $V + V' = +38.269$

*Cupric bromide*:  $e + e' = 111.7$ ;  $f = 17300$  cal.;  $V \pm V' = +39.039$ .

Calculations with tin bromides, mercury bromides, mercury iodides, &c., lead to similar results. Since  $V \pm V'$  is the sum or difference of the thermodynamical equivalents of the two elements in each system; it is necessary to obtain the constants of some of the elements from different sets of compounds, care being taken to use only thermochemical data referred to the solid state. The following table gives the thermodynamical equivalents of several elements, these values referring in each case to that quantity of the element which is equivalent to 1 gram of hydrogen:—

|          |        |          |        |          |        |
|----------|--------|----------|--------|----------|--------|
| K .....  | 45.221 | S .....  | 47.874 | Al ..... | 48.218 |
| Na ..... | 49.768 | Tl ..... | 5.223  | Zn ..... | 13.073 |
| Hg ..... | 9.079  | Ag ..... | 12.786 | Pb ..... | 5.155  |
| Br ..... | 44.171 | Cu ..... | 4.999  | Si ..... | 37.519 |
| I .....  | 32.416 | Ca ..... | 50.309 |          |        |

**The Law of Volumes in Chemistry.** By T. S. HUNT (*Chem. News*, **54**, 206—207).—The author advocates the universal application of the law of volumes to solids, liquids, and gases, which would render the application of the atomic hypothesis to explain the law of definite proportions wholly unnecessary. From this standpoint, the union of many volumes of vapour or gas to form a single volume of vapour or solid would be regarded as chemical combination; the reverse, namely vaporisation, would be chemical decomposition, which would be without specific difference in the case of integral volatilisation, or

with definite changes, as in cases now regarded as dissociation. The difference between chemical and physical molecules would hence be quite evident.

D. A. L.

**Velocity of Dissociation.** By H. LESCEUR (*Compt. rend.*, **103**, 931—933).—The velocity of dissociation of acid sodium acetate,  $C_2H_3O_2Na, 2C_2H_4O_2$ , was determined by placing the compound in a small bell-jar which also contained soda-lime; the temperature of the whole being kept at  $100^\circ$ . The mean velocity of dissociation during a given interval is determined by dividing the time into the loss of weight of the compound. The results indicate the existence of a biacetate,  $C_2H_3O_2Na, C_2H_4O_2$ , and a sesquiacetate,  $2C_2H_3O_2Na + C_2H_4O_2$ .

Velocity of dissociation does not depend on the temperature alone, as Müller-Ertzbach supposes, but also on the physical condition of the substance which is undergoing dissociation. In this particular case, the rate of dissociation increased fourfold when the acetate became solid, although the tension of dissociation did not change, and similar phenomena are observed with copper sulphate crystals, &c.

C. H. B.

**Nature of Liquids.** By W. RAMSAY and S. YOUNG (*Chem. News*, **54**, 203—205).—It is proved by various investigations that, above a certain pressure and temperature, all liquids show an increase in the density of their saturated vapours beyond that deducible from the molecular formulæ, varying of course with the liquid. Some liquids, however, known to be dissociable, in addition show an increase also on fall of temperature and pressure below a certain temperature and pressure characteristic of the liquid. Reasoning from these facts, the following difference is suggested between stable and dissociable liquids:—In the former, the molecules exhibit physical but not chemical attraction; in the latter both physical and chemical attraction are evident, inasmuch as, besides cohesion and surface tension, there is evidence of molecular combination. The behaviour of vapours at the moment the liquid is visible support this theory, for whereas vapours from dissociable liquids continue to rise in pressure in spite of the decrease in volume and condensation of liquid (evidence of non-homogeneity of the vapour, owing in these instances to formation of molecules of higher molecular weight), vapours from stable liquids do not behave in this manner, but the pressure in such case is the vapour-pressure corresponding with the temperature; hence it may be concluded that the latter show no tendency to form complex molecular groups.

With regard to the solvent action of a fluid above its critical point, the authors have worked with a solution of eosin in alcohol, taking the fluorescence as indicating solution. They find that solution existed at least for a short time at temperatures a little above the critical point, and at volumes smaller than the critical volume; apparently, however, after some time the solid is wholly deposited as such on the walls of the tube. This is not conclusive, as the translucent red substance deposited on the glass interfered with the detection of the fluorescence. According to the authors' view of the nature of liquids,

solution should be possible above the critical point provided the volume is sufficiently small.

D. A. L.

**Capillary Constants and Meniscus Angle.** By J. TRAUBE (*J. pr. Uhem.* [2], 34, 292—311).—Determinations are given for the value of the function  $\alpha^2 \cos \theta$  according to the formula  $rh = \alpha^2 \cos \theta$ , for aqueous solutions of the alcohols of the paraffinoid series and acids of the acetic series at various degrees of concentration (comp. Abstr., 1885, 1033). The principal points to be noticed are that both propyl and isopropyl alcohols show a minimum value for the function with mixtures of equal weights of the alcohol with water, and that the curve for butyric acid at first decreases with increase of concentration up to 30 per cent., thence increases up to 50 per cent., and subsequently decreases.

After a historical review of the literature on the magnitude of drops, an account is given of experiments, made with an apparatus previously described, permitting of the formation of drops from a capillary tube under constant or variable conditions of temperature and pressure. The weight of the drops was ascertained by determinations of the specific gravity and the number of drops in a constant volume. The results obtained with the above-mentioned alcohols and acids show that the *volume of the drops is proportional to the rise in height in the capillary tube, or their weight is proportional to the product of the height and the specific gravity*. If then the mean weight of the drop is divided by the circumference  $\frac{C}{2r\pi}$ , then for all liquids examined this quotient is less than the capillary constant  $\alpha \cos \theta$ , and secondly this quotient increases with decrease of radius of the tube. Both these statements are deducible from the previous observations of Hagen and Quincke.

Again the diameter of the capillary tube determines the shape of the drop; thus with tubes of less than 3—4 mm. their form is more or less spheroidal, with tubes of 1 mm. the form is cylindrical with a convex base, and with tubes of larger diameter it is paraboloidal.

V. H. V.

**Crystallisation by Diffusion.** By C. E. GUIGNET (*Compt. rend.*, 103, 873—875).—The experiments described in this paper are an extension of Becquerel's researches on electro-capillary reactions.

The introduction of any solid into a saturated solution of another solid determines the crystallisation of the latter, provided that the solid introduced is soluble in the particular solvent. For example, solid paraffin introduced into a saturated solution of sulphur in carbon bisulphide causes the separation of crystals of sulphur, and *vice versâ*; sodium thiosulphate introduced into a saturated solution of ammonio-cupric sulphate yields violet needles of ammonio-cupric thiosulphate.

If crystals of sodium sulphate are placed in a saturated solution of barium chloride, the crystals become opaque but retain their form, and when the crystals are broken each one is found to be a sort of

miniature lode with crystals of barium sulphate. Barium chloride introduced into a saturated solution of sodium sulphate yields only amorphous barium sulphate, probably because the chloride dissolves too quickly. Ordinary sodium phosphate placed in magnesium sulphate solution produces crystallised magnesium phosphate.

In order to observe these phenomena with two liquids, if the action is merely physical, a saturated solution of a solid is covered with a layer of the solvent, and on this is poured a second liquid in which the solid is somewhat less soluble than in the first. The liquids gradually mix by diffusion, and the solid separates in very distinct crystals. If a saturated solution of sulphur in carbon bisulphide is covered with a layer of the bisulphide, and on this is poured a layer of oil, alcohol, glacial acetic acid, benzene, petroleum, &c., octahedral crystals of sulphur are deposited. A saturated solution of lead chloride in hydrochloric acid covered in a similar manner with a layer of hydrochloric acid and a layer of water, yields fine crystals of lead chloride.

Where chemical action takes place between the liquids, one is placed in a crystallising dish which is filled nearly to the top, and this is placed inside another vessel which contains the second liquid. Water is then carefully poured into both dishes until it is just higher than the edge of the inner dish. Diffusion takes place through the supernatant water, and crystals are formed. Sodium sulphate and calcium chloride give long crystals of calcium sulphate; sodium sulphate and barium chloride give crystallised barium sulphate; sodium sulphate and lead acetate give crystals of lead sulphate; and potassium ferrocyanide and lead acetate yield long pale-yellow needles of lead ferrocyanide.

On a large scale, wooden vessels with a leaden partition which does not quite reach to the top are used. The liquids are poured one into each compartment, and the latter are then filled up with water until the water just flows over the top of the partition. In this way very large crystals can be obtained. C. H. B.

**Influence of some Normal Salts on the Decomposition of Methyl Acetate by Hydrochloric and Sulphuric Acids.** By H. TREY (*J. pr. Chem.* [2], 34, 353—377).—Ostwald investigated (*J. pr. Chem.* [2], 23, 209) the difference in the action of acids caused by the presence of their normal salts; the author has repeated these experiments with a view to obtaining a satisfactory explanation of this action. The experiments were made with hydrochloric and sulphuric acids, and the salts of these acids with the alkalis and alkaline earths. The methyl acetate method was used, in the manner previously described, with normal acids (1 gram-equivalent in 1 litre) and normal acids to which  $\frac{1}{4}$ ,  $\frac{1}{2}$ , 1, &c., equivalents of their normal salts had been added. These normal solutions were also used  $2\frac{1}{2}$ , 5, and  $12\frac{1}{2}$  times diluted. The results were calculated according to the formulæ given by Ostwald (this Journal, 1884, 581), and are given in a series of tables. These values are not strictly comparable, but require correcting for the increase of volume caused by the addition of salt and the consequent decrease of the velocity of the reaction. The

mean values found are given below; the second line in each case gives the corrected value.

*Hydrochloric Acid and Alkaline Chlorides.*

| $\frac{1}{5}$ normal . . . .        | 1·000             | 1·011                                     | 1·041                         | 1·181                         | 1·009                                    | 1·032                        | 1·005                        |
| $\frac{1}{12\frac{1}{2}}$ normal .. | 1·000             | 1·009                                     | 1·009                         | 1·054                         | 1·000                                    | 1·000                        | 1·093                        |

For the stronger solutions, the increase of the action of the hydrochloric acid is proportional to the amount of salt present; for the weaker solutions, the increase is so small as to fall within the errors of experiment.

Hydrochloric acid and lithium, magnesium, calcium, strontium, and barium chlorides, gave the following numbers:—

|                          | HCl<br>(1 litre). | HCl<br>(1 litre)<br>+ 4LiCl. | HCl<br>(1 litre)<br>+ 2MgCl <sub>2</sub> . | HCl<br>(1 litre)<br>+ 2CaCl. | HCl<br>(1 litre)<br>+ 2SrCl <sub>2</sub> . | HCl<br>(1 litre)<br>+ 1BaCl <sub>2</sub> . |
|--------------------------|-------------------|------------------------------|--|------------------------------|--|--|
| Normal ....              | { 31·27<br>—      | 56·83<br>61·31               | 66·56<br>69·26                             | 59·43<br>62·69               | 58·55<br>62·06                             | 42·46<br>44·07                             |
| $\frac{1}{2}$ normal.... | { 5·62<br>—       | 5·97<br>6·44                 | 6·33<br>6·59                               | 6·24<br>6·56                 | 6·20<br>6·58                               | 5·84<br>6·07                               |

These numbers gave the following ratios for the accelerating action of the salts:—

|                          | HCl<br>(1 litre) | HCl<br>(1 litre)<br>+ 4LiCl. | HCl<br>(1 litre)<br>+ 2MgCl <sub>2</sub> . | HCl<br>(1 litre)<br>+ 2CaCl. | HCl<br>(1 litre)<br>+ 2SrCl <sub>2</sub> . | HCl<br>(1 litre)<br>+ 1BaCl <sub>2</sub> . |
|--------------------------|------------------|------------------------------|--|------------------------------|--|--|
| Normal .....             | 1·000            | 1·961                        | 2·215                                      | 2·005                        | 1·985                                      | 1·409                                      |
| $\frac{1}{2}$ normal.... | 1·000            | 1·146                        | 1·173                                      | 1·167                        | 1·171                                      | 1·080                                      |

From these results the author concludes that the accelerative influence of the chlorides stands in the inversive ratio to the atomic weights of the respective series. Thus, calculated for 1 equivalent of chloride, the numbers are:—

| LiCl. | NaCl. | KCl.  | MgCl <sub>2</sub> . | CaCl <sub>2</sub> . | SrCl <sub>2</sub> . | BaCl <sub>2</sub> . |
|-------|-------|-------|---------------------|---------------------|---------------------|---------------------|
| 1·240 | 1·199 | 1·121 | 1·304               | 1·251               | 1·246               | 1·205               |

These results agree with those found by Reicher (Abstr., 1885, 1034) for the saponification of ethyl acetate by alkalis.

The action of sulphuric acid in the presence of normal sulphates is the reverse of that of hydrochloric acid. The action is retarded nearly proportionally with  $\frac{1}{4}$  to 1 equivalent salt, but in a less degree with 2 equivalents. The following tables give the mean values for normal and  $\frac{1}{2}$  normal solutions:—

|                      | $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre).              | $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre)<br>+ $\frac{1}{2}\text{Na}_2\text{SO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre)<br>+ $\frac{1}{4}\text{Na}_2\text{SO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre)<br>+ $\frac{1}{2}\text{Na}_2\text{SO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre)<br>+ $1\text{Na}_2\text{SO}_4$ . |
|----------------------|---|--|--|--|--|
| Normal.              | $\left\{ \begin{array}{l} 16\cdot62 \\ - \end{array} \right.$ | $\begin{array}{l} 14\cdot71 \\ 14\cdot71 \end{array}$                                      | $\begin{array}{l} 12\cdot58 \\ 12\cdot64 \end{array}$                                      | $\begin{array}{l} 9\cdot50 \\ 9\cdot62 \end{array}$  | $\begin{array}{l} 6\cdot89 \\ 7\cdot08 \end{array}$                              |
| $\frac{1}{2}$ normal | $\left\{ \begin{array}{l} 3\cdot34 \\ - \end{array} \right.$  | $\begin{array}{l} 3\cdot04 \\ 3\cdot04 \end{array}$  | $\begin{array}{l} 2\cdot68 \\ 2\cdot69 \end{array}$  | $\begin{array}{l} 2\cdot16 \\ 2\cdot19 \end{array}$  | $\begin{array}{l} 1\cdot62 \\ 1\cdot67 \end{array}$                              |
| Normal.              | 1·000   | 0·885  | 0·760  | 0·578  | 0·426  |
| $\frac{1}{2}$ normal | 1·000   | 0·910  | 0·805  | 0·656  | 0·500  |

With sulphuric acid, the retarding influence of the sulphates on the velocity of the action appears to *increase* with the atomic weight of the elements of the series, thus:—

| $\frac{1}{2}\text{H}_2\text{SO}_4$<br>(1 litre). | $\frac{1}{2}\text{H}_2\text{SO}_4$ (1 litre)<br>+ $\frac{1}{2}\text{MgSO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$ (1 litre)<br>+ $\frac{1}{2}\text{Li}_2\text{SO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$ (1 litre)<br>+ $\frac{1}{2}\text{Na}_2\text{SO}_4$ . | $\frac{1}{2}\text{H}_2\text{SO}_4$ (1 litre)<br>+ $\frac{1}{2}\text{K}_2\text{SO}_4$ . |
|--|--|---|---|--|
| 1·000  | 0·787  | 0·620   | 0·579   | 0·530  |

Dithionic acid in the presence of its normal salts was influenced in the same way as hydrochloric acid, so also was the bibasic methylenedisulphonic acid, whilst dichloroacetic acid behaved like sulphuric acid. This method of investigation will therefore throw no light on the basicity of dithionic acid, but the author thinks the results show that it does not form acid salts in aqueous solution.

G. H. M.

**Preservation of Gases over Mercury.** By H. B. DIXON (*Chem. News*, 54, 227—228).—From the author's experiments, it is shown that, provided due precautions are taken to prevent the formation of a film between the glass and the mercury, gases may be safely preserved over mercury for a considerable time.

D. A. L.

**Cracking Glass with Certainty.** By E. BECKMANN (*Zeit. anal. Chem.*, 25, 530—531).—A scratch is made with a file; at both sides of this, pads of wetted filter-paper are wrapped round the object, leaving a space of a few millimetres between them. The flame of a Bunsen or gas blowpipe is applied to this space, when the crack will be carried round from the scratch midway between the two pads.

M. J. S.

**Apparatus for Chemical Laboratories.** By J. WALTER (*J. pr. Chem.* [2], 34, 427—432).—A new form of condenser, and flasks for use with it, both for ordinary and fractional distillation.

### Action of Hypochlorous Anhydride on Iodine Trichloride.

By H. BASSETT and E. FIELDING (*Chem. News*, **54**, 205—206).—Iodic anhydride is the main product of the reaction when solutions of iodine trichloride and hypochlorous anhydride in carbon tetrachloride are mixed, or when a current of hypochlorous anhydride is passed through a solution of iodine trichloride, or even over solid trichloride. In the last case, the action is very slow. D. A. L.

### Saturation of Selenious Acid by Bases.

By C. BLAREZ (*Compt. rend.*, **103**, 804—806).—With cochineal or helianthin (methyl-orange), selenious acid is monobasic. With litmus, it is monobasic to ammonia, lime, strontia, and baryta, but if soda or potash is used the litmus only becomes blue-violet when about 1.5 equivalent of alkali is added. With phenolphthaleïn and potash, soda, ammonia, lime or strontia, the colour change takes place when somewhat more than 1.5 equivalent of alkali is added, but with phenolphthaleïn and baryta selenious acid is bibasic, and the colour change is sharp and distinct.

Selenious acid can be accurately titrated by means of standard baryta solution, using helianthin or phenolphthaleïn as indicator. The baryta has double the value with the first indicator that it has with the second. Both indicators can be used in the same solution; the rose colour of the helianthin disappears when the acid is half saturated, and the rose colour due to the change of the phenolphthaleïn becomes visible when saturation is complete.

As no basic barium selenite is formed when baryta is present in excess, an excess of baryta can be determined by means of phenolphthaleïn and a standard acid in the liquid containing the precipitated barium selenite.

Selenious acid, like sulphurous acid, can be estimated in presence of other acids by means of baryta, provided that the total basicity of these acids is indicated by helianthin. Helianthin and phenolphthaleïn are both added to the same solution, and the amount of selenious acid is calculated from the quantity of baryta solution required to produce the second colour change, this quantity being exactly half that which would be required to neutralise the selenious acid alone with phenolphthaleïn as the indicator. C. H. B.

### Formation of Nitrites.

By S. KAPPEL (*Arch. Pharm.* [3], **24**, 897—900).—The author has extended his observations made on the action of copper, iron, and zinc in contact with the air, and solutions of ammonia and the fixed alkalis (*Abstr.*, 1883, 282, 286), employing in recent experiments magnesium, aluminium, and tin. Magnesium exposed to the air in contact with aqueous potash, gave small quantities of nitrous acid, ozone, and hydrogen peroxide. With ammonia solution, strong indications of nitrous acid were obtained. Aluminium in potassium hydrate produced nitrous acid readily, even in the cold,

nitric acid and hydrogen peroxide were also easily detected. With ammonia the action was much slower. Tin foil gave scarcely any reaction; nitrous acid was not produced, but hydrogen peroxide was perceptible.

J. T.

**Compounds of Arsenious Anhydride with Halogen Salts.** By F. RÜDORFF (*Ber.*, 19, 2668—2679).—In this paper the preparation and properties of compounds of the halogen salts of the alkali metals with arsenious anhydride are described. These are best obtained by passing carbonic anhydride into a mixed solution of potassium arsenite and the halogen salt. These compounds separate either in the amorphous form or in indistinct crystals, of the general formula  $MX, 2As_2O_3$ , sparingly soluble in water, insoluble in alkaline carbonates, but very soluble in the free alkalis; when heated, they decompose with elimination of arsenious anhydride, the compound  $KI, 2As_2O_3$  decomposing at  $350^\circ$ ;  $KBr, 2As_2O_3$  at  $300^\circ$ ; and  $KCl, As_2O_3$  at  $240^\circ$ ; a compound,  $KCl, 2As_2O_3$ , is also described. The ammonium compounds  $NH_4I, As_2O_3$ ,  $NH_4Br, 2As_2O_3$ , and  $NH_4Cl, As_2O_3$ , are also described, those of sodium being reserved for a future communication.

V. H. V.

**Some Probable New Elements.** By A. PRINGLE (*Chem. News*, 54, 167—168).—The author claims to have discovered some new substances, including five metals and a substance resembling selenium, called *hesperisium*, in some "Lower Silurian" rocks, situated in the county of Selkirk. One metal is said to be like iron, but gives neither the thiocyanate nor the tannic acid reaction; one is like lead in appearance, is easily fused and volatilised; and yields yellow and green salts; another which is charcoal-black, is called *erebodidium*; its equivalent is 95.4, and it forms several oxides. A fourth, *gadenium*, with equivalent about 43.6, a light-grey powder, forms a red monoxide and a cream-coloured dioxide, yielding respectively white and yellow salts. Another, *polymnestum* (Pm), is a rather dark-coloured metal, with equivalent about 74. A preliminary description of four oxides,  $PmO$ ,  $PmO_2$ ,  $PmO_3$ , and (?)  $PmO_5$ , of two sulphides,  $PmS$  and  $PmS_3$ , and of other compounds is given.

D. A. L.

**Production of Alkali Metals.** By H. Y. CASTNER (*Chem. News*, 54, 218—219).—Iron reduced by hydrogen or carbonic oxide is mixed with tar in proper proportions, so that after the mixture is coked it has a composition about  $= FeC_2$ . The coke is finely ground, mixed with caustic soda (or potash) in proportions  $= 3NaHO + FeC_2$ , or about 100 NaHO to 15 of coke. This mixture is introduced into a cast-iron crucible, and heated in a specially arranged furnace (described in the paper). The reduction and distillation commence at a temperature of  $1000^\circ$ . When the operation is finished the crucible is removed, and another immediately put in its place. The residue consists of some sodium carbonate, and finely divided iron; the sodium carbonate is recovered, the iron used to make fresh reducing coke, and the crucible is used over and over again. The advantages over the old method are manifest.

D. A. L.

**Crystalline Scale formed in the Manufacture of Sodium Hydrogen Carbonate.** By G. W. LEIGHTON (*Amer. J. Sci.*, **32**, 318—319).—This scale was formed in the manufacture of sodium hydrogen carbonate by the ammonia process, at Syracuse, New York. It was deposited on the inner surface of an iron tank, and had the appearance of boiler-scale, being 1 to 2 inches thick, with a vitreous lustre, and a greenish-grey colour. It is usually covered with crystal planes, proving to be the termination of prisms (probably monoclinic). Analysis gave the following results :—

| NaCl. | Na <sub>2</sub> CO <sub>3</sub> . | MgCO <sub>3</sub> . | CaCO <sub>3</sub> . | FeCO <sub>3</sub> . | H <sub>2</sub> O. | CO <sub>2</sub> . | Total. |
|-------|-----------------------------------|---------------------|---------------------|---------------------|-------------------|-------------------|--------|
| 22·23 | 40·62                             | 31·57               | 3·56                | 0·08                | 0·63              | 0·64              | 99·33  |

The scale is evidently a triple salt, represented by the formula  $\text{MgCO}_3, \text{Na}_2\text{CO}_3, \text{NaCl}$ . It is, in fact, a definite crystalline product of an interesting constitution, not unlike that of several well-defined mineral species, in which an alkaline chloride appears to be in molecular combination with heterogeneous materials. B. H. B.

**Strontia Dihydrate.** By C. HEYER (*Ber.*, **19**, 2684—2690).—When strontium hydroxide is heated to bright redness, it is converted into strontium oxide. When the latter is exposed to air saturated with aqueous vapour, and then to dry air at the ordinary temperature, strontia dihydrate,  $\text{SrO}, 2\text{H}_2\text{O}$ , is obtained as a white, crystalline powder.

Dry strontia dihydrate, when heated with dry carbonic anhydride, is completely converted into carbonate; the monohydrate, however, absorbs only traces of carbonic anhydride. The water in the dihydrate was determined by passing dry carbonic anhydride over the substance for five hours at  $26\cdot5^\circ$ , and for 40 minutes at  $121\cdot5^\circ$ , and absorbing the water in sulphuric acid bulbs. These results are not in accordance with those obtained by Scheibler (*Abstr.*, 1886, 927).

N. H. M.

**Calcium Borate.** By B. BLOUNT (*Chem. News*, **54**, 208—209).—The salt obtained by fusing freshly calcined lime with boric anhydride over a Bunsen burner is  $\text{CaB}_4\text{O}_7$ . It is possible that the salt obtained on a platinum wire loop before the blowpipe, with large excess of boric anhydride, contains a larger proportion of boric acid.

D. A. L.

**Calcium Ammonium Arsenate and Calcium Arsenates.** By C. L. BLOXAM (*Chem. News*, **54**, 168—170; 193—194).—In a previous communication (*Abstr.*, 1886, 920), mention is made of a calcium ammonium arsenate. Various observers differ as to the composition of this salt and as to the amount of water it contains. The amount of water appears to vary somewhat with the state of the atmosphere, and hence, probably, the cause of the difference of opinion on this point. It is now shown theoretically and experimentally that the precipitate produced by arsenic acid in a solution of calcium chloride containing free ammonia has the following composition :—

|   |  |
|---|--|
| Air-dried.....  | $\text{CaNH}_4\text{AsSO}_4 + 7\text{H}_2\text{O}$ .                       |
| Dried in a vacuum over sulphuric acid, $\text{Ca}_3\text{NH}_4\text{H}_2(\text{AsO}_4)_3 + 3\text{H}_2\text{O}$ . |  |
| Dried at $100^\circ$ .....  | $\text{Ca}_6\text{NH}_4\text{H}_5(\text{AsO}_4)_6 + 3\text{H}_2\text{O}$ . |
| Ignited .....   | $\text{Ca}_2\text{As}_2\text{O}_7$ .                                       |

It is suggested to use the precipitation of calcium as calcium ammonium arsenate for quantitative purposes; it is convenient, the precipitate being crystalline and bulky, but is not susceptible of such great accuracy as the oxalate method. It is recommended for checking hardness determinations in water analysis. Its various advantages and disadvantages as a method are discussed. On evaporating down a hydrochloric acid solution of calcium ammonium arsenate with platinic chloride, the platinochloride after ignition was observed to be mixed with fine, white, opaque, prismatic crystals of the orthoarsenate  $\text{Ca}_3(\text{AsO}_4)_2$ , insoluble in acids. A repetition of the experiment resulted in the production of a substance somewhat similar in appearance, namely the meta-arsenate  $\text{Ca}(\text{AsO}_4)_2$ ; the same substance is formed when mixtures of arsenious anhydride and calcium carbonate are ignited, and is left as an insoluble, crystalline powder when the ignited mass is treated with hydrochloric acid. D. A. L.

**Artificial Lead Silicate from Bonne Terre, Missouri.** By H. A. WHEELER (*Amer. J. Sci.*, **32**, 272—273).—E. S. Dana and S. L. Penfield have given (*Abstr.*, 1886, 317) some crystallographic determinations and analyses of this artificial mineral from the Desloge Lead Co., of Bonne Terre. Since the publication of that paper, the author has examined some specimens in the metallurgical collection of Washington University. The results of his analysis are as follows:—

|         | $\text{SiO}_2$ . | $\text{PbO}$ . | $\text{Fe}_2\text{O}_3$ . | $\text{Al}_2\text{O}_3$ . | $\text{CaO}$ . | $\text{MgO}$ . |
|---------|------------------|----------------|---------------------------|---------------------------|----------------|----------------|
| I ....  | 17.11            | 73.66          | 0.80                      | 0.53                      | 2.35           | 0.22           |
| II .... | 18.51            | 72.93          | 1.31                      | 0.62                      | 1.66           | 0.20           |

|         | Cl.    | $\text{Na}_2\text{O}$ . | $\text{NiO}$ . | Total. |
|---------|--------|-------------------------|----------------|--------|
| I ....  | 0.08   | 2.22                    | 3.06           | 100.03 |
| II .... | undet. | undet.                  | undet.         | 95.23  |

I, coarse crystals; II, fine crystals. The iron in these analyses was assumed to be in the form of ferric oxide. B. H. B.

**Equivalent of Gadolinium Oxide.** By A. E. NORDENSKIÖLD (*Compt. rend.*, **103**, 795—798).—Gadolinium oxide is the mixture of yttrium, erbium, and ytterbium oxides, which was first obtained from the gadolinite found at Ytterby. It is precipitated by ammonia and ammonium oxalate as well as by potassium sulphate, and the three constituents cannot be separated quantitatively.

The gadolinium oxide obtained from kainosite, the silicocarbonate of yttrium, erbium, and ytterbium, recently discovered at Hitterö, in Norway, has the molecular weight 260.2 if  $\text{O} = 16$  and the formula of the oxide is taken as  $\text{M}_2\text{O}_3$ . This number is practically identical with the molecular weight of the similar mixture of oxides obtained

by different observers (Nordenskiöld, Lindström, Engström, Clève) from gadolinite, kinosite, azzhenite, xenotime, fergusonite, cleveite, fluocerite, and eudialite. These minerals are found in different localities, and contain the oxides in combination with different acids, such as silicic, phosphoric, niobic, or tantalic acid. Moreover, the oxides have been separated by somewhat different methods, and yet in all cases the greatest variation from the mean value for the molecular weight, 261.9, is one per cent., a variation which is within the error of experiment, and is not greater than the alterations which have been made in recent times in the atomic weights of some of the better known elements. It follows therefore that *gadolinite oxide*, although not the oxide of a simple substance, but a mixture of three isomorphous oxides, has a constant molecular weight, even when obtained from totally different minerals found in widely separated localities. This is the first instance of the coexistence of three isomorphous substances in constant proportions. The explanation of this fact seems to be a problem analogous to that of the origin of the minor planets.

C. H. B.

**Formation of Ultramarine in the Wet Way.** By F. KNAPP (*J. pr. Chem.* [2], 34, 328—340).—An account of some further experiments on the formation of ultramarine by the exposure of a heated mixture of kaolin, soda, and sulphur, to a damp atmosphere, or treatment of the same with liver of sulphur (Abstr., 1886, 306). The various conditions necessary for success are discussed in full, such as the degree of aggregation of the liver of sulphur and the form of silicate or silica used. Thus experiments with quartz were unsuccessful, and those with silicic acid jelly from soluble glass led to the production of a bluish-green material, which turned to a deep blue on warming. Pure alumina led to no result, but sodium aluminate gave a very satisfactory product. Salts of sodium, such as the thio-sulphate, or even calcium phosphate, produced very fine specimens of ultramarine-blue.

V. H. V.

**Sodium Dichromate.** By A. STANLEY (*Chem. News*, 54, 194—196).—Sodium dichromate crystallises with 2 mols.  $H_2O$ , in prisms and plates belonging to the triclinic system; its sp. gr. is 2.5246 at 13°; it is deliquescent. It loses 1 mol.  $H_2O$  below 75°, and all below 100°, leaving a light brown, anhydrous salt, which fuses to a transparent dark red liquid at 320°, and on cooling crystallises in the same forms as the hydrated salt. When treated with water, the anhydrous salt causes a rise, and the hydrated salt a fall in temperature. 100 parts of the saturated aqueous solution contain—

|                     |       |       |       |       |       |       |
|---------------------|-------|-------|-------|-------|-------|-------|
| Temperature..       | 0°    | 15°   | 30°   | 80°   | 100°  | 139°  |
| Parts $Na_2Cr_2O_7$ | 107.2 | 109.2 | 116.6 | 142.8 | 162.8 | 209.7 |

The saturated solution boils at 139°. A table of the sp. gr. of solutions of various strengths is given. Sodium dichromate is insoluble in ether, slightly soluble in alcohol. It is very hygroscopic, in 48 hours an exposed sample absorbed one-third its weight of water; a sample of calcium chloride under similar circumstances absorbed

nearly its own weight of water. It decomposes slightly above its melting point, and at a dull red heat leaves sodium chromate and chromic oxide. In its reactions generally it resembles potassium dichromate.

By dissolving the dichromate in warm aqueous chromium trioxide, the trichromate separates on cooling in dark red crystals; these are very soluble in water, and are deliquescent.

By the action of sodium dichromate on freshly prepared cupric hydroxide, a brown powder is formed, consisting of microscopic crystals of the composition  $\text{Na}_2\text{CrO}_4, \text{CuCr}_2\text{O}_7, 2\text{CuO} + 4\text{H}_2\text{O}$ . It is almost insoluble in water, and but slightly soluble in alcohol. It loses all its water below  $100^\circ$ , and partially decomposes at higher temperatures, cupric oxide separating.

Magnesium sodium chromate, prepared by neutralising sodium dichromate with magnesia, crystallises with 3 mols.  $\text{H}_2\text{O}$ , in yellow four-sided prisms and plates. It is soluble in water and alcohol, but insoluble in ether. The 3 mols.  $\text{H}_2\text{O}$  are driven off below  $200^\circ$ , leaving a dark reddish-brown powder, which fuses at a red heat with partial decomposition.

D. A. L.

**Reduction of Inorganic Thio-salts by Hydrogen.** By G. KRÜSS and H. SOLEREDER (*Ber.*, 19, 2729—2739).—By the reduction of molybdothio-salts by hydrogen at a red heat, salts of a lower molybdosulphide could not be obtained; potassium thiomolybdate and ammonium dithiomolybdate are gradually reduced to a mixture of molybdenum and potassium sulphide and to molybdenum. In the case of ammonium dithiomolybdate, no oxysulphide could be obtained.

Potassium thallium sulphide,  $\text{K}_2\text{Tl}_2\text{S}_4$ , behaves in a similar manner, being reduced to potassium sulphide and thallium.

The salts of such thio-acids as remain unchanged in a current of hydrogen are not reduced; for example:  $\text{K}_2\text{S}, 3\text{ZnS}$ ;  $\text{K}_2\text{S}, 3\text{CdS}$ , &c. If the thio-acid is merely reduced to a lower stable sulphide, the corresponding thio-salt yields also the lower sulphide or its thio-salt in the case of its having the properties of a thio-acid. Examples:  $\text{K}_2\text{S}, 3\text{Cu}_2\text{S}, \text{Cu}_2\text{S}_2$ ,  $\text{K}_2\text{S}, \text{Fe}_2\text{S}_3$ .

N. H. M.

**Atomic Weight of Tungsten.** By J. WADDELL (*Amer. Chem. J.*, 8, 280—288).—Scheelite was decomposed by nitric acid, and the impure tungsten trioxide freed from silica as follows:—The mixture is fused with an equal weight of hydrogen potassium sulphate until in a state of limpid fusion; the cool mass is digested with water and filtered; water containing ammonium carbonate must be used for the further washing to keep the fluid from running through turbid, and to assist in the solution of the tungstate. If the silica is to be estimated it will probably require a second fusion, &c., with acid potassium sulphate. Another method of separating tungstic acid and silica is by means of ammonia, but here also the extraction is apt to be incomplete. Commercial metallic tungsten is but slowly attacked by acids, it cannot be fused with nitre without attacking the crucible, and is therefore best oxidised by a current of air at a red heat. The product is fused with sodium carbonate, and after dissolution

filtered from unoxidised material. The filtrate boiled with ammonium carbonate gave a small precipitate of alumina. To remove molybdenum, tartaric acid is added (half the weight), then hydrochloric acid (no tungstic acid is precipitated), and sulphuretted hydrogen passed. The blue filtrate is decolorised by a current of air, and the tungsten separated in 11 fractions by boiling with hydrochloric acid. Fractions 3, 7, and 10 were purified for determination of the atomic weight by solution in ammonia, reprecipitation by hydrochloric acid, and roasting of the precipitate in a current of air. The analysis was effected by heating gradually in a current of hydrogen, using a porcelain boat and tube, and a Fletcher's blast furnace. No. 3 gave  $W = 184.50$ , No. 7  $184.00$ , and No. 10  $183.67$ , when  $O = 16$ . The first number is to be considered most accurate, namely,  $W = 184.50$ ,  $O = 16$ ; or  $W = 184.64$ ,  $O = 15.96$ . The specific gravity of this sample of metal is  $18.77$ . H. B.

**Compounds of Gold and Nitrogen.** By F. RASCHIG (*Annalen*, 235, 341—368).—*Aurous oxide*,  $Au_2O$ , is most conveniently prepared by boiling a solution of mercurous nitrate with an excess of auric chloride, as described by Figuier (*Ann. Chim. Phys.* [3], 11, 336). The precipitate dried over phosphoric anhydride contains 2 mols.  $H_2O$ . When strong ammonia is added to water containing aurous oxide in suspension, a black explosive powder,  $NAu_3.NH_3$ , is obtained. Boiling with water, or with dilute acids, converts the *sesqui-auroamine* into *triauramine*,  $NAu_3$ . Methylamine also acts on aurous oxide, forming *diauromethylamine*,  $NMeAu_2$ . This compound also loses half its nitrogen when boiled in water for 15 minutes. Gold monoxide,  $AuO$ , was first obtained in a pure state by Schottländer (*Abstr.*, 1883, 853). It is converted by strong ammonia into the very explosive compound *sesquihydraurylamine*,  $NH_3.N(AuOH)_3$ . Warm hydrochloric acid dissolves two-thirds of the gold, but one-third is left in the metallic state. On boiling with water, half the nitrogen is expelled, and *trihydraurylamine* remains. Methylamine unites with gold monoxide, forming the compound  $MeN(AuOH)_2$ ; this loses half its nitrogen in the form of methylamine when boiled in water. The author confirms the accuracy of Damas's formula,  $(AuN + NH_3)_2 + 3H_2O$ , for the fulminating gold prepared by the action of ammonia on auric oxide,  $Au_2O_3$ ; but he proves that the substance which is precipitated by ammonia from a solution of auric chloride is a mixture of the preceding compound and *auric imidochloride*,  $NH:AuCl$ . The latter compound is obtained in an impure state when a few drops of ammonia are added to a large excess of auric chloride. Only a portion of the chlorine can be removed by digestion with ammonia.

Fulminating gold is slowly attacked by boiling water, losing ammonia. Boiling with nitric acid renders the compound more explosive. Dilute sulphuric acid does not liberate ammonia, but forms a very explosive substance of the composition  $(AuN_2H_3)_4.H_2SO_4$ .

The constitution of auric diamine is represented by the formula  $NH_2Au:NH$ . The decomposition it undergoes when boiled with water is probably  $2NH_2AuNH = NH:AuN : AuNH_2 + NH_3$ .

Methylamine yields a yellow precipitate with auric chloride, soluble

in an excess of the reagent. On warming the solution, a brown precipitate which contains a large quantity of chlorine is deposited. Auric oxide yields a red compound with methylamine.

W. C. W.

**Complex Inorganic Acids.** By W. GIBBS (*Amer. Chem. J.*, 8, 289—290).—Compounds have been obtained comparable with the chlorplatinophosphoric acids of Schutzenberger. These compounds are to be regarded as phosphoric acid in which one atom of oxygen is replaced by platinous chloride, bromide or oxide, or the corresponding compounds of palladium, iridium, ruthenium, and osmium. Moreover the phosphorus may be replaced by arsenic or antimony. The following formulæ are given to the compounds so far studied:—

H. B.

**Roseo-rhodium Salts.** By S. M. JÖRGENSEN (*J. pr. Chem.* [2], 34, 394—406; compare *Abstr.*, 1883, 1058).—*Roseo-rhodium nitrate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})(\text{NO}_3)_6$ , is obtained by adding moderately dilute nitric acid to a concentrated solution of roseo-rhodium hydroxide, when it separates as a white precipitate consisting of microscopic, quadratic tables. It loses 2 mols. of water at  $100^\circ$ , and is converted into nitratopurpureo-rhodium nitrate. It is easily soluble in water.

*Roseo-rhodium platinochloride nitrate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})(\text{NO}_3)_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , is obtained as a beautiful, orange-yellow, crystalline precipitate on adding hydrogen platinochloride to a solution of the nitrate. It easily loses 2 mols. of water at  $100^\circ$ , the other 2 mols. are given off more slowly, and nitratopurpureo-rhodium platinochloride is formed; on treating this with dilute hydrochloric acid all the platinum is dissolved, leaving white nitratopurpureo-rhodium chloride undissolved. A solution of the latter in water gives with sodium dithionate a precipitate of the characteristic nitratopurpureo-dithionate.

*Roseo-rhodium bromide*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})\text{Br}_6$ , is prepared by adding concentrated hydrogen bromide to a solution of roseo-rhodium hydroxide. It forms a crystalline powder consisting of small octohedrons or six-sided tables. At  $100^\circ$ , it loses 2 mols.  $\text{H}_2\text{O}$  and is converted into the bromopurpureo-bromide. It is easily soluble in cold water, and its aqueous solution gives the same reactions as the nitrate.

*Roseo-rhodium sulphate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})(\text{SO}_4)_3 + 2\text{H}_2\text{O}$ , is prepared by saturating the hydroxide with dilute sulphuric acid, and precipitating with alcohol. It forms a white precipitate of very small octohedral crystals. In contrast to the other roseo-rhodium salts, it is not converted into the purpureo-salt by solution in boiling water; it crystallises in large, quadratic prisms, terminated by a quadratic pyramid, apparently isomorphous with roseocobalt sulphate. At  $100^\circ$ , it quickly loses 4 mols.  $\text{H}_2\text{O}$ , and then more slowly another  $\frac{1}{2}$  mol., undergoing a similar change to the analogous roseocobalt salt, form-

ing luteo-salts. An aqueous solution gives all the reactions of the nitrate; with potassium iodide, it gives a white precipitate, consisting of microscopic octohedrons of the *roseoiodide sulphate*,

*Roseo-rhodium platinochloride sulphate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})\text{PtCl}_6(\text{SO}_4)_2$ , is obtained as a beautiful, silky, buff precipitate of very thin six-sided tables, by adding a solution of hydrogen platinochloride to a cold solution of the roseo-sulphate. It seems to be isomorphous with the corresponding roseo- and luteo-salts of cobalt and chromium.

*Roseo-rhodium orthophosphate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})(\text{PO}_4\text{H})_3 + 4\text{H}_2\text{O}$ , is prepared by adding a 10 per cent. solution of phosphoric acid to a concentrated solution of the hydroxide. It forms a white, crystalline powder which behaves like the corresponding cobalt salt.

*Sodium roseo-rhodium pyrophosphate*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})_2\text{P}_2\text{O}_7\text{Na} + 23\text{H}_2\text{O}$ , is obtained by adding sodium pyrophosphate to a solution of the hydroxide in dilute hydrochloric acid until the amorphous precipitate at first formed is redissolved; on shaking, the salt then separates as a silky, white crystalline precipitate. It agrees in all respects with the cobalt salt.

*Roseo-rhodium cobalticyanide*,  $(\text{Rh}_2, 10\text{NH}_3, 2\text{H}_2\text{O})\text{CO}_2\text{Cy}_{12}$ , is obtained as small pale-yellow crystals on adding a solution of potassium cobalticyanide to the hydroxide, neutralised with dilute sulphuric acid.

G. H. M.

**Nitratopurpureo-rhodium Salts.** By S. M. JÖRGENSEN (*J. pr. Chem.* [2], **34**, 40(—109).—*Nitratopurpureo-rhodium nitrate*,

is easily obtained by heating the roseonitrate or by dissolving this salt in hot water, adding an equal volume of concentrated nitric acid, heating the mixture for some time on the water-bath and then allowing it to cool, when the salt separates in small, octohedral, white crystals with a greenish-yellow tinge. Heated over a flame, the salt explodes. It is only slightly soluble in water.

*Nitratopurpureo-rhodium chloride*,  $(\text{NO}_3)_2(\text{Rh}_2, 10\text{NH}_3)\text{Cl}_4$ , is obtained as a pale greenish-yellow precipitate on filtering a cold solution of the nitrate into an ice-cold mixture of 3 vols. hydrochloric acid and 1 vol. water. An aqueous solution gives all the reactions of the nitrate.

*Nitratopurpureo-rhodium dithionate*,  $(\text{NO}_3)_2(\text{Rh}_2, 10\text{NH}_3)(\text{S}_2\text{O}_6)_2 + 2\text{H}_2\text{O}$ , is prepared by precipitating a cold saturated solution of the nitrate or chloride with sodium dithionate. It forms white, silky X-shaped aggregations resembling the corresponding cobalt salt. The air-dried salt loses all its water at  $100^\circ$ . It is quite insoluble in water.

G. H. M.

**Xantho-rhodium Salts.** By S. M. JÖRGENSEN (*J. pr. Chem.* [2], **34**, 410—423).—*Xantho-rhodium nitrate*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH})(\text{NO}_3)_4$ , is prepared by dissolving the chloropurpureochloride in dilute sodium hydroxide on the water-bath, and then adding pure sodium nitrite and dilute nitric acid; the salt separates as a white, crystalline powder which can be recrystallised from hot water. Heated over a flame, the

salt explodes and leaves a voluminous residue of rhodium. The xanthonitrate is fairly soluble in cold, easily in hot water; insoluble in alcohol. Its aqueous solution, unlike that of the nitratonitrate, is not converted into the roseonitrate by boiling. It is also unacted on by sodium hydroxide, ammonium sulphide, &c.

*Xantho-rhodium chloride*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)\text{Cl}_4$ , is prepared in the same way as the nitrate, adding dilute hydrochloric acid, however, instead of nitric acid after the sodium nitrite, when the salt separates as a white powder; or from the nitrate, by filtering a concentrated solution of the latter into dilute hydrochloric acid, the addition of alcohol then throws down a yellowish-white precipitate of small octahedrons. When heated, the salt is decomposed, and leaves a residue of pure rhodium. Treated with silver oxide and water, the chloride yields a solution of *xantho-rhodium hydroxide*, which behaves as a strong alkali.

*Xantho-rhodium platinochloride*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)(\text{PtCl}_6)_3$ , is obtained as a buff-coloured precipitate consisting of microscopic needles by adding hydrogen platinochloride to a solution of the nitrate. This salt is analogous to the corresponding cobalt and chromium salts.

*Xantho-rhodium bromide*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)\text{Br}_4$ , is obtained as a white, crystalline precipitate on adding concentrated hydrobromic acid to a cold solution of the nitrate. It is easily soluble in water, and the solution gives all the reactions of the nitrate.

*Xantho-rhodium dithionate*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)(\text{S}_2\text{O}_6)_2 + 2\text{H}_2\text{O}$ , is prepared by filtering a cold solution of the nitrate into an excess of sodium dithionate. It forms a white, crystalline precipitate consisting of microscopic prisms. It loses all its water at  $100^\circ$ .

*Xantho-rhodium sulphates* are prepared by treating the chloride with strong sulphuric acid, &c. (a) The normal salt,

crystallises in flat, brilliant, needles many centimetres long. It may also be obtained by precipitating a solution of the acid salt with alcohol. The salt explodes on heating. With a solution of iodine in potassium iodide, it yields a periodide.

(b) The acid salt,  $2[(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)(\text{SO}_4)_2] \cdot (\text{H}_2\text{SO}_4)_3$ , crystallises in long, white needles. The salt decomposes quietly on heating, leaving the rhodium in pseudomorphs of the crystals.

*Xantho-rhodium silicofluoride*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)(\text{SiF}_6)_3$ , is obtained as a snow-white, silky precipitate on adding a cold solution of the nitrate to an excess of hydrofluosilicic acid. Under the microscope, it consists of small rhombic tables resembling the chloropurpureo-rhodium silicofluoride. Dilute nitric acid decomposes it, forming the nitrate and free acid.

*Xantho-rhodium oxalate*,  $(\text{NO}_2)_2(\text{Rh}_2, 10\text{NH}_3)(\text{C}_2\text{O}_4)_3$ , is obtained as a white precipitate consisting of microscopic prisms, by adding a solution of the nitrate to excess of ammonium oxalate. Nitric acid decomposes it in the same way as the silicofluoride.

The roseo- and purpureo- as well as the xantho-salts of rhodium show a most unmistakable resemblance to those of cobalt and chromium. The xantho-rhodium salts are, however, much more stable

than those of cobalt and chromium. The nitrate is especially so, showing that the xantho-salts are really nitritopurpureo-salts. The great stability of the nitrate is partly accounted for by the nature of the metal, and also probably partly by the fact that pentad nitrogen is combined with pentad nitrogen, thus:—

G. H. M.

## Mineralogical Chemistry.

**Twin Crystal of Molybdenite.** By W. E. HIDDEN (*Amer. J. Sci.*, 32, 210).—This crystal was found near Renfrew, Canada, with other remarkable crystals, some of which weighed nearly a pound. The method of twinning seems to prove that molybdenite should be referred to the hexagonal system.

B. H. B.

**Limonite-pseudomorphs after Iron Pyrites.** By J. G. MEEM (*Amer. J. Sci.*, 32, 274—276).—These limonite pseudomorphs are found near Lexington, Rockbridge Co., Virginia, occurring in the soil. In colour they vary from light-brown to almost black. Most of the crystals have undergone a complete alteration, there being no iron pyrites visible to the naked eye. In some, the unaltered iron pyrites is found forming a nucleus at the centre, in others it forms the bulk of the crystal. The most common form of these pseudomorphs is the octahedron; this generally occurs combined with the cube. On nearly all the octahedral faces, striations running at right angles to the edges of these faces are observed. (Compare Abstr., 1886, 992.)

B. H. B.

**Brookite from Magnet Cove, Arkansas.** By E. S. DANA (*Amer. J. Sci.*, 32, 314—317).—S. L. Penfield (Abstr., 1886, 989) described a crystal of brookite of unusual form, from Magnet Cove. The author has studied the large series of brookite crystals from this locality in the collection of C. S. Bement. The planes he has determined on these crystals are as follows:—Pinacoids,  $\infty P\infty$ ,  $0P$ ; prisms,  $\infty P^2$ ,  $\infty P$ ,  $\infty P^2$ , new; brachydome,  $2P\infty$ ; pyramids,  $\frac{1}{2}P$ ,  $\frac{1}{2}P^2$ ,  $\frac{3}{4}P^{\frac{3}{2}}$ ,  $1P^2$ .

B. H. B.

**Turquoise from New Mexico.** By F. W. CLARKE and J. S. DILLER (*Amer. J. Sci.*, 32, 211—217).—At Los Cerillos, New Mexico, about 22 miles south-west of Santa Fé, are mines of turquoise which have been worked for centuries. The turquoise has never been fully analysed. It occurs buried in its matrix, sometimes in nodules, often in veins. It varies in colour from pure sky-blue to dark-green. For analyses, three typical samples were selected—1, bright blue, faintly translucent; 2, pale-blue, opaque, earthy, sp. gr. 2.805; 3, dark-green, opaque. The results were as follows:—

| H <sub>2</sub> O. | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | P <sub>2</sub> O <sub>5</sub> . | CuO. | SiO <sub>2</sub> . | CaO. | Total. |
|-------------------|----------------------------------|----------------------------------|---------------------------------|------|--------------------|------|--------|
| 19·80             | 39·53                            |                                  | 31·96                           | 6·30 | 1·15               | 0·13 | 98·87  |
| 19·60             | 36·88                            | 2·40                             | 32·86                           | 7·51 | 0·16               | 0·38 | 99·79  |
| 18·49             | 37·88                            | 4·07                             | 28·63                           | 6·56 | 4·20               | —    | 99·83  |

In discussing these results, it is advisable to compare them with the figures given by Church for the Persian variety (*Chem. News*, 10, 290), and with those given by Moore (Abstr., 1885, 958) for Californian turquoise, pseudomorphous after apatite. These analyses, ignoring the dark-green variety (3), agree well with each other in their atomic ratios. The turquoise is shown by these analyses to be a variable mixture of the salts, 2Al<sub>2</sub>O<sub>3</sub>, P<sub>2</sub>O<sub>5</sub>, 5H<sub>2</sub>O, and 2CuO, P<sub>2</sub>O<sub>5</sub>, 4H<sub>2</sub>O. The former formula may be regarded as that of normal turquoise, and may be within Al<sub>2</sub>HPO<sub>4</sub>(OH)<sub>4</sub>. The copper salt to which the mineral owes its colour is to be considered as an impurity, a view confirmed by the analysis of the dark-green variety (3).

A microscopic study of the turquoise indicates that the mineral may have been derived from the alteration of another substance (apatite) with which the vein was formerly filled. The turquoise-bearing rock appears to be eruptive, and probably of tertiary age. Under the microscope, it is seen to be composed of felspar, with a considerable amount of biotite, epidote, iron pyrites, limonite, and some amorphous substance.

B. H. B.

**A Remarkable Crystal of Herderite.** By W. E. HIDDEN (*Amer. J. Sci.*, 32, 209).—This crystal was found at the locality near Stoneham, Maine (Abstr., 1884, 827, 1102). Excepting 3P2, ∞P2̄, and ∞P3̄, all the planes observed in the American crystals occur on this crystal, and one new plane, P∞, is seen to be present. The crystal has a diameter of 25 mm., and in point of size and perfection is unequalled. The planes occurring are 13 in number, with several others slightly indicated. The mean index of refraction for this species for yellow rays is found by Des Cloizeaux to be 1·609.

B. H. B.

**Pseudomorphs of Garnet.** By S. L. PENFIELD and F. L. SPERRY (*Amer. J. Sci.*, 32, 307—311).—Pseudomorphs of garnet occur in abundance in a bed of chloritic schist overlying the great magnetite bed of the Spurr-Michigamme iron range. The crystals are invariably dodecahedral, varying in sp. gr. from 4·11 to 3·22; the heaviest crystals being nearly pure garnet, and the lightest ones almost wholly the decomposition product. Analysis of the garnet and of the decomposition products gave the following results:—

|      | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO.  | MnO. | MgO. | CaO. |
|------|--------------------|----------------------------------|----------------------------------|-------|------|------|------|
| I.   | 38·03              | 20·83                            | —                                | 36·15 | 2·14 | 0·97 | 2·73 |
| II.  | 27·45              | 19·53                            | 6·26                             | 29·42 | —    | 6·04 | —    |
| III. | 29·08              | 19·94                            | 3·91                             | 30·48 | 0·20 | 5·56 | 0·25 |

|      | Na <sub>2</sub> O. | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|------|--------------------|-------------------|-------------------|--------|
| I.   | —                  | —                 | —                 | 100·85 |
| II.  | 0·42               | 2·64              | 7·50              | 99·26  |
| III. | 0·29               | 3·66              | 6·53              | 99·90  |

I, pure garnet; II, decomposition product from a crystal having a sp. gr. of 3.281; III, the same from a crystal having a sp. gr. of 3.22. The decomposition product appears to be closely related to Sandberger's aphrosiderite. The material in which the garnets are embedded is a ferriferous chlorite, differing from the alteration product of the garnet, and agreeing closely with thuringite.

The pseudomorph garnets from Salida, Chaffee Co., Colorado, differ from the Lake Superior garnets in that the decomposition product forms only a coating, whilst the interior of the crystal is quite homogeneous. The following are analyses (I) of the pure garnet, sp. gr. 4.163, and (II) of the decomposition product, after deducting 1.04 per cent. of garnet:—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO.  | MnO. | MgO.  | CaO. |
|-----|--------------------|----------------------------------|-------|------|-------|------|
| I.  | 37.61              | 22.70                            | 33.83 | 1.12 | 3.61  | 1.44 |
| II. | 28.20              | 22.31                            | 19.11 | —    | 17.68 | 0.48 |

|     | Na <sub>2</sub> O. | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|-----|--------------------|-------------------|-------------------|--------|
| I.  | —                  | —                 | —                 | 100.31 |
| II. | 0.72               | 1.03              | 10.90             | 100.43 |

The changes which have been previously noted in garnet, differ from those described by the authors, in that they have been the alteration of pyrope into ripidolite or serpentine-like magnesium silicates.

B. H. B.

**Phenacite from Colorado.** By W. E. HIDDEN (*Amer. J. Sci.*, 32, 210—211).—Since the original announcement of the discovery by the author, of phenacite at Florissant (Abstr., 1885, 878), many additional crystals have been found; the best of them being sent to Professor Des Cloizeaux for examination. He observed 12 planes, amongst which  $\frac{1}{2}P2$  is new for this species.

B. H. B.

**North Carolina Mineral Localities.** By W. E. HIDDEN and A. DES CLOIZEAUX (*Amer. J. Sci.*, 32, 204—208).—*Spodumene* has been discovered in Sharpe's Township, Alexander Co. Physically the emerald-green spodumene (hiddenite) found, is identical with the yellow spodumene (triphane) of Brazil. The three indices of refraction were found to be:  $\alpha = 1.677$ ;  $\beta = 1.669$ ;  $\gamma = 1.651$  for yellow rays.

*Black tourmaline*, noteworthy from the brilliancy and number of the planes presented, occurs at the same locality. Twelve planes have been identified.

*Xenotime* was discovered about 3 miles east of the Emerald and Hiddenite Mine, in Alexander Co. The colour of the crystals is hair-brown, and some of them are perfectly transparent. Sp. gr. 4.45 to 4.52. The cleavage is prismatic, and the habit long prismatic.

*Twin crystals of monazite* occur with the xenotime. Few finer examples of this rare mineral have ever been found. The crystals are transparent, red, and highly polished. They vary in size from 4 to 20 mm. in length and thickness. They are prismatic from an unusual extension of + P and + P $\infty$ . A distinct but imperfect cleavage parallel to the clinopinacoid was observed on several crystals, whilst

the common basal cleavage was absent. The fact that common monazite is described as having perfect basal cleavage suggests that the difference may be due to the thorium silicate often present as an impurity.

*Quartz crystals with basal plane.*—Genuine basal planes are of very rare occurrence in the so-called basal-plane quartz crystals from North Carolina. In most cases, the planes observed have been produced by compression or juxtaposition, and when carefully measured do not meet the requirements.

B. H. B.

**Mica from Leon Co., Texas.** By G. W. LEIGHTON (*Amer. J. Sci.*, 32, 317—318).—This mica attracted notice, as it presents characters intermediate between those of the vermiculites and the muscovites. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | MgO. | CuO.  | Na <sub>2</sub> O. | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|--------------------|----------------------------------|----------------------------------|------|-------|--------------------|-------------------|-------------------|--------|
| 48.95              | 25.17                            | 9.40                             | 1.69 | trace | trace              | 11.08             | 4.31              | 100.60 |

This composition agrees very closely with that of the mica from Hirschburg. It appears to be an early stage in the alteration of muscovite to vermiculite.

B. H. B.

**Ceriferous Hainstadt Clays.** By J. R. STROHECKER (*Chem. News*, 54, 207—208).—The author replies to the criticisms of Blomstrand and of Schertel (*Abstr.*, 1886, 678) and re-affirms the correctness of his statements (*Abstr.*, 1886, 314, 424) as to the presence of the cerium metals in these clays.

**Crystalline Structure of Iron Meteorites.** By O. W. HUNTINGTON (*Amer. J. Sci.*, 32, 284—303).—From an exhaustive study of the very large collection of meteorites at Harvard College, the author concludes that many of the masses of meteoric iron now known are cleavage crystals, broken off probably by the impact of the mass against the atmosphere. These masses show cleavages parallel to the planes of all the three fundamental forms of the isometric or regular system. The Widmanstätten figures and Neumann lines are sections of planes of crystalline growth parallel to the same three fundamental forms of the isometric system. On different sections of meteorites, Widmanstätten figures and Neumann lines can be exhibited in every degree with no break where a natural line of division can be drawn. The features of the Widmanstätten figures are due to the elimination of incompatible material during the process of crystallisation.

The results of this investigation confirm the theory that the process of crystallisation must have been very slow; the most probable theory of the origin of meteorites seems to be that these masses were thrown off from a sun among the fixed stars, and that they were slowly cooled, while revolving in a zone of intense heat.

B. H. B.

**New Meteoric Iron from Texas.** By W. E. HIDDEN (*Amer. J. Sci.*, 32, 304—306).—This meteorite was found in 1882, in Maverick Co., Texas. It weighs 97½ lbs., and measures 12 by 10 by 6 inches

in its three diameters; its shape being a nearly symmetrical ovoid, somewhat flattened. The surface is quite smooth, and coated with the usual thin black crust. When a small surface is etched a peculiar appearance was presented. There are no Widmanstätten figures, except in traces. There are, however, two series of fine lines, crossing each other at angles of  $70^\circ$  and  $110^\circ$ , which the author concludes to be due to twinning lamellæ. The metal is of unusual whiteness, and is very soft. Analysis gave the following results:—

| Fe.     | P.   | Ni + Co. | Total. | Sp. gr. |
|---------|------|----------|--------|---------|
| 94.90   | 0.23 | (4.87)   | 100.00 | 7.522   |
| B. H. B |      |          |        |         |

**Meteoric Iron from Glorieta Mt., New Mexico.** By G. F. KUNZ (*Amer. J. Sci.*, **32**, 311—313).—Since the publication of the account of the three masses of meteoric iron from Glorieta Mt. (Abstr., 1886, 321), three more masses of the meteorite have been found by J. H. Bullock, and a small piece was found by a Mexican, but it disappeared before it could be secured. Seven fragments have thus far been obtained. No. 4 weighs 2.65 lbs.; No. 5, 2.48 lbs.; and No. 6, 2.31 lbs. All these fragments are figured and described by the author.

A meteorite was recently presented to the Colorado Scientific Society by the Boston and Colorado Silver Mining Company, who received it from Albuquerque, New Mexico, as silver bullion. Its weight before cutting was about 5 lbs. An analysis of the iron gave the following results:—

| Fe.   | Ni.  | Co.  | Cu.  | Zn.  | C.   | P.   | S.   | Si.  | Total. |
|-------|------|------|------|------|------|------|------|------|--------|
| 88.76 | 9.86 | 0.51 | 0.03 | 0.03 | 0.41 | 0.18 | 0.01 | 0.04 | 99.83  |

The striking similarity between this analysis and that of the Glorieta meteorite, leads the author to believe that this iron is the seventh fragment of the meteorite found by the Mexican, and mistaken by him for silver bullion.

B. H. B.

**Two hitherto undescribed Meteoric Stones.** By E. S. DANA and S. L. PENFIELD (*Amer. J. Sci.*, **32**, 226—231).—1. *Meteorite from Utah.*—This was found in 1869, in the prairie between Salt Lake City and Echo, and is now in the Yale collection. Its weight is 875 grams. It is oblong in shape, about 12 cm. long, and 9 cm. in its greatest width. The surface is comparatively smooth; the colour of the crust being reddish-black. The interior of the stone is of a dark bluish-grey colour, distinctly mottled by its chondritic character, and showing a rather large proportion of iron irregularly distributed through it, with minute patches of troilite. Olivine is the most prominent constituent. Bronzite appears in irregular crystal fragments scattered through the mass, and plagioclase feldspar is sparingly present in crystalline fragments. The sp. gr. of the meteorite was found to be 3.66. Analysis gave 17.16 per cent. of nickeliferous iron, and 82.84 per cent. of the mineral part, including the troilite and silicates. The iron gave on analysis—

| Fe.   | Ni.  | Co.  | Cu.  | Total. |
|-------|------|------|------|--------|
| 91.32 | 8.04 | 0.60 | 0.04 | 100.00 |

The mineral portion was divided into:—Soluble in hydrochloric acid; troilite, 6.70 per cent. with 0.62 of NiS; silicates, 48.85 per cent. Insoluble in hydrochloric acid, including chromite, 43.97. Water, 1.14. Total, 100.66.

Analyses of the soluble (I) and insoluble (II) portions gave:—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO.  | MgO.  | CaO. | Na <sub>2</sub> O. |
|-----|--------------------|----------------------------------|-------|-------|------|--------------------|
| I.  | 40.33              | 0.51                             | 21.33 | 35.15 | 1.66 | 0.33               |
| II. | 54.83              | 4.82                             | 8.64  | 24.56 | 3.34 | 1.98               |

|     | K <sub>2</sub> O. | P <sub>2</sub> O <sub>5</sub> . | Chromite. | Total. |
|-----|-------------------|---------------------------------|-----------|--------|
| I.  | 0.04              | 0.65                            | —         | 100.00 |
| II. | 0.12              | —                               | 1.71      | 100.00 |

The composition of the insoluble part implies that it is made up of bronzite with a little plagioclase. The Chantonay meteorite seems to bear the closest resemblance to the new stone.

2. *Meteorite from Cape Girardeau, Missouri.*—This stone fell at 3 P.M., on August 14, 1846, accompanied by a loud report. It became the property of the Yale Museum several years ago. The stone in the museum consists of two parts fitted together, and weighing together 2058 grams. The general shape of the stone is roughly rectangular, with dimensions of 12 by 10 by 10 cm. The surface is smooth, and, where fresh, is of a light grey colour. The metallic particles are scattered uniformly through the mass. The chondritic character is distinct. The sp. gr. of the stone was found to be 3.67. The analysis showed a relation of native iron to troilite and silicates very near that of the Utah meteorite, namely, 17.90 to 82.10 per cent. The iron gave on analysis—

| Fe.   | Ni.  | Co.  | Cu.  | Total. |
|-------|------|------|------|--------|
| 91.93 | 7.39 | 0.63 | 0.05 | 100.00 |

The analysis of the mineral portion gave:—Soluble in hydrochloric acid: troilite, 6.95; silicates, 42.68. Insoluble in hydrochloric acid, including chromite, 50.19. Water, 0.58. Total 100.40. The soluble (I) and insoluble (II) parts gave—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO.  | MgO.  | CaO. | Na <sub>2</sub> O. |
|-----|--------------------|----------------------------------|-------|-------|------|--------------------|
| I.  | 36.32              | —                                | 22.31 | 40.23 | —    | 0.28               |
| II. | 55.79              | 5.54                             | 7.91  | 23.65 | 3.35 | 1.85               |

|     | K <sub>2</sub> O. | P <sub>2</sub> O <sub>5</sub> . | Chromite. | Total. |
|-----|-------------------|---------------------------------|-----------|--------|
| I.  | 0.04              | 0.82                            | —         | 100.00 |
| II. | 0.24              | —                               | 1.67      | 100.00 |

The insoluble part is evidently bronzite, with some felspar. The stone belongs to the light grey chondrite type of meteorites.

B. H. B.

## Organic Chemistry.

**Methods for Determining the Relative Stability of the Alkyl Bromides.** By I. REMSEN and H. W. HILLYER (*Amer. Chem. J.*, **8**, 251—262).—The bromides in molecular proportion were treated in alcoholic solution with the several reagents, and the hydrobromic acid formed estimated by silver nitrate solution with ferric thiocyanate as indicator. The relative results are embodied in the following table, Column I showing the action of zinc and dilute sulphuric acid; II, the action of cobalt-zinc couples and acetic acid; III and IV, the action of alcoholic soda under certain conditions; V, the action of cobalt-zinc couples in presence of soda, but after deducting the action of the soda itself; VI, that of ammonia; and VII, that of silver nitrate or acetate. The action of sodium amalgam is unsatisfactory, owing to the constant variation of the alkalinity of the solution, and the authors believe that the best results are to be obtained by the action of caustic soda or ammonia, or of silver salts.

H. B.

**Derivatives of Diethylene Bisulphide.** By W. MANSFIELD (*Ber.*, **19**, 2658—2668).—In continuation of former work (*Abstr.*, 1886, 525), other derivatives of diethylene bisulphide,  $C_4H_8S_2$  (compare Masson, *Trans.*, 1886, 234), are described.

The methiodide,  $C_4H_8S_2MeI$ , is converted by silver chloride into the corresponding chlorine compound, a crystalline substance melting at  $225^\circ$ ; it yields crystalline precipitates with platinic, mercuric, and auric chlorides. With moist silver oxide, the methiodide yields the corresponding hydroxide,  $C_4H_8S_2Me\cdot OH$ , the solution of which possesses well-marked basic properties, absorbs carbonic anhydride, and precipitates solutions of the heavy metals. The salts obtained by its neutralisation with acids are exceedingly deliquescent; the most stable is the picrate, which crystallises in golden needles melting at  $192$ — $193^\circ$ . The dimethiodide,  $C_4H_8S_2\cdot 2MeI$ , melts at  $207$ — $208^\circ$ , and yields a corresponding chloro-derivative, which gives precipitates with the chlorides of the platinum-group of metals. In the course of the preparation of the dimethiodide, a periodide of the composition  $C_4H_8S_2MeI\cdot I_2$  is obtained, which melts at  $92$ — $93^\circ$ , and crystallises in the monoclinic system ( $a : b : c = 0.89 : 1 : 0.67$ ).

Experiments made with a view of obtaining the hydroxides by

evaporation of their aqueous solutions were unsuccessful; an oil of composition  $C_5H_{10}S_2$  was formed (to this substance Masson ascribes the formula  $C_{12}H_{24}S_5$ , *ibid.*, 247). The author considers that this compound is derived from dithioglycocine by the displacement of both sulphhydryl hydrogen-atoms by the methyl and vinyl groupings respectively, thus,  $SM\cdot C_2H_4\cdot S\cdot CH:CH_2$ ; and in accordance with this view it is shown that the compound takes up four atoms of bromine. Diethylene bisulphide combines readily with benzyl halogen compounds; thus with the bromide it forms a substance,  $C_4H_8S_2\cdot C_7H_7\cdot Br$ , which melts at  $146^\circ$ , and crystallises in the rhombic system. The corresponding iodine compound crystallises in pale yellow needles, decomposing when heated at  $145^\circ$ , and the chlorine compound in colourless needles melting at  $143^\circ$ . On heating the above bromine compound with alkalis, an oil of the composition  $C_{11}H_{24}S_2$  is produced.

V. H. V.

**Disulphones.** By R. ESCALES and E. BAUMANN (*Ber.*, 19, 2814—2817).—*Ethylidenediethylsulphone*,  $CHMe(SO_2Et)_2$ , is prepared by the action of potassium permanganate on  $\alpha$ -dithioethylpropionic acid (from pyruvic acid and mercaptan). It forms plates rather soluble in water, more soluble in alcohol and ether. It melts at  $60^\circ$ , and distils without decomposition. The *bromo-derivative*,  $CBrMe(SO_2Et)_2$ , crystallises in small prisms melting at  $115^\circ$ ; it is sparingly soluble.

*Ethylidenediphenylsulphone*,  $CHMe(SO_2Et)_2$ , is prepared by gradually treating a very dilute solution of potassium dithiophenylpropionate (*Abstr.*, 1886, 878) with 1 per cent. permanganate solution. It is insoluble in water, alkalis, and acids, sparingly soluble in alcohol and ether, more readily in benzene. It melts at  $101$ — $102^\circ$ . It is isomeric with Blomstrand and Ewerloff's ethylenediphenylsulphone (*Ber.*, 4, 716; compare also Otto and Damköhler, *J. Pharm. Chem.*, 30, 171 and 321).

N. H. M.

**Disulphcnes.** By E. BAUMANN (*Ber.*, 19, 2806—2814).—*Diethylsulphonedimethylmethane*,  $CMe_2(SO_2Et)_2$ , is prepared by shaking dithioethyldimethylmethane with 5 per cent. permanganate solution, and occasionally adding a few drops of acetic or sulphuric acid. When no more permanganate is decolorised, the liquid is heated and filtered, and the filtrate evaporated to half its bulk. The greater part of the disulphone separates on cooling. It crystallises in thick prisms, melts at  $130$ — $131^\circ$ , and boils with slight decomposition at about  $300^\circ$ . It is readily soluble in warm alcohol and water, rather soluble in ether, benzene and chloroform. Sulphuric acid dissolves it very readily, and decomposes it when warmed; nitric acid and bromine both dissolve it, but are without further action.

*Diethylsulphonepropylmethylmethane*,  $CMePr(SO_2Et)_2$ , crystallises from water in long needles melting at  $86^\circ$ ; it dissolves sparingly in water, readily in alcohol, ether, and chloroform.

*Ethylic  $\beta$ -diethylsulphonebutyrate*,  $CMe(SO_2Et)_2\cdot COOEt$ , is prepared by oxidising ethylic  $\beta$ -dithioethylbutyrate. It crystallises from water in slender needles more than an inch long, melts at  $63^\circ$ , and dissolves very sparingly in cold water, more readily in alcohol and ether.

*Diethylsulphonemethane*,  $\text{CH}_2(\text{SO}_2\text{Et})_2$ , is obtained by oxidising ethyl orthothioformate (Gabriel, this Journal, 1877, ii, 311) with potassium permanganate in presence of sulphuric acid. It crystallises in lustrous plates melting at  $104^\circ$ ; and dissolves sparingly in ether, readily in benzene and alcohol. When the aqueous solution is treated with bromine-water, the *dibromo-derivative*,  $\text{CBr}_2(\text{SO}_2\text{Et})_2$ , is formed. This crystallises from boiling water in lustrous needles melting at  $131^\circ$ .

The disulphone is probably formed by the oxidation of the sulphide  $\text{CH}_2(\text{SEt})_2$  present in the thio-ether. N. H. M.

**Reagent for the Hydroxyl-group.** By H. A. LANDWEHR (*Ber.*, 19, 2726).—The substance to be tested is added in excess to 10 to 20 c.c. of a solution of ferric chloride (prepared by adding two drops of a 10 per cent. solution of ferric chloride to 60 c.c. of water) contained in a white dish. The production of a sulphur colour denotes the presence of hydroxyl. All hydroxy-acids and all alcohols and carbohydrates which dissolve in water give the reaction. Ether, alkyl salts, formic, propionic, butyric, oxalic, fumaric, and malonic acids give negative results. N. H. M.

**Non-acid Constituents of Beeswax.** By F. SCHWALB (*Annalen*, 235, 106—149).—Repeated boiling with alcohol extracts about 5 per cent. of cerotic acid from beeswax. The residue is saponified with alcoholic soda, and after the alcohol has been removed by distillation and by boiling with water, the soap is separated by the addition of common salt. To remove any free alkali, the soap is pressed in a cloth, redissolved in hot water, and again salted out. This operation is repeated several times. The soap is thoroughly dried at  $110$ — $120^\circ$ , and the non-acid constituents are separated by fractional solution in, and recrystallisation from, light petroleum. The most soluble portion of the extract, melting between  $55^\circ$  and  $65^\circ$ , contains two hydrocarbons; one melting at  $60.5^\circ$  appears to be identical with Krafft's normal heptacosane,  $\text{C}_{27}\text{H}_{56}$  (*Abstr.*, 1882, 1273), and the other which melts at  $67^\circ$ , is probably identical with normal hentriacontane,  $\text{C}_{31}\text{H}_{64}$ . It is probable that other hydrocarbons are also contained in the wax.

The myricyl alcohol is less soluble in light petroleum than the hydrocarbons. It appears to have the formula  $\text{C}_{31}\text{H}_{64}\text{O}$ , and is not identical with the alcohol  $\text{C}_{30}\text{H}_{62}\text{O}$ , contained in carnauba wax (*Abstr.*, 1884, 1281). It melts at  $85$ — $85.5^\circ$ , and resolidifies at  $84^\circ$ . When heated with soda lime, it is converted into the salt of an acid,  $\text{C}_{31}\text{H}_{62}\text{O}_2$ . This acid is sparingly soluble in the usual solvents at the ordinary temperature, but it dissolves in hot light petroleum, and is deposited from the solution in white needle-shaped crystals, which melt at  $88.5$ — $89^\circ$ . The lead salt melts at  $115$ — $116^\circ$ , and dissolves freely in acetic acid and in boiling toluene. The silver salt is amorphous. It melts at  $180^\circ$ , with decomposition. The copper and magnesium salts are also amorphous. They dissolve in boiling benzene. The methyl and ethyl salts crystallise in needles. They dissolve freely in warm

ether and warm alcohol. The methyl salt melts at  $71-71.5^{\circ}$ , and the ethyl salt at  $69.5-70^{\circ}$ . Heated under the ordinary atmospheric pressure, the ethyl salt decomposes before boiling into ethylene and the free acid.

Beeswax also contains two lower alcohols, namely, ceryl alcohol,  $C_{26}H_{54}O$  or  $C_{27}H_{56}O$ , and an alcohol of the formula,  $C_{24}H_{50}O$  or  $C_{25}H_{52}O$ .  
W. C. W.

**Conversion of Starch into Glucose by means of Hydrochloric Acid.** By S. HARVEY (*Analyst*, **11**, 221—223).—In reference to the process used by Heisch, heating in a boiling water-bath is as good as heating over a naked flame. In the author's experiments, whenever the conversion of starch was complete, the results obtained were too low, owing to destruction of the glucose; in fact, it appears impossible to limit the time of heating, so as to prevent the glucose being attacked.  
D. A. L.

**Carbohydrates.** By M. HÖNIG and S. SCHUBERT (*Monatsh. Chem.*, **7**, 455—484).—In a former paper (*Abstr.*, 1886, 44), the authors have shown that by the action of sulphuric acid on cellulose and starch, a series of sulphuric acid-derivatives are formed of the general composition  $C_nH_{10n}O_{5n-x}(SO_4)_x$ . These are decomposed in alcoholic solution with production of sparingly soluble compounds, containing a smaller proportion of sulphuric acid, which in their turn are decomposed at a higher temperature with formation of various dextrins. The different phases of these changes in the case of cellulose, starch, and grape-sugar are worked out more fully in this paper. From cellulose, a series of derivatives is obtained from a form of soluble cellulose to dextrose, according to the temperature ( $5-33^{\circ}$ ) at which the change is effected; these increase in specific rotatory power and solubility, the lower members of the series giving a blue coloration with iodine, the intermediate a red, and the end products no coloration, corresponding with the formation of an achroo-dextrin. These substances also differ from one another as regards their conversion by diastase; the end members are unaltered, whilst the others are converted into dextrins.

From starch, a similar series of compounds was obtained; although in this case the specific rotatory power diminishes from that of starch to that of a dextrin similar to the final product from cellulose, but differing from it in possessing a slight cupric oxide reducing power.

With grape-sugar also, similar results were obtained.

In conclusion, the question is discussed whether the starch molecule is compounded of other less complex units, differing among themselves, a view represented by the formula  $15(C_{12}H_{20}O_{10})$ , assigned by Brown and Heron, or whether it is decomposed into these less complex molecules by a chemical change rather than by a process of disintegration.  
V. H. V.

**Identity of Cadaverine with Pentamethylenediamine.** By A. LADENBURG (*Ber.*, **19**, 2585—2586).—Cadaverine and pentamethylenediamine show the same boiling point, solubility and odour,

and agree in their general reactions. The mercuriochloride of pentamethylenediamine has the formula  $C_5H_{14}N_2 \cdot 2HCl \cdot 3HgCl_2$ , whilst, according to Brieger, that of cadaverine mercuriochloride is

The imine obtained from cadaverine is identical in its properties with piperidine, which the author has previously shown to be the imine of pentamethylenediamine (Abstr., 1886, 139, 269).

W. P. W.

**Compounds of Aldehydes and Ketones with Mercaptan.** By E. BAUMANN (*Ber.*, 19, 2803—2806).—When furfuraldehyde and mercaptan are treated with dry hydrogen chloride, the reaction is accompanied by considerable development of heat, which causes a further decomposition. Fatty aldehydes and ketones and aromatic aldehydes also react with mercaptan with development of heat; with fatty aromatic ketones, the mixture must be warmed, whilst in the case of benzophenone the reaction only takes place in presence of zinc chloride.

When dithiophenyldimethylmethane,  $CMe_2(SPh)_2$  (Abstr., 1885, 749), is prepared, avoiding development of heat, a solid product is obtained instead of an oil. It forms large, clear crystals, which melt at  $56^\circ$ , and dissolve readily in alcohol, ether, benzene, &c., and are insoluble in water. When heated at  $100^\circ$ , it decomposes into a mixture of several substances, which no longer solidifies. Dithioethyldimethylmethane,  $CMe_2(SET)_2$  (*loc. cit.*), was also prepared at a lower temperature, and was obtained as a mobile, strongly refractive liquid, boiling at  $190$ — $191^\circ$ ; it combines directly with methyl iodide, yielding a crystalline substance.

N. H. M.

**Linoleic Acid.** By K. PETERS (*Monatsh. Chem.*, 7, 552—555).—The formula generally ascribed to linoleic acid is  $C_{18}H_{32}O_2$ ; it would thus be the isologue of palmitic acid, and convertible into it by hydrogenising agents. It is here shown that the analytical results of a sample of an acid, purified by means of its barium salt, are more in accordance with the formula  $C_{18}H_{32}O_2$ , and when heated with phosphorus and hydriodic acid, it yields not palmitic, but stearic acid.

V. H. V.

**Acetylævulinic Acid. Constitution of  $\gamma$ -Ketonic Acids.** By J. BREDT (*Annalen*, 236, 225—232).—Acetylævulinic acid is formed by the action of acetic anhydride on lævulinic acid at  $100^\circ$ . It is deposited from an alcoholic solution in crystals, resembling those of potassium nitrate. It melts at  $78$ — $79^\circ$ , and boils about  $140^\circ$ , under 15 mm. pressure; under the ordinary atmospheric pressure, it splits up on boiling into acetic acid and  $\alpha$ - and  $\beta$ -angelica lactones.

As the compound is neither decomposed by water nor by a cold solution of sodium carbonate, the author regards it as a hydroxy-lactone-derivative, not as an anhydride. This is evidence in favour of the formula  $CH_2 < \overset{CH_2}{\underset{CO \cdot O}{\curvearrowright}}} CMe \cdot OH$  for lævulinic acid.

W. C. W.

**New Reaction of Aluminium Chloride; Syntheses in the Acetic Series.** By A. COMBES (*Compt. rend.*, 103, 814—817).—When aluminium chloride is added to a solution of acetic chloride in carbon bisulphide or chloroform, there is abundant evolution of hydrogen chloride, and a white, crystalline solid of the composition  $C_{12}H_{14}O_5Al_2Cl_8$  is obtained. It remains unaltered in dry air, but is immediately decomposed by water with evolution of carbonic anhydride. If the water is added carefully to the solid, or if the latter is thrown into water in small quantities at a time, a clear liquid is obtained, which, when extracted with ether, or better, chloroform, yields a colourless liquid boiling at  $136-137^\circ$  under a pressure of 750 mm. It has the composition  $C_5H_8O_2$ , and is lighter than water, in which it is readily soluble without undergoing any decomposition. The action of aluminium chloride on acetic chloride is represented by the equation—

and the solid compound is decomposed by water with formation of aluminium hydroxide and the acid  $COMe \cdot CH_2 \cdot CO \cdot CH_2 \cdot COOH$ , which immediately loses carbonic anhydride and yields acetylacetone,  $C_5H_8O_2$ .

*Acetylacetone* has the properties of a diketone, and combines, with development of heat, with a concentrated solution of sodium hydrogen sulphite. It is not affected by phosphorous chloride or acetic chloride, but is decomposed by potash or soda, with formation of acetone and an acetate. When treated with sodium amalgam, it yields isopropyl alcohol, pinacone, and sodium acetate. If slowly hydrogenised in an acid solution, it should yield symmetrical amylic isoglycol,  $CH_2(CHMe \cdot OH)_2$ . Bromine acts energetically on acetylacetone, with formation of acetic bromide and penta- and tetra-bromacetone. Phosphoric chloride removes the oxygen, and yields a tetrachloride which immediately loses 2 mols. HCl, and yields chlorides of the composition  $C_5H_6Cl_2$ , derived from an unknown valerylene.

When the solid product of the action of aluminium chloride on acetic chloride is treated with absolute alcohol instead of water, no gas is evolved. The products will be described in a subsequent paper.

This reaction is general, and takes place with propionic and butyric chlorides, and with chloral.

C. H. B.

**Gluconic Acids.** By F. VOLTERT (*Ber.*, 19, 2621—2623).—*Ethyl pentacetylgluconate* is a white, crystalline substance, readily soluble in alcohol and water; it melts at  $103.5^\circ$ . Ammonium and potassium gluconate crystallise well in plates and needles. Comparative experiments made with Hoenig's paragluconic acid (*Abstr.*, 1881, 893) show that it is identical with gluconic acid.

N. H. M.

**Action of Thiocarbamide on Ethyl Acetoacetate.** By R. LIST (*Annalen*, 236, 1—32) — In the preparation of thiomethyluracil from thiocarbamide and ethyl acetoacetate, by the process previously described by the author (*Abstr.*, 1886, 443), it is found that the pre-

sence of ammonium thiocyanate increases the yield of the product. *Thiomethyluracil*,  $\text{CS} \begin{smallmatrix} \text{NH} \cdot \text{CMe} \\ \text{NH} \cdot \text{CO} \end{smallmatrix} \text{CH}$ , is very sparingly soluble in alcohol, ether, and cold water. It crystallises in plates, and begins to decompose at  $280^\circ$ . The silver and copper salts are amorphous. The mercuric salt forms anhydrous, microscopic needles. The potassium salt,  $\text{C}_5\text{H}_5\text{N}_2\text{OSK} + \frac{1}{2}\text{H}_2\text{O}$ , is insoluble in alcohol, but freely soluble in water. The sodium salt,  $\text{C}_5\text{H}_5\text{N}_2\text{OSNa} + 2\text{H}_2\text{O}$ , crystallises in prisms, which effloresce on exposure to the atmosphere. The methyl salt melts at  $219\text{--}220^\circ$ , but begins to sublime at  $120^\circ$ , forming plates or needle-shaped crystals. The addition of silver nitrate to the ammoniacal solution of this substance precipitates the compound  $\text{C}_6\text{H}_7\text{N}_2\text{SOAg}$ . The ethyl compound melts at  $144\text{--}145^\circ$ .

*Ethyl thiomethyluracilacetate* is obtained in needle-shaped crystals by the action of ethyl monochloracetate on thiomethyluracil. *Thiomethyluracilacetic acid* crystallises in needles or plates, and melts at  $203\text{--}204^\circ$ . It is very sparingly soluble in cold water, alcohol, and ether.

Thiomethyluracil unites with hydrogen bromide to form an unstable crystalline additive product. Bromine acts on thiomethyluracil suspended in water, eliminating the sulphur and forming dibromoxymethyluracil. By a similar reaction, dichloroxymethyluracil is obtained in transparent plates, soluble in hot water and in warm alcohol. Thiomethyluracil is converted into methyluracil by boiling with freshly precipitated silver or mercuric oxide, and also by the action of ammonia or strong hydrochloric acid at  $150^\circ$ , and of acetic acid at  $180^\circ$ .

W. C. W.

**Nitro-derivatives of Methyluracil.** By A. KÖHLER (*Annalen*, **236**, 32—57).—Behrend (*Annalen*, **229**, 32) obtained nitrouracilcarboxylic acid and a compound,  $\text{C}_5\text{H}_2\text{N}_4\text{O}_5$ , by the action of strong nitric acid on methyluracil. Nitrouracilcarboxylic acid,  $\text{C}_5\text{H}_3\text{N}_3\text{O}_6 + 2\text{H}_2\text{O}$ , crystallises in rhombic prisms;  $a : b : c = 0.323 : 1 : 1.081$ . On boiling the aqueous solution, carbonic anhydride is evolved and nitrouracil,  $\text{C}_4\text{H}_3\text{N}_3\text{O}_4$ , is formed. *Ethyl nitrouracilcarboxylate*, prepared by saturating the alcoholic solution of the acid with hydrogen chloride, crystallises in monoclinic prisms. It is less soluble in alcohol and water than the free acid, and it does not split up on boiling with water. The salt melts at about  $250^\circ$  with partial decomposition. The constitution of this substance may be represented by the formula

$$\text{NH} \begin{smallmatrix} \text{CO} \text{---} \text{NH} \\ \text{CO} \cdot \text{C}(\text{NO}_2) \end{smallmatrix} \text{C} \cdot \text{COOEt}.$$

*Amidouracilcarboxylic acid*,  $\text{C}_5\text{H}_5\text{N}_3\text{O}_4$ , is formed by the action of tin and hydrochloric acid on the nitro-acid, but a better yield is obtained by the reduction of the ethyl salt. The product, consisting of a mixture of the ethyl salts of amidouracilcarboxylic and hydroxyuracilcarboxylic acids, is saponified by boiling with an aqueous solution of potassium hydroxide. Amidouracilcarboxylic acid is deposited from its aqueous solution in needles. Between  $150^\circ$  and  $160^\circ$ , it splits up into carbonic anhydride and amidouracil. The potassium salt,  $\text{C}_5\text{H}_6\text{N}_3\text{O}_5\text{K} + \text{H}_2\text{O}$ , crystallises in prisms; the barium,

copper, and mercury salts are amorphous. The sparingly soluble lead and silver salts are crystalline. The ethyl salt is insoluble in alcohol and sparingly soluble in water. It melts at  $260^{\circ}$  with partial decomposition.

A good yield of nitrouracil is obtained by adding 5 c.c. of strong sulphuric acid to 4 grams of methyluracil suspended in 10 c.c. of fuming nitric acid. The yield of the sparingly soluble compound,  $C_5H_2N_4O_5$ , which is obtained as a bye-product by the action of nitric acid on methyluracil, is increased by warming the mixture as soon as the reaction ceases.

This compound unites with bases to form salts.  $C_5HN_4O_5 \cdot NH_4 + \frac{1}{2}H_2O$  crystallises in yellow glistening needles;  $C_5HN_4O_5K + 1\frac{1}{2}H_2O$ , red needles, sparingly soluble in water; the solution decomposes on boiling. The barium salt,  $(C_5HN_4O_5)_2Ba + 4H_2O$ , forms prismatic needles, freely soluble in water. On reduction with tin and hydrochloric acid, the amido-compound,  $C_5H_4N_4O_3 + H_2O$ , is obtained in slender needles, sparingly soluble in water. After evaporation with hydrochloric acid, the residue yields the murexide reaction.

W. C. W.

**New Mode of Formation of Dibromo- and Dichloro-barbituric Acids.** By R. BEHREND (*Annalen*, 236, 57—68).—The most convenient method of preparing bromomethyluracil (Abstr., 1886, 338) is to convert methyluracil into dibromoxymethyluracil by the action of bromine-water (*Annalen*, 229, 18), and to decompose the product by boiling in alcohol. *Dichloroxymethyluracil* resembles the corresponding bromo-derivative in its properties and in its mode of preparation. It crystallises in triclinic plates, and is not decomposed by boiling with alcohol. It is decomposed by alcohol or water at  $150^{\circ}$ , forming a sparingly soluble compound, and is converted into monochloromethyluracil by the action of stannous chloride and hydrochloric acid. Chloromethyluracil is insoluble in ether, sparingly soluble in water and alcohol. It crystallises in needles.

Dibromoxymethyluracil is oxidised to *dibromobarbituric acid* by fuming nitric acid. This is identical with the dibromobarbituric acid described by Baeyer (*Annalen*, 130, 130). Hot fuming nitric acid converts dichloroxymethyluracil into *dichlorobarbituric acid*,  $C_4H_2Cl_2N_2O_3$ . This substance crystallises in rhombic prisms or plates,  $a : b : c = 0.7766 : 1 : 0.8929$ . The crystals are isomorphous with those of dibromobarbituric acid, and are much more soluble in alcohol, ether, and water. A small quantity of barbituric acid is formed in the preparation of dichlorobarbituric acid by this process.

W. C. W.

**Relation of the so-called  $\alpha$ -Thiophenic Acid to the Normal Thiophencarboxylic Acids.** By V. MEYER (*Annalen*, 236, 200—224).—In former communications (Abstr., 1885, 1207; 1886, 227, 534), the author has pointed out that the derivatives of  $\alpha$ - and  $\beta$ -thiophenic acids (melting at  $118^{\circ}$  and at  $126.5^{\circ}$  respectively), are identical in crystalline form, solubility, and melting point, but that on decomposition the  $\alpha$ -derivatives yield the  $\alpha$ -acid, and the  $\beta$ -derivatives the  $\beta$ -acid. The so-called  $\alpha$ -acid is really a mixture of the  $\beta$ - and  $\gamma$ -acids, which cannot be separated by recrystallisation. It is formed on

oxidising a mixture of  $\beta$ - and  $\gamma$ -thiotolens, but is not obtained by mixing together the ready-formed  $\beta$ - and  $\gamma$ -acids. In the thiophen-group the tendency for the isomeric compounds to crystallise together is much stronger than in any other series.

W. C. W.

**Halogen Carriers.** By C. WILLGERODT (*J. pr. Chem.* [2], **34**, 264—292).—An account of experiments on the effective value of various elements and their compounds in the chlorination of benzene (compare Abstr., 1885, 1034). Two cases occur on the passage of chlorine into benzene in presence of these foreign substances, namely, either the formation of benzene hexachloride attended by a considerable gain in weight of the benzene and practically no evolution of hydrogen chloride, or the displacement of hydrogen by chlorine with corresponding evolution of hydrogen chloride. The details of the various experiments are given in full. To the substances inducing the first reaction belong aluminium hydroxide and sulphate; those inducing the latter reaction are again separable into those elements the presence of which induces the production of mono- or di-substitution-derivatives, and those forming a chloride of the formula  $XCl_3$  or  $(XCl_2)_n$ , which lead to the production of tetra- or penta-substitution-derivatives. The function of these is conditioned by the atomic mobility of the chlorine-atoms in its compound, and in fact to the affinity of some kind or another of the inorganic chloride for the carbon compound. Adopting the periodic system of classification, the members of the first two groups are inactive, those of the second, fifth, seventh, and eighth groups are eminently active, and those of the fourth are, with the exception of tin, inactive.

The experiments of Lothar Meyer, Friedel and Crafts, and others on the chlorination of carbon compounds by means of such substances as aluminium or ferric chloride, seem to indicate that at first a hydrogen-atom of the hydrocarbon is displaced by the grouping  $M_2Cl_5$  with separation of hydrogen chloride, and to this compound a molecule of chlorine adds itself on and finally takes the place of the hydrogen. The compounds  $Al_2Cl_6, 6C_6H_6$  (or  $6C_7H_8$ ) obtained by Gustavson, the author regards as combinations of a molecule of metallic chloride with one of the hydrocarbon, the remaining five molecules functioning in like manner to water of crystallisation.

V. H. V.

**Preparation of Organic Fluorides.** By O. WALLACH (*Annalen*, **235**, 255—271).—*Fluorobenzene*,  $C_6H_5Fl$ , can easily be prepared by pouring 20—30 c.c. of strong hydrofluoric acid into a flask containing 10 grams of benzene diazopiperidine. The flask is connected with a receiver by means of a spiral condenser surrounded by a freezing mixture. A tube passes through the doubly perforated cork which closes the receiver, and dips into mercury. On gently warming the flask, the reaction commences and the fluorobenzene collects in the receiver. *Fluorotoluene* is prepared from toluene paradiazopiperidine. As it is much easier to condense than fluorobenzene, the apparatus may be simplified by omitting the tube dipping under mercury. Fluorotoluene resembles benzonitrile in odour. It is oxidised by chromic acid, yielding fluorobenzoic acid.

*Nitrobenzeneparadiazopiperidide* forms golden, needle-shaped crystals. It melts at 96—97°, and dissolves freely in ether and warm alcohol. It is decomposed by hydrofluoric acid, yielding *parafluoronitrobenzene*. This compound is also formed by nitrating fluorobenzene. It melts at 21—22° and boils at 204—206°.

*Acetamidobenzene metadiazopiperidide*,  $C_6H_4(NHAc)N:N_2C_5H_{10}$ , is deposited from weak alcohol in thick prisms which melt at 100—101°. It is decomposed by hydrofluoric acid, yielding *metafluor-aniline*; an oily liquid resembling aniline. *Parafluor-aniline* is formed by reducing an alcoholic solution of parafluoronitrobenzene with stannous chloride and hydrochloric acid. The nitrate, hydrochloride, and sulphate crystallise well. Acetic anhydride converts parafluor-aniline into *acetofluor-anilide*. This compound is sparingly soluble in water, but dissolves readily in alcohol.

The replacement of hydrogen by fluorine increases the sp. gr., but has very slight effect on the boiling points of the compounds.

|                             | Sp. gr. | B. p.   |
|-----------------------------|---------|---------|
| Benzene .....               | 0·899   | 80·5°   |
| Toluene .....               | 0·882   | 111     |
| Nitrobenzene .....          | 1·2     | 205     |
| Aniline .....               | 1·036   | 184     |
| Fluorobenzene .....         | 1·024   | 84—85   |
| Parafluorotoluene .....     | 0·992   | 116°    |
| Parafluoronitrobenzene .... | 1·326   | 205—206 |
| Parafluor-aniline .....     | 1·153   | 185—189 |

Fluorobenzenesulphonic acid and fluorodiphenyl, when added to an alkaline solution of piperidine, form the compounds

and  $C_5NH_{10} \cdot N_2 \cdot C_6H_4 \cdot C_6H_4 \cdot N_2 \cdot C_5NH_{10}$  respectively.

W. C. W.

**Reaction of Potassium Cyanide with Orthonitrobenzyl Chloride.** By E. BAMBERGER (*Ber.*, 19, 2635—2642).—In the reaction between potassium cyanide and orthonitrobenzyl chloride there are formed, besides orthonitrobenzyl cyanide, an orthodinitrocyano-dibenzyl and substances of the composition  $C_{22}H_{14}N_4O_5$  and  $C_{15}H_9N_3O_3$ , the constitution of which is uncertain.

*Orthonitrobenzyl cyanide*,  $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot CN$ , previously described by Salkowski, crystallises in pale-yellow prisms which melt at 82·5°; its solutions give a blue-violet coloration on addition of a trace of alkali; the dye formed is, however, unstable.

*Orthodinitrocyano-dibenzyl*,  $NO_2 \cdot C_6H_4 \cdot CH(CN) \cdot CH_2 \cdot C_6H_4 \cdot NO_2$ , crystallises in snow-white prisms, melts at 110·5° and is soluble in benzene, alcohol, and acetic acid. This substance is also obtained directly from orthonitrobenzyl chloride and the corresponding cyanide. It is very stable towards acids; when heated with alkalis and the product heated with mineral acids, a compound,  $C_{15}H_9N_3O_3$ , separates out in voluminous, yellow flocculæ, which can be crystallised from alcohol in silky leaflets melting at 235—238°. The same substance is also a subsidiary product in the above reaction.

The compound  $C_{22}H_{14}N_4O_5$ , mentioned above, crystallises in thick glistening prisms which melt at  $190.5^\circ$ ; it is sparingly soluble in alcohol, readily in acetic acid; it behaves towards acids and alkalis as a perfectly indifferent substance.

V. H. V.

**Oxidation of Nitromesitylene.** By W. H. EMERSON (*Amer. Chem. J.*, 8, 268—271).—Schmitz has pointed out that as paranitromesitylenic acid is produced during the preparation of mononitromesitylene, it is probable that the first-named substance is produced by the oxidation of the last-named, and therefore here as in other cases, except with mesitylene sulphonamide, the presence of the nitro-group protects those hydrocarbon side-chains that occupy the ortho-position relatively to the negative nitro-group. This oxidation has before been attempted but without success; by dissolving both the substance and the chromic acid in glacial acetic acid, however, the paranitromesitylenic acid was actually obtained and recognised by its properties and by those of the corresponding amido-acid.

H. B.

**Intramolecular Changes in the Propyl-group of the Cumene Series.** By O. WIDMAN (*Ber.*, 19, 2769—2780).—*Propylhydrocarbostyryl*,  $C_{12}H_{15}NO$ , is obtained by treating a solution of orthamidocumenylacrylic acid (Abstr., 1886, 465) in soda with an excess of sodium amalgam. Acetic acid is then added, which precipitates a yellow substance melting at  $80^\circ$ ; this changes in a short time to propylhydrocarbostyryl melting at  $134^\circ$ . The latter crystallises in well-formed rhombic prisms,  $a : b : c := 0.87978 : 1 : 1.64451$ ;  $\beta = 1.620435$ , and is very readily soluble in alcohol and benzene. The compound is also obtained by reducing orthamidoparapropylcinnamic acid (Abstr., 1886, 464). In the latter reaction, the isopropyl-group must have undergone an intermolecular change; propylhydrocarbostyryl is therefore a normal compound of the formula

Cumenylpropionic acid (Perkin, this Journal, 1877, i, 400) is best prepared by boiling pure cumenylacrylic acid for 45 minutes with 20 times its weight of hydriodic acid (sp. gr. 1.7) and an equal weight of red phosphorus. The product is filtered, washed with water, and dissolved in ammonia; it is precipitated with acid, pressed, and dried. It melts sharply at  $75.5^\circ$  (not  $70^\circ$ ). When gradually treated with fuming nitric acid (10 parts) at  $-5^\circ$  to  $0^\circ$ , and the product poured into water, a white crystalline *nitro-acid* is precipitated; it crystallises from 50 per cent. acetic acid in well-formed plates melting at  $99^\circ$ . When reduced, it yields propylhydrocarbostyryl. When cumenylpropionic acid is oxidised by potassium permanganate, it is converted into orthonitrohydroxyisopropylbenzoic acid (Abstr., 1886, 466).

The above experiments show that a conversion of isopropyl into normal propyl occurs in the successive conversion of cumenylacrylic acid into cumenylpropionic acid, orthonitrocumenylpropionic acid, and propylhydrocarbostyryl. The same molecular change also takes place when cumenylacrylic acid is converted successively into

orthonitrocumenylacrylic acid, orthamidocumenylacrylic acid, and propylhydrocarbostyryl. The author considers that the so-called "cumenylpropionic acid" contains normal propyl, and that it is *parapropylhydrocinnamic acid*. The propionic radicle, therefore, as well as the methyl and acrylic acid radicles, influences a propyl-group in the para-position, causing the formation of normal propyl.

N. H. M.

**Reciprocal Transformations of Cymene- and Cumene-derivatives.** By O. WIDMAN (*Ber.*, 19, 2781—2785).—With regard to the change of cumene- into cymene-derivatives, the author objects to Fileti's suggested law (this vol., p. 36) on the ground that the nature of the group has not been determined in any of the compounds containing these elements or groups (Cl, Br, Cy, COOH, &c.), and mentions experiments previously described by him (*Abstr.*, 1886, 464) which show Fileti's view to be quite incorrect.

N. H. M.

**Octylbenzene.** By F. AHRENS (*Ber.*, 19, 2717—2725).—Octylbenzene (v. Schweinitz, *Abstr.*, 1886, 540) boils at 262—264° (uncorr.), sp. gr. 0.852 at 14°. It solidifies at -7° to a crystalline mass, is insoluble in water, miscible with alcohol, ether, and benzene. *Chlorooctylbenzene*,  $C_6H_4Cl \cdot C_8H_{17}$ , is prepared by the action of chlorine in presence of iodine on the hydrocarbon. It is a yellowish oil, almost without odour, readily soluble in alcohol and ether; it boils at 270—275°. *Bromooctylbenzene*,  $C_6H_4Br \cdot C_8H_{17}$ , boils at 285—287°. The *moniodo-derivative* is prepared by the action of iodine and mercury oxide on octylbenzene diluted with light petroleum. It is a yellow oil, insoluble in water, soluble in alcohol and ether. It solidifies at -4°, and does not distil without decomposition. It is very susceptible towards light and heat. *Metanitro-octylbenzene*,  $NO_2 \cdot C_6H_4 \cdot C_8H_{17}$ , is formed by the action of fuming nitric acid on octylbenzene in the cold. It crystallises in long needles insoluble in water and ether; sparingly soluble in alcohol and chloroform; it melts at 123—124°, and sublimes unchanged at a high temperature. When oxidised with potassium permanganate, it yields metanitrobenzoic acid. *Orthonitro-octylbenzene* is obtained, together with the para-derivative, by heating the mother-liquor from the preparation of the meta-compound. The heavy oil so formed is washed with hot water. It is a thick, yellow oil with a peculiar aromatic odour. It begins to decompose at 100°, and cannot be distilled; at 130° it suddenly carbonises. *Paranitro-octylbenzene* is obtained by first nitrating octylbenzene in the cold, separating the liquid from the crystals of metanitro-octylbenzene, and heating for 12 hours. It is then filtered and again heated, and this is repeated until all the hydrocarbon has dissolved. The crystalline substance is gently heated to sublime any metanitro-derivative present, and then strongly heated, when the para-compound sublimes. It forms small, yellowish, lustrous needles, having a slight odour of benzaldehyde; it melts at 204°, is insoluble in water, soluble in alcohol and ether. *Dinitro-octylbenzene*,

was formed when crystals of metranitro-octylbenzene containing

fuming nitric acid were washed with ether. Water was poured on to stop the violent reaction which at once took place. It melts at  $226^{\circ}$ , and sublimes below this temperature in transparent crystals with a vitreous lustre, soluble in ether and alcohol, insoluble in water; its constitution was not determined. *Orthamido-octylbenzene hydrochloride*,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{C}_8\text{H}_{17}\cdot\text{HCl}$ , is prepared by reducing the nitro-compound with tin and hydrochloric acid; it forms small, lustrous, white plates; when heated, it becomes red. N. H. M.

**A Fourth Monobromophenol, and a Second Monobromobenzene.** By F. FITTICA (*Ber.*, 19, 2632—2634).—In this communication, the author still maintains the existence of the fourth monobromophenol described by him in a former work, the conclusions from which were subsequently shown by Hand to be erroneous (*Abstr.*, 1886, 1017). The preparation of a second monobromobenzene is also described, but it was not obtained of constant boiling point ( $60\text{--}66^{\circ}$ ), and the analytical results are far from satisfactory. V. H. V.

**Constitution of Nitranilic Acid.** By R. NIETZKI (*Ber.*, 19, 2727).—When diamidotetrahydroxybenzene (obtained by reducing nitranilic acid) is distilled with zinc-dust, paraphenylenediamine is formed. This is fresh evidence that nitranilic acid is paradinitro-dihydroxyquinone (compare Hantzsch, *Abstr.*, 1886, 1021). N. H. M.

**Aniline and its Homologues.** By L. LEWY (*Ber.*, 19, 2728—2729; compare *Abstr.*, 1886, 872).—When paratoluidine is boiled with water, splendid crystals of the *hydrate* separate on cooling; when exposed to air they effloresce.

The xylidines and cumidines behave towards phosphoric acid as orthotoluidine does, and yield only primary phosphates.

As paratoluidine forms a secondary phosphate, and orthotoluidine a primary phosphate, the para-compound behaves like an element having the atomic weight 214, whilst the ortho-compound behaves like an element having the atomic weight 107. In estimating the phosphoric acid in a mixture of the two phosphates, the relative amounts of paratoluidine and orthotoluidine can therefore be determined. N. H. M.

**Alkyl-derivatives of Aniline.** By A. CLAUS and H. HIRZEL (*Ber.*, 19, 2785—2791).—*Methylpropylaniline*,  $\text{NPhMePr}$ , is prepared by heating methylaniline and propyl iodide for eight hours in a water-bath. The product is dissolved in water, extracted with ether, and treated with alkali. It is a yellowish oil, boiling at  $212^{\circ}$  (uncorr.). The *hydrochloride* melts at  $106^{\circ}$  (uncorr.); it is very hygroscopic. The *ethiodide*,  $\text{NPhMePr}\cdot\text{EtI}$ , is a viscous substance readily soluble in water. When boiled with concentrated aqueous potash, methyl-ethylaniline is formed.

*Ethylpropylaniline*,  $\text{NPhEtPr}$ , is obtained by the action of propylaniline (Claus and Roques, *Ber.*, 16, 909) on ethyl bromide, or from ethylaniline and propyl bromide. It is a bright yellow oil boiling at

216° (uncorr.). The *hydrochloride* is a crystalline substance, and melts at 131° (uncorr.). The *methiodide* is a syrup having all the properties of methylpropylaniline ethiodide.

Methylethylaniline was prepared by the method of Claus and Howitz (Abstr., 1884, 1005); it was obtained in the crystalline state. The *hydrochloride* melts at 114°. The propiodide is identical with the iodide mentioned above. When the aqueous solution of the iodide is heated, or kept in contact with ether, decomposition takes place, with formation of propyl alcohol and methylethylaniline hydriodide.

N. H. M.

**Action of Ethyl Imidocarbonate on Aromatic Ortho-compounds.** By T. SANDMEYER (*Ber.*, 19, 2650—2657).—In continuation of former experiments on the reactions between ethyl imidocarbonate and the amines of the aromatic series (Abstr., 1886, 611), the preparation and properties of various derivatives of phenylene and toluylene diamines are described.

*Ethoxymethenyltoluylenediamine*,  $C_7H_6<\begin{smallmatrix} NH \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OEt$ , prepared from toluylenediamine hydrochloride and ethyl imidocarbonate, crystallises in golden needles which melt at 163°, insoluble in cold, sparingly soluble in hot water, moderately soluble in alcohol. Its aqueous solution gives a voluminous, white precipitate with mercuric chloride. With acids, it forms very soluble salts.

When heated with hydrochloric acid, it yields *hydroxymethenyltoluylenediamine*,  $C_7H_6<\begin{smallmatrix} NH \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OH$ . This substance crystallises in small needles, melts at 290°, and is sparingly soluble in boiling alcohol, readily in water. From its formation, it would seem to contain the hydroxyl-group, but it is also identical with a compound obtained directly from carbamide and toluylenediamine, which would contain the carbonyl-group; the atomic transformation of the  $-N-COH$ -group into  $-NH-C:O$  is however of frequent occurrence.

*Ethoxymethenylphenylenediamine*,  $C_6H_4<\begin{smallmatrix} NH \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OEt$ , prepared in like manner from phenylenediamine, crystallises in reddish glistening leaflets which melt at 160°. In its solubility and physical properties, it resembles its homologue. With hydrochloric acid, it yields hydroxymethenylphenylenediamine,  $C_6H_4<\begin{smallmatrix} NH \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OH$ , which crystallises in leaflets, and is identical with phenylenecarbamide obtained directly from orthonitrophenylurethane.

*Ethoxymethenylamidophenol*,  $C_6H_4<\begin{smallmatrix} O \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OEt$ , prepared from amido-phenol and ethyl imidocarbonate, is a colourless oil, boiling at 225—230°, of peculiar odour. It is converted by hydrochloric acid into *hydroxymethenylamidophenol*,  $C_6H_4<\begin{smallmatrix} O \\ \diagdown \quad \diagup \\ N \end{smallmatrix}>C \cdot OH$ , crystallising in red prisms, which lose their colour on exposure or when separating slowly from solution.

The reaction of the amido-acids on ethyl imidocarbonate differs

from those of the amines and the amidophenols; thus with anthranilic acid an amidine of the composition

is formed. This crystallises in white needles, melts at  $223^\circ$ , and is sparingly soluble in boiling water, soluble in hot alcohol. It would appear from its formation that this substance should be a bibasic acid, yet its silver salt contains only one atom of the metal in the molecule.

V. H. V.

**Decomposition of Diazo-compounds by Alcohol: Paradiazotolueneorthosulphonic Acid.** By I. REMSEN and A. G. PALMER (*Amer. Chem. J.*, 8, 243—251).—The authors expected to be able to prepare benzoic sulphinide by the oxidation of orthotoluenesulphonamide, itself prepared from the orthotoluenesulphonic acid obtained by boiling the diazo-compound of paramidotolueneorthosulphonic acid with alcohol. This method seemed all the more promising, as Jensen and Ascher have described the actual elimination of the diazo-group in the above compound.

The authors find no difficulty in the conversion of paranitrotoluene into paradiazotolueneorthosulphonic acid; but this, when boiled with alcohol under pressure, yields, contrary to the statements of Jensen and Ascher, not tolueneorthosulphonic acid as the principal product, but ethoxytolueneorthosulphonic acid. The reaction will not proceed without the application of pressure; it commences at 90 mm., and the two compounds are then formed in equal quantities, but the yield is very bad, the reaction slow, and the product is black with tarry matters. At 150 mm. thrice as much of the ethoxy-compound as of the toluenesulphonic acid is formed, and at 500 mm. the ethoxy-compound is formed almost alone; the reaction takes only a few minutes, and the product is far purer. The acid product of the reaction cannot be purified by means of the barium salts, but has to be converted into the acid amide, and it is to be noted that ethoxytoluenesulphamide,  $\text{OEt} \cdot \text{C}_6\text{H}_3\text{Me} \cdot \text{SO}_2\text{NH}_2$  [4 : 1 : 2], melts at  $143\text{--}144^\circ$ , and not at  $136^\circ$ , as described by Heffter.

This action has not been satisfactorily explained. It is at present assumed by all writers that the normal reaction of the diazo-compounds when boiled with alcohol is that which results in the displacement of the diazo-group by hydrogen; it is, however, certain that the reaction frequently takes place in such a way as to form phenetols: thus the sulphate or nitrate of diazobenzene yields benzene in extremely small quantity, but phenetol in very considerable quantity, and it appears probable that the normal reaction is the one that gives the phenetol. A list of 15 similar cases is cited in illustration.

The action in the above case is therefore represented not by the equation generally given, but by

H. B.

**Diazo- and Diazoamido-compounds.** By O. WALLACH (*Annalen*, 235, 233—255).—Some of the diazo-compounds of the monacetic derivatives of the diamines (Abstr., 1883, 584) are quite stable in the dry state, and their hydrobromides can be obtained in a pure state owing to their relatively slight solubility in water and alcohol. Acetic anhydride decomposes the dry diazo-compounds, yielding the acetic derivative of a phenol, thus acetoparatoluidine orthodiazobromide yields diacetamidocresol,  $\text{OAc}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{NHAc}$ . The diazo-compounds unite with nitro-ethane to form the mixed azo-compounds discovered by V. Meyer (this Journal, 1875, 1202, and 1876, ii, 93), and they also combine with secondary amines, forming diazoamido-compounds. The latter substances are decomposed by boiling with strong hydrochloric, hydrobromic, and hydriodic acids according to the equation  $\text{RN}:\text{N}\cdot\text{NR}' + 2\text{HCl} = \text{RCl} + \text{N}_2 + \text{NHR}', \text{HCl}$ . Phenols are the chief products of the action of dilute sulphuric acid on the mixed diazoamido-compounds.

*Benzene diazopiperidide*,  $\text{C}_5\text{NH}_{10}\cdot\text{N}_2\cdot\text{Ph}$ , first described by Baeyer and Jaeger (this Journal, 1876, i, 273), can be readily prepared by pouring a dilute ice-cold solution of diazobenzene chloride (from 100 parts of aniline) into a dilute cold aqueous solution of piperidine, 100 parts by weight mixed with 60 of potassium hydroxide. Every precaution must be taken to prevent the temperature of the mixture rising above  $0^\circ$ . The piperidide melts at  $43^\circ$ . It is decomposed by warm hydrochloric, hydrobromic, and hydriodic acids, yielding chloro-, bromo-, or iodo-benzene respectively, and piperidine.

*Toluene paradiazopiperidide*,  $\text{C}_6\text{H}_4\text{Me}\cdot\text{N}_2\cdot\text{C}_5\text{NH}_{10}$ , crystallises in colourless prisms. It is soluble in alcohol, light petroleum, and ether, and melts at  $41^\circ$ . It unites with 2 mols.  $\text{HCl}$  to form an unstable compound. *Toluene orthodiazopiperidide* and *orthonitrotoluene paradiazopiperidide* are oily liquids. *Paranitrotoluene orthodiazopiperidide* melts at  $50\text{--}51^\circ$ , and is decomposed by hydrobromic acid, yielding bromonitrotoluene,  $\text{C}_6\text{H}_3\text{MeBr}\cdot\text{NO}_2$  [1 : 2 : 4]. *Nitrobenzene metadiazopiperidide* and *benzene diazoconine* and *toluene paradiazoconine* are oily liquids.

By the action of sodium nitrite on a solution of acetotoluylenediamine in hydrobromic acid, the diazobromide,

is obtained as a yellow precipitate. In the dry state, this diazobromide is remarkably stable. It acts on an alcoholic solution of nitroethane and sodium ethoxide, yielding a red precipitate of *acetoparatoluidine orthodiazonitroethane*,

The precipitate dissolves in alkalis, and is reprecipitated by acids. It is deposited from an ethereal alcoholic solution in red needles melting at  $143^\circ$ .

*Acetoparatoluidine orthodiazodiethylamide*,  $\text{NHAc}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{N}_2\cdot\text{NEt}_2$ , is deposited in colourless prisms when acetoparatoluidine orthodiazobromide is added to a cold solution of diethylamine. It melts at  $108^\circ$ .

*Acetoparatoluidine orthodiazopiperidide* melts at  $154^{\circ}$ , and dissolves in alcohol and in ether. When hydrogen chloride is passed into the alcoholic solution, the diazochloride,  $\text{NHAc}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{N}_2\text{Cl}$ , is precipitated in a state of purity. In a dry state, the diazochloride is stable. It explodes when heated, and is decomposed by boiling with water or weak alcohol, yielding acetamidocresol. The diazopiperidide is decomposed by warm hydrochloric or hydrobromic acid, yielding orthochloro- or orthobromo-acetoparatoluidine and monochloro- or monobromotoluidine.

W. C. W.

**Hydrazines.** By E. FISCHER (*Annalen*, **236**, 198—199).—*Phenylhydrazine* distils without decomposition under 35 mm. pressure. It boils at  $241\text{--}242^{\circ}$  under a pressure of 750 mm. (column of mercury surrounded by vapour). At  $22.7^{\circ}$  the sp. gr. of the base is  $1.097^{\circ}$ , compared with water at  $4^{\circ}$ .

In the preparation of methylphenylhydrazine, the author finds that the reduction of the nitrosamine (Abstr., 1878, 312) may be carried out in aqueous instead of in alcoholic solution. The base boils at  $131^{\circ}$  under 35 mm. pressure, and at  $227^{\circ}$  under 745 mm.

W. C. W.

**Phenylhydrazine-compounds.** By C. BÜLOW (*Annalen*, **236**, 194—197).—Malic, tartaric, and mucic acids unite with phenylhydrazine at  $130^{\circ}$ , forming diphenylhydrazides. The malic compound,  $\text{OH}\cdot\text{C}_2\text{H}_3(\text{CO}\cdot\text{N}_2\text{H}_2\text{Ph})_2$ , melts at  $218^{\circ}$ , the tartaric compound,  $\text{C}_2\text{H}_2(\text{OH})_2(\text{CO}\cdot\text{N}_2\text{H}_2\text{Ph})_2$ , melts at  $226^{\circ}$ , and the mucic compound at  $238\text{--}240^{\circ}$ . *Phenylacetic phenylhydrazide*,  $\text{CH}_2\text{Ph}\cdot\text{CO}\cdot\text{N}_2\text{H}_2\text{Ph}$ , melts at  $168\text{--}169^{\circ}$ , and dissolves freely in alcohol and acetic acid. *Ethyl oxalate phenylhydrazide* crystallises in plates and melts at  $119^{\circ}$ . *Benzil phenylhydrazine*,  $\text{COPh}\cdot\text{CPh}\cdot\text{N}_2\text{HPh}$ , is formed by warming equal molecular weights of benzil and phenylhydrazine. It melts at  $128\text{--}129^{\circ}$ .

W. C. W.

**Dicyanphenylhydrazine-compounds.** By J. A. BLADIN (*Ber.*, **19**, 2598—2604).—The anhydro-compound,  $\text{NPh}\langle\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{C}(\text{CN})\text{:N} \end{smallmatrix}\rangle$ , previously obtained by the action of acetic anhydride on dicyanphenylhydrazine (Abstr., 1885, 979) can be prepared by adding the calculated quantity of pyruvic acid to an alcoholic solution of the cyanocompound and warming gently. The author regards this compound as a derivative of the hypothetical triazole,  $\text{NH}\langle\begin{smallmatrix} \text{N}:\text{CH} \\ \text{CH}:\text{N} \end{smallmatrix}\rangle$ ; it will therefore be *phenylmethylecyantriazole*.

The salts of the corresponding *phenylmethylecyantriazolecarboxylic acid*,  $\text{C}_2\text{N}_3\text{MePh}\cdot\text{COOH}$ , are described. The *copper* salt with  $1\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ , is obtained in the form of microscopic needles; the *silver* salt with  $1\frac{1}{2}$  mols.  $\text{H}_2\text{O}$  does not crystallise well; and the *lead* salt with  $2\frac{1}{2}$  mols.  $\text{H}_2\text{O}$  forms small, white needles; all these salts are sparingly soluble, whilst those of barium and the alkalis are easily soluble in water. The *ethyl* salt,  $\text{C}_2\text{N}_3\text{MePh}\cdot\text{COOEt}$ , is a thick, bright-yellow oil, insoluble in water, but readily soluble in alcohol, ether and benzene. With hydro-

chloric acid, a *hydrochloride*,  $C_2N_3MePh \cdot COOH, HCl$ , is obtained in small, colourless tables, which are decomposed by water. The *amide*, which can be obtained by the action of hydrogen peroxide on dicyanophenylhydrazine, crystallises in small, colourless prisms, soluble in water and alcohol, less soluble in ether, and melting at  $170^\circ$ . The *amidoxime* is sparingly soluble in water, but more so in alcohol, and crystallises in colourless leaflets melting at  $208-210^\circ$ . Acids and alkalis, with the exception of ammonia, dissolve it, whilst with acetic anhydride a compound crystallising in needles and melting at  $148^\circ$  is obtained.

*Phenylmethyltriazole*,  $C_2N_3HMePh$ , obtained by heating the acid at  $180^\circ$ , is an oil which does not solidify at  $-15^\circ$ . It forms a *platinochloride*,  $(C_2N_3HMePh)_2, H_2PtCl_6 + H_2O$ , which crystallises from alcohol in lemon-yellow tables melting at  $122-124^\circ$ ; it is decomposed by water.

To the compound  $CN_4Ph \cdot CN$  obtained by the action of nitrous acid on dicyanophenylhydrazine (Abstr., 1886, 146), the author gives the name *phenyleyantetrazole*, regarding it as a derivative of the hypothetical tetrazole,  $N \leq \begin{smallmatrix} CH \cdot NH \\ N = N \end{smallmatrix} >$ .

W. P. W.

**Phenazine-derivatives.** By A. BERNTHSEN and H. SCHWEITZER (*Ber.*, 19, 2604—2607).—On diazotising Witt's toluylene-red,  $C_{15}H_{16}N, HCl$  (*Trans.*, 1879, 356), a compound, *dimethamidomethylphenazine*,

$NMe_2 \cdot C_6H_3 \begin{smallmatrix} \diagup N \\ | \\ \diagdown N \end{smallmatrix} C_6H_3Me$ , is obtained, which forms beautiful dark-red

needles or flat prisms having a greenish lustre. It dissolves in dilute acids with a violet, and in concentrated sulphuric acid with a reddish-brown coloration. Alcohol dissolves it to a red, and ether to a yellowish-red solution exhibiting golden-yellow fluorescence. It shows considerable analogy to eurhodine, and, like that base, sublimes without decomposition.

When, instead of nitrosodimethylaniline, 1:4 phenylenediamine acts on metatoluylenediamine in the presence of oxidising agents, a "simple" toluylene-blue, and subsequently a "simple" toluylene-red are produced. On diazotising, the latter yields methylphenazine; this class of dyes must therefore be regarded as derived from phenazine. The formation of toluylene-blue is represented by the equation  $NMe_2 \cdot C_6H_4 \cdot NH_2 + NH_2 \cdot C_6H_3Me \cdot NH_2 - 4H =$

$NMe_2 \cdot C_6H_4 \begin{smallmatrix} \diagup N \\ | \\ \diagdown NH \end{smallmatrix} C_6H_2Me \cdot NH_2$ . This, on further oxidation, yields

toluylene-red,  $NMe_2 \cdot C_6H_3 \begin{smallmatrix} \diagup N \\ | \\ \diagdown N \end{smallmatrix} C_6H_2Me \cdot NH_2$ . The constitutional

formula of the leuco-toluylene-red,  $NH \begin{smallmatrix} \diagup C_6H_3(NMe) \\ | \\ \diagdown C_6H_2Me(NH_2) \end{smallmatrix} NH$ , shows a remarkable similarity to that of leucomethylene-blue. W. P. W.

**Constitution of the Safranines.** By A. BERNTHSEN (*Ber.*, 19, 2690—2693; comp. preceding Abstract).—The fact that an indamine

is formed as an intermediate product in the preparation of phenosafranines makes it probable that the phenyl-group in the latter is combined with the same nitrogen-atom which connects the two other benzene nuclei. The constitution of leucophenosafranine (formed by oxidising equal mols. of paradiamidodiphenylamine and aniline) would thus be  $\text{NPh} \begin{smallmatrix} \text{C}_6\text{H}_3(\text{NH}_2) \\ \text{C}_6\text{H}_3(\text{NH}_2) \end{smallmatrix} \text{NH}$ . This reaction, and the formation of safranines by the oxidation of a paradiamine (1 mol.) with a monamine (2 mols.), explains why the para-position to the amidonitrogen cannot be taken up, and shows that 2 atoms of nitrogen are present in safranine as amido-groups.

The following constitutional formulæ are suggested for phenosafranine hydrochloride:—

The first formula is in accordance with the analogy of the dye with the thionine-group, and the fact that rosaniline yields a triazo-derivative, although its salts contain one imido- and two amido-groups. On the other hand, the presence of two intact amido-groups in the safranine dye, and the fact that toluylene-red can also be diazotised, are in favour of the second formula (comp. also Abstr., 1885, 1026).

N. H. M.

**Metanitromethylsalicylaldehyde and its Derivatives.** By A. SCHNELL (*Chem. Centr.*, 1886, 469—470).—All attempts to prepare a hydroxymethoxybenzaldehyde by the amidation and diazotation of the above compound (first prepared by Voswinckel, Abstr., 1882, 189) were unsuccessful. An amide was formed, but was so unstable that it could not be isolated.

When metanitromethylsalicylaldehyde is heated with sodium acetate and acetic anhydride, *metanitro-orthomethoxycinnamic acid*,

is formed. It melts at 238°, and when reduced with ammonia and ferrous sulphate yields *metamido-orthomethoxycinnamic acid*, which forms yellow needles melting at 189°. Sodium nitrite and concentrated hydrochloric acid convert this acid into *orthomethoxycinnamic acid diazo-chloride*,  $\text{C}_6\text{H}_4(\text{OMe})(\text{C}_3\text{H}_3\text{O}_2) \cdot \text{N} : \text{NCl}$ , which is very unstable. The corresponding *nitrate* is much more stable; it explodes at 151—152°. When either of these salts is heated with water, *metahydroxy-orthomethoxycinnamic acid* is formed, and yields yellow crystals melting at 179—180°. When this acid is fused with potash, it is almost completely decomposed; when methylated, it yields *methyl metorthodimethoxycinnamate (dimethylgentisate)*, a thick, red-brown oil, which yields the *acid* on saponification. The acid melts at 143°: Tiemann and Müller (Abstr., 1882, 53) give the melting point as 76°. This

acid when oxidised with alkaline permanganate yields dimethyl-gentisaldehyde.

These results prove the nitro-group to be present in the meta-position.

L. T. T.

**New Chlorine-derivatives of Acetophenone.** By H. GAUTIER (*Compt. rend.*, **103**, 812—814).—*Trichloracetophenone*,  $\text{COPh}\cdot\text{CCl}_3$ .—60 grams of trichloroacetic chloride is mixed with 100 grams of benzene, heated to the boiling point of the latter, and aluminium chloride added in small quantities. After treatment with water, the dried product is fractionated under reduced pressure, and the portion boiling at  $135\text{--}155^\circ$  under a pressure of 25 mm. is re-fractionated. About 20 to 25 grams of trichloracetophenone is thus obtained as a colourless liquid with a pungent odour and extremely burning taste. It remains liquid at  $-21^\circ$ , and boils without decomposition at  $145^\circ$  under a pressure of 25 mm., and with slight decomposition at  $249^\circ$  under atmospheric pressure; sp. gr. at  $16^\circ = 1.427$ . It is very slowly oxidised by alkaline potassium permanganate, yielding benzoic acid; when subjected to prolonged boiling with water, or when treated with very dilute alcoholic potash, the product is likewise benzoic acid.

*Dichloracetophenone*,  $\text{COPh}\cdot\text{CHCl}_2$ , is obtained in the same manner from 50 grams of dichloroacetic chloride and 100 grams of benzene; the yield being about 20 grams. It is a colourless liquid, with an odour and taste resembling those of the tri-derivative. It boils unchanged at  $143^\circ$  under a pressure of 25 mm., and with slight decomposition at  $247\text{--}248^\circ$  under atmospheric pressure; sp. gr. at  $15^\circ = 1.338$ . It is as difficult to oxidise as the tri-derivative, and is not sensibly affected by boiling water. When subjected to prolonged treatment with an alcoholic solution of potassium acetate, the whole of the chlorine is removed with formation of potassium chloride and a product which has not yet been examined.

These derivatives afford further illustration of the stability of chlorine in combination with the carbonyl-group. It is attacked with difficulty by reagents which readily remove the chlorine from the side-chains of benzene hydrocarbons, whilst energetic reagents act on the ketonic group, and give rise to simpler substitution derivatives of benzene.

C. H. B.

**Action of Sulphuric Acid on Aromatic Ketones.** By K. KREKELER (*Ber.*, **19**, 2623—2628; comp. Abstr., 1886, 538).—*Benzyl-methylketonesulphonic acid*,  $\text{SO}_3\text{H}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{COMe}$ , is prepared by heating benzyl methyl ketone with sulphuric acid on a water-bath. *Acetophenonesulphonic acid*,  $\text{SO}_3\text{H}\cdot\text{C}_6\text{H}_4\cdot\text{COMe}$ , is obtained by gradually adding pyrosulphuric acid (4 grams) to acetophenone (1 gram) kept well cooled; the intensely red liquid is then heated for half an hour on a water-bath. The *lead salt* dissolves very readily in water. The sulphonic acid reacts with phenylhydrazine, and yields the compound  $\text{N}_2\text{HPh}\cdot\text{COMe}\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\text{H}(\text{N}_2\text{HPh})$ ; this crystallises in lustrous plates, readily soluble in alcohol.

*Isobutyrothiënonesulphonic acid*,  $\text{CHMe}_2\cdot\text{CO}\cdot\text{C}_4\text{SH}_2\cdot\text{SO}_3\text{H}$ , is obtained

by acting on the thiënone with pyrosulphuric acid in the cold. The *lead* and *barium salts* are very readily soluble in water, and can be crystallised from dilute alcohol. The *phenylhydrazine-derivative*,  $N_2HPh : CPr^{\beta} \cdot C_4SH_2 \cdot SO_3H \cdot (N_2HPh)$ , crystallises in lustrous plates, readily soluble in alcohol, very sparingly in cold water.

N. H. M.

**Plöchl's Phenylglycidic Acid.** By E. ERLÉNMEYER, Jun. (*Ber.*, 19, 2576—2577).—The phenylglycidic acid prepared by Plöchl's method (*Abstr.*, 1884, 604) yields well characterised hydroxylamine- and phenylhydrazine-derivatives, and also gives the Laubenheimer-Victor Meyer thiophen reaction. From these facts, the author draws

the conclusion that the formula  $\begin{array}{c} \text{CHPh} \cdot \text{CH} \cdot \text{COOH} \\ \diagdown \quad \diagup \\ \text{O} \end{array}$  suggested by Plöchl cannot be sustained, and advances the view that the compound is probably phenylpyruvic acid.

W. P. W.

**Para- and Ortho-nitrophenyloxyacrylic Acid.** By A. LIPP (*Ber.*, 19, 2643—2650).—*Paranitrophenyloxyacrylic acid*, first obtained by Erlenmeyer, is readily prepared by heating paranitrophenyl- $\alpha$ -chlorolactic acid with alkalis; it crystallises in glistening leaflets, which melt at 186—188° with complete decomposition; when heated with sulphuric acid it yields paranitrophenylglyceric acid, which crystallises from water in small interlaced leaflets, melting at 167—168°. In order to determine whether the constitution of this acid is that of a glycide,  $\begin{array}{c} \text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH} \cdot \text{CH} \cdot \text{COOH} \\ \diagdown \quad \diagup \\ \text{O} \end{array}$ , or of a  $\beta$ -hydroxy-acid, its

reaction with hydrochloric acid was studied; nitrophenyl- $\beta$ -chlorolactic acid was formed, thus confirming the former view. This  $\beta$ -lactic acid resembles the corresponding  $\alpha$ -acid in appearance and behaviour towards solvents; it forms small, glistening crystals which melt at 167—168°. When boiled with water, it is completely decomposed into hydrochloric acid, carbonic anhydride, and a red resin; its *barium* salt when heated yields paranitrophenethylaldehyde and carbonic anhydride. Since the paranitrophenyl- $\alpha$ - and - $\beta$ -chlorolactic acids yield the same nitrophenylacrylic acid, which in its turn is reconverted into the  $\beta$ -lactic acid, the constitution of the oxyacrylic acid is analogous to that of glycidic acid, according to the formula written above.

The orthonitrophenylacrylic acid, obtained by Baeyer, behaves like the above in combining directly with hydrochloric and hydrobromic acids; its constitution therefore is analogous.

V. H. V.

**Amido-acids.** By R. STEPHAN (*Chem. Centr.*, 1886, 470—471).—Tiemann, Friedländer, and Priest (*Abstr.*, 1882, 50 and 56) have shown that the cyanhydrins of aromatic aldehydes form an easy source for the preparation of substituted amido-acids. The author finds that the same holds good in the case of aldehydes of the fatty series.

Acetaldehyde cyanhydrin, when heated on the water-bath with aniline, yields  $\alpha$ -anilidopropionitrile,  $NHPh \cdot CHMe \cdot CN$ , melting at 92°.

The *hydrochloride* forms crystals melting at  $86^{\circ}$ , and giving up hydrogen chloride very easily. The nitrile dissolves in boiling water with partial decomposition into its components. Neither hydrochloric acid nor potash causes hydrolysis, but when heated with these reagents the nitrile undergoes decomposition. When the nitrile is slowly added to concentrated sulphuric acid,  $\alpha$ -*anilidopropionamide* is formed; this melts at  $140$ — $141^{\circ}$ , and is decomposed when heated with strong potash. With hydrochloric acid, it yields  $\alpha$ -*anilidopropionic acid*, which melts at  $163^{\circ}$  and sublimes unchanged.

Ortho- and para-toluidine form compounds similar to the above.  $\alpha$ -*Paratoluidopropionitrile* melts at  $82^{\circ}$ ; the *amide*,

melts at  $145^{\circ}$ , and is more unstable than the anilido-amide; the free *acid* forms colourless, hygroscopic scales melting at  $152^{\circ}$ .

$\alpha$ -*Orthotoluidopropionitrile* melts at  $72$ — $73^{\circ}$ , the *amide* at  $125^{\circ}$ , and the *acid* at  $116^{\circ}$  when separated from alcoholic, but at  $123^{\circ}$  from aqueous solutions.

The hydrochlorides of these nitriles yield unstable, crystalline platinochlorides.

Bromine forms tribromo-substitution products.  $\alpha$ -*Tribromanilidopropionitrile*,  $\text{C}_6\text{H}_2\text{Br}_3\cdot\text{NH}\cdot\text{CHMe}\cdot\text{CN}$ , forms yellow needles melting at  $130^{\circ}$ ;  $\alpha$ -*orthotoluidodibromopropionitrile* melts at  $105^{\circ}$ , and  $\alpha$ -*paratoluidodibromopropionitrile* at  $117^{\circ}$ .

**Derivatives of Methyl Carbanilate.** By W. HENTSCHEL (*J. pr. Chem.* [2], 34, 423—427).—In a former communication (Abstr., 1885, 792), the author has described the formation of methyl amidosulphobenzoate from methyl carbanilate by the action of sulphuric acid. When the substance is decomposed with excess of bromine-water, and the solution allowed to remain for some days, a substance of the formula  $\text{C}_8\text{H}_7\text{O}_2\text{NBr}_2$  separates, which crystallises in needles, and melts at  $96.5^{\circ}$ .

This substance, in which two atoms of bromine have taken the place of the sulphonic group, when warmed with sulphuric acid yields dibromaniline sulphate, which on decomposition with sodium hydroxide gives ordinary dibromaniline (1 : 2 : 4).

When treated with nitric acid of sp. gr. 1.45, the brominated substance gives a nitro-compound, crystallising in silky needles, melting at  $152^{\circ}$ , and having the constitution

When heated with aqueous ammonia in a sealed tube, the nitro-compound yields dibromonitraniline (m. p.  $127.5^{\circ}$ ).

The acid liquid containing methyl amidosulphobenzoate yields a nitrocarbanilide when treated with strong nitric acid. This forms colourless plates or prisms, melts at  $189^{\circ}$ , and when heated with strong hydrochloric acid in sealed tubes, yields a dinitraniline which agrees in all respects with unsymmetrical metadinitraniline.

G. H. M.

**Ethyl Phthalylacetoacetate.** By C. BÜLOW (*Annalen*, **236**, 184—194).—Ethyl phthalylacetoacetate, prepared by the method described by Fischer and Koch (*Abstr.*, 1883, 806), is decomposed by the action of sulphuric acid at 65° for half an hour, yielding alcohol and acetic and phthalylacetic acids. It is also decomposed by prolonged boiling with water or with alkalis, but with a cold alcoholic solution of potassium hydroxide it yields a deliquescent crystalline compound,  $C_{14}H_{12}K_2O_8 + C_2H_6O$ , which is very soluble in water. At the ordinary temperature, ammonia converts ethyl phthalylacetoacetate into phthalylidiamide, but at a temperature of 100° phthalimide is formed.

*Ethyl phenylhydrazinephthalylacetoacetate*,  $C_{20}H_{18}N_2O_4$ , forms thick plates, soluble in alcohol, in strong acetic and sulphuric acids, and in alkalis. It melts at 236—238°, and on reduction with zinc-dust and acetic acid yields the ethylic salt of benzylacetoacetic-orthocarboxylic acid. This compound melts at 92°, and dissolves freely in hot water, alcohol, ether, chloroform, and acetic acid. It is decomposed by boiling with baryta-water, yielding *benzylacetoneorthocarboxylic acid*,  $COOH \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot C(OMe)_2$ . This acid dissolves freely in the usual solvents, and melts at 114°. The *phenylhydrazine* compound of *ethyl benzylacetoaceticorthocarboxylate*,  $COOH \cdot C_6H_4 \cdot CH_2 \cdot CH(COOEt) \cdot C(OMe)_2 : N_2HPh$ , forms pale-yellow, needle-shaped crystals. It melts with decomposition at 235°, and dissolves freely in alcohol, ether, chloroform and carbon bisulphide. At the ordinary temperature, and more rapidly at 100°, the compound splits up into alcohol, water, and a new substance,  $C_{18}H_{16}N_2O_3$ , which melts at 228—229°. W. C. W.

**Benzoic Sulphinide.** By I. REMSEN and A. G. PALMER (*Amer. Chem. J.*, **8**, 223—227).—Benzoic sulphinide may be sublimed; it is decomposed by simple evaporation with strong hydrochloric acid or by boiling with strong baryta-water, yielding orthosulphobenzoic acid. The following salts are described:— $C_7H_5SO_3NK + H_2O$ , very soluble crystals;  $C_7H_5SO_3NAg$ , sparingly soluble in boiling water, and separating in long needles;  $(C_7H_5SO_3N)_2Ba + 1\frac{1}{2}H_2O$ , easily soluble in water and difficult to crystallise; the methyl salt has also been prepared, but not completely examined. H. B.

**Parethoxybenzoic Sulphinide.** By I. REMSEN and A. G. PALMER (*Amer. Chem. J.*, **8**, 227—229).—Ethoxytoluenesulphonamide (this vol., p. 136) was oxidised in warm dilute aqueous solution with potassium permanganate; from the filtered and concentrated solution, hydrochloric acid precipitated *parethoxybenzoic sulphinide*,

The substance forms needle-shaped crystals, melting at 257—258°; it has not a sweet taste. The potassium and silver salts,  $C_9H_5SO_4NK$  and  $C_9H_5SO_4NAg$ , are described. H. B.

**Parabromobenzoic Sulphinide.** By I. REMSEN and W. S. BAYLEY (*Amer. Chem. J.*, 8, 229—235).—Parabromotoluenesulphonamide (Hübner and Post, this Journal, 1874, 57) was oxidised with potassium permanganate in considerable excess, when besides the sulphinide, there is also formed a considerable quantity of parabromosulphobenzoic acid; this substance is not formed if potash is also added during the oxidation. *Parabromobenzoic sulphinide* is sparingly soluble in cold water, volatilises at about  $200^{\circ}$ , melts at  $217^{\circ}$ , and is characterised by an extremely sweet taste, followed by an after-taste of extreme bitterness. The following salts are described:— $(C_7H_3O_3SNBr)_2Ba + 7\frac{1}{2}H_2O$ ;  $(C_7H_3O_3SNBr)_2Ca + 7\frac{1}{2}H_2O$ ;  $C_7H_3O_3SNBrAg + 2\frac{1}{2}H_2O$ . When treated with phosphorus pentachloride, and then with alcohol, the ethyl salt,  $C_7H_3O_3SNBrEt$ , is obtained as a substance which after recrystallisation from hot alcohol melts at  $199$ — $199.5^{\circ}$ . Attempts to prepare the ethyl salt from the silver salt and ethyl iodide were unsuccessful, a mixture of at least two substances being obtained.

H. B.

### **Benzoyltoluenesulphonamide and some of its Derivatives.**

By I. REMSEN and C. S. PALMER (*Amer. Chem. J.*, 8, 235—243).—Somewhat similar to the sulphinides is the class of substances represented by benzoylbenzenesulphonamide,  $Ph \cdot CO \cdot NH \cdot SO_2 \cdot Ph$ , and benzoyltoluenesulphonamide,  $Ph \cdot CO \cdot NH \cdot SO_2 \cdot C_6H_4Me$ , obtained by the action of benzoic chloride on the corresponding amides. But the constitution of these substances has not been definitely proved, and Wolkow has shown that benzamide when treated with benzenesulphochloride yields not benzoylbenzenesulphonamide, but toluenesulphonic acid and phenyl cyanide, and it is, therefore, possible that the above two substances are represented, not by  $R \cdot SO_2 \cdot NH \cdot COR$ , but by  $R \cdot SO_2 \cdot N : C(OH)R$ . On the first of these suppositions, two ethyl salts should be obtained, one,  $R \cdot SO_2 \cdot NEt \cdot COR$ , from the silver or lead salts and ethyl iodide, and the other,  $R \cdot SO_2 \cdot N : CR \cdot OEt$ , by acting on the sulphonamide with phosphorus pentachloride and alcohol; on the second supposition, only one ethyl salt can be prepared by either method, namely,  $R \cdot SO_2 \cdot N : CR \cdot OEt$ . It has already been shown, and is confirmed by the authors, that ethereal salts of benzoyltoluene-sulphonamide cannot be obtained by the action of phosphorus pentachloride and alcohol. Neither can they be obtained by the action of ethyl iodide on the lead or silver salts of the sulphonamide; similar negative results have been recorded by other writers.

But although the ethereal salts of the sulphonamides cannot be obtained from the sulphonamides, they may nevertheless be prepared indirectly. *Benzoylmethyltoluenesulphonamide*,  $C_7H_5O \cdot NMe \cdot C_6H_4SO_2$ , crystallises with difficulty; it melts at  $58^{\circ}$ , and is prepared by the action of benzoic chloride on *methylparatoluenesulphonamide*,  $NHMe \cdot SO_2 \cdot C_6H_4$ . On adding water to its alcoholic solution, the latter crystallises in plates melting at  $75^{\circ}$ , is very stable, and is obtained by treating paratoluenesulphochloride with methylamine.

*Benzylethyltoluenesulphonamide* was prepared, but not analysed; it is obtained from benzoic chloride and *ethylparatoluenesulphonamide*,

$\text{NHEt} \cdot \text{SO}_2 \cdot \text{C}_7\text{H}_7$ , melting at  $58^\circ$ , and prepared like the above methyl-compound.

*Benzoylphenyltoluenesulphonamide* crystallises readily from alcohol; the crystals melt at  $149^\circ$ ; when boiled with alcoholic potash, it yields benzoic acid and toluene-sulphanilide. It is prepared from *phenyl-paratoluenesulphonamide*,  $\text{NHPh} \cdot \text{SO}_2 \cdot \text{C}_7\text{H}_7$ , melting at  $103^\circ$ , and already prepared by Müller. H. B.

**Separation of the Two Isomeric Toluidinesulphonic Acids.** By E. A. SCHNEIDER (*Amer. Chem. J.*, 8, 274).—The potassium and sodium salts of paratoluidinemetasulphonic acid are very soluble in water, but insoluble in cold aqueous potash, whilst the potassium and sodium salts of paratoluidineorthosulphonic acid are very easily soluble in the same liquid at ordinary temperature.

H. B.

**Action of Concentrated Sulphuric Acid on Hydrazine-toluenesulphonic Acids.** By E. A. SCHNEIDER (*Amer. Chem. J.*, 8, 271—273).—It was hoped that condensation might be effected between the hydrazine- and sulphonic-groups. Parahydrazinetoluenesulphonic acid apparently underwent no change. Parahydrazine-toluenemetasulphonic acid reacts violently with sulphuric acid at  $80^\circ$ ; the product poured into water gives a bright red precipitate, not further examined, and the filtrate, with excess of soda, gives a yellow precipitate which resembles in all its properties the basic substance obtained by Gallinek and Richter (*Abstr.*, 1886, 236) by heating paratolylhydrazine with sulphuric acid, and is probably identical with it. H. B.

**Oxidation by Means of Potassium Permanganate.** By I. REMSEN and W. H. EMERSON (*Amer. Chem. J.*, 8, 262—268).—It has been stated "that acid oxidising agents tend to transform para-groups (hydrocarbon-chains) and leave ortho-groups unchanged, and that alkaline oxidising agents tend to transform ortho-groups and leave para-groups unchanged," and R. Meyer and Baur (*Abstr.*, 1881, 46) have adduced in favour of this the case of cymenesulphonic acid [ $\text{Me} : \text{SO}_3\text{H} : \text{Pr} = 1 : 2 : 4$ ], which with permanganate yields hydroxypropylsulphobenzoic acid [ $\text{COOH} : \text{SO}_3\text{H} : \text{C}_3\text{H}_7\text{O} = 1 : 2 : 4$ ], but with nitric acid yields sulphoparatoluic acid [ $\text{CH}_3 : \text{SO}_3\text{H} : \text{COOH} = 1 : 2 : 4$ ]. On the other hand, Jacobsen has shown that metaxylenesulphonamide [ $\text{SO}_3\text{H} : \text{Me} : \text{Me} = 1 : 2 : 4$ ] yields the same product of oxidation [ $\text{SO}_3\text{H} : \text{Me} : \text{COOH} = 1 : 2 : 4$ ] with either chromic acid or potassium permanganate.

Jacobsen's work is fully confirmed, and it is also shown that paraxylenesulphonic acid and paraxylenesulphonamide yield the same oxidation products with permanganate, namely, sulphoterephthalic acid and a sulpho- or sulphamido-paratoluic acid. By fusing the last-named compounds with potash, they are both converted into one and the same hydroxytoluic acid,  $\alpha$ -orthohomometahydroxybenzoic acid [ $\text{Me} : \text{OH} : \text{COOH} = 1 : 2 : 4$ ], and hence the methyl-group first oxidised is not that which is in the ortho-position relatively to the sulphonic group.

The work of Meyer and Baur was then repeated and fully confirmed, and finally the behaviour of cymene itself with alkaline permanganate was examined. It was found that the products of the oxidation were almost equal quantities of terephthalic acid and of hydroxypropylbenzoic acid,  $\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{C}_3\text{H}_7\text{O}$ , which was recognized by converting it into propenylbenzoic acid and isopropenylbenzoic acid. Cymene treated with chromic acid yields as the first product toluic acid, and hence the cause of the different behaviour of cymenesulphonic acid towards alkaline permanganate solution, and towards acid oxidising agents (nitric acid) is not to be sought for in the influence of the sulphonic group on the hydrocarbon side-chains (Meyer), but in the difference between the side-chains themselves, the isopropyl-group yielding most easily to acid oxidising agents, the methyl-group yielding most easily to alkaline oxidising agents. (Compare Abstr., 1886, 541.) H. B.

**Action of Bromine and Water on  $\alpha$ -Metaisocymenesulphonic Acid: Constitution of  $\alpha$ - and  $\beta$ -Metaisocymenesulphonic Acids.** By W. KELBE and N. v. CZARNOMSKI (*Annalen*, 235, 272—299).—In addition to the results which have previously appeared in this Journal (Abstr., 1882, 619; 1884, 1355; and 1886, 355), the authors describe the following compounds:—

*Lead  $\beta$ -bromometaisocymenesulphonate*,  $\text{Pb}(\text{C}_{10}\text{H}_{12}\text{BrSO}_3)_2 + \text{H}_2\text{O}$ , crystallises in needles, and is soluble in alcohol and in hot water. The barium salt forms colourless plates; the copper salt glistening green plates containing 4 mols.  $\text{H}_2\text{O}$ ; and the potassium salt,  $\text{C}_{10}\text{H}_{12}\text{Br} \cdot \text{SO}_3\text{K} + \text{H}_2\text{O}$ , silky needles. The sulphonamide,

melts at  $162^\circ$  and dissolves in strong alcohol, from which solvent it is deposited in transparent needles.

*$\alpha$ -Bromisocymenesulphonic acid* is very hygroscopic. After drying over sulphuric acid, it melts at  $126^\circ$ . Its salts are much more soluble than those of the  $\beta$ -acid. The barium and copper salts crystallise with 7 mols.  $\text{H}_2\text{O}$ . The potassium salt crystallises in needles containing 1 mol.  $\text{H}_2\text{O}$ . It dissolves readily in water or alcohol. The sodium salt contains 2 mols.  $\text{H}_2\text{O}$ . The sulphonamide forms long, white, needle-shaped crystals. It melts at  $170.5^\circ$ , and dissolves in hot water and alcohol.

Pure  $\alpha$ -bromisocymene,  $\text{C}_{10}\text{H}_{13}\text{Br}$ , boils at  $225^\circ$  instead of  $235^\circ$  as previously stated (Abstr., 1882, 618).

*Dibromocymene* is prepared by the action of bromine on an aqueous solution of  $\alpha$ -bromocymenesulphonic acid. It is an oily liquid boiling at  $272$ — $273^\circ$ . Pure bromocymene is obtained as a strongly refractive liquid when potassium  $\beta$ -bromometaisocymenesulphonate is decomposed by superheated steam. It boils at  $224^\circ$ , one degree lower than the  $\alpha$ -compound, and is slowly oxidised by nitric acid, yielding bromometatoluic acid (m. p.  $152^\circ$ ),  $\text{C}_6\text{H}_3\text{MeBr} \cdot \text{COOH}$  [1 : 4 : 3].

*General Conclusions.*—When metaisocymene dissolves in sulphuric acid, the  $\text{SO}_3\text{H}$  group displaces the H atoms at 4 or 6. Bromine

displaces the H atom at 4 in  $\alpha$ -cymenesulphonic acid, and at 6 in the  $\beta$ -acid.

When bromocymenes are dissolved in sulphuric acid, the sulphonic group takes the position 4 in the  $\alpha$ -compound, and 6 in the  $\beta$ -compound. The constitution of these compounds is shown in the following table :—

|  | $\alpha$ . | $\beta$ . |

**Synthesis of Indole-derivatives.** By E. FISCHER (*Annalen*, 236, 116—126).—Many of the results contained in this paper have already been published (Abstr., 1884, 52, 1180; and 1886, 835).—The fæcal odour of indole is most marked in skatole, and in the mono- and di-methyl compounds with the exception of those substances in which the methyl-group is united to the N-atom. The odour and volatility of the compounds is destroyed by the introduction of the phenyl-group. All indole-derivatives form crystalline picrates, and all the indoles with the exception of the carboxylic acids are reduced by zinc and hydrochloric acid to hydro-bases. The pine-wood reaction is not exhibited by the carboxylic acids, nor by those derivatives in which both the 2' and 3'\* hydrogen-atoms are replaced by methyl, ethyl, &c.

Nitrous acid converts indole and 1' methylindole into nitroso-compounds. It forms complicated products with 2' methyl or phenyl indole, and converts 3' or 2', 3' substituted indoles into nitrosamines.

The following is a list of indoles derived from the hydrazines.

|                            | Melting point. | Boiling point. |
|----------------------------|----------------|----------------|
| Monomethyl { 1'.....       | liquid         | 240°           |
| { 2'.....                  | 60°            | 272            |
| { 3'.....                  | 95             | 265–266        |
| Dimethyl .. { 2': 3' ..... | 106            | 285            |
| { 1': 2' .....             | 56             | ?              |

W. C. W.

**Indoles from Phenylhydrazine.** By E. FISCHER (*Annalen*, 236, 126—151).—Most of the compounds mentioned in this paper have already been described by the author (Abstr., 1886, 805). 2', 3' *Dimethylindole*,  $C_8NH_5Me_2$ , prepared from the phenylhydrazine compound of methyl ethyl ketone, melts at 106° and boils at 285°. The nitrosamine,  $C_8NH_4Me_2 \cdot NO$  [ $NO = 1'$ ], melts at 61—62°, and decomposes at a higher temperature. 2' 3' *Methylethylindole*,  $C_8NH_5MeEt$ , prepared from the phenylhydrazine of methyl propyl ketone, is an oily liquid boiling at 291—293°. The picrate crystallises in dark red needles. Phenylhydrazinelævulinic acid,

melts at 108°, and at a higher temperature splits up into water and the anhydride,  $C_{11}H_{12}N_2O$ . This substance crystallises in colourless plates. It melts at 106—107° and boils between 340° and 350° with partial decomposition. Ethyl phenylhydrazinelævulinate melts at 110°. *Methylindoleacetic acid*, prepared from this ethyl salt, melts between 195° and 200°, and splits up into carbonic anhydride and 2', 3' dimethylindole.

W. C. W.

**Indoles from Methylphenylhydrazine.** By J. DEGEN (*Annalen*, 236, 151—164).—The preparation of 1', 2' dimethylindole, 1', 2' methylphenylindole, and 1', 2', 3' dimethylindolecarboxylic acid from the compounds of methylphenylhydrazine with acetone, acetophenone, and ethyl acetoacetate, respectively, has already been described (Abstr., 1886, 805). Dimethylindolecarboxylic acid crystallises in six-sided plates. It melts at 185° with partial decomposition into carbonic anhydride and 1', 2' dimethylindole. 1', 2', 3' Dimethylindoleacetic acid (*loc. cit.*) melts at 188° and decomposes at 200°, yielding 1', 2', 3' *trimethylindole*, an oily liquid which boils about 280° without decomposition. The picrate melts at 150°. Trimethylindole is obtained in a less pure state by the action of zinc chloride on the compound of methylphenylhydrazine with methyl ethyl ketone. 1', 3' Dimethylindole is obtained in an impure state by acting on propyldenemethylphenylhydrazine with zinc chloride.

W. C. W.

**Indoles from Metahydrazinebenzoic Acid.** By A. RÖDER (*Annalen*, 236, 164—173).—Metahydrazinebenzoic acid is con-

veniently prepared by adding the theoretical quantity of sodium nitrite to 100 grams of metamidobenzoic acid suspended in a mixture of 400 grams of water and 190 grams of strong hydrochloric acid. The liquid is poured into an ice-cold solution of sodium sulphite (4 mols.  $\text{Na}_2\text{SO}_3$  to 1 mol. amido-acid). As soon as the mixture turns yellow, strong hydrochloric acid is added to precipitate the hydrochloride of metahydrazinebenzoic acid. The free acid is obtained by adding sodium acetate to a solution of the hydrochloride. The acetone compound is formed when acetone and sodium acetate or potassium hydroxide are added to a solution of the hydrochloride. This substance forms colourless needles melting at  $150^\circ$ . It is freely soluble in alcohol and acetic acid, and is easily decomposed by warm mineral acids into acetone and hydrazinebenzoic acid. The *ethylic* salt  $\text{C}_{10}\text{H}_{11}\text{N}_2\text{O}_2\text{Et}$ , melts at  $90-91^\circ$  and dissolves freely in alcohol, ether and acetic acid. *Hydrazinebenzopyruvic acid*,  $\text{C}_{10}\text{H}_{10}\text{N}_2\text{O}_4 + \text{H}_2\text{O}$ , melts at  $206-208^\circ$  with decomposition, and is freely soluble in ammonia and fixed alkalis. The barium and sodium salts are crystalline. The *ethyl* salt,  $\text{C}_{10}\text{H}_9\text{N}_2\text{O}_4\text{Et}_2$ , melts at  $101-102^\circ$ . It dissolves freely in alcohol, ether, and in warm benzene. By the action of zinc chloride on this compound, the ethyl salt of indoledicarboxylic acid is formed, together with indole and a small quantity of another substance. *Monethyl indoledicarboxylate* crystallises in needles and melts at  $250^\circ$  with decomposition. It is freely soluble in alcohol. The free acid melts at  $250^\circ$  with decomposition. It dissolves freely in hot alcohol and in acetic acid. It has the constitution  $[(\text{COOH})_2 = 4:2' \text{ or } 3:2']$ . Hydrazinebenzoic acid unites with benzaldehyde, forming *benzylidenehydrazinebenzoic acid*. This acid crystallises in plates, melts at  $170-172^\circ$ , and is freely soluble in alcohol and acetic acid. *Phenylglucosazonecarboxylic acid* melts at  $206-208^\circ$  with decomposition. Metahydrazinebenzoic acid unites with phenyl isothiocyanate, forming *diphenylthiosemicarbazidecarboxylic acid*,  $\text{C}_{14}\text{H}_{13}\text{N}_3\text{O}_2$ . This substance crystallises in colourless needles and melts at  $204-205^\circ$  with decomposition.

W. C. W.

**Aluminium Chloride Reaction.** By R. ANSCHÜTZ (*Annalen*, 235, 150—229 and 299—341). The experimental results of the author's research on the aluminium chloride reactions have already been published (Abstr., 1883, 807, 809, 1132; 1884, 326, 753, 754, 1034; 1885, 269, 768, 769). The following conclusions are deduced from these results.

Dibenzyl and unsymmetrical diphenylethane (obtained by the action of aluminium chloride and benzene on the isomeric dibromethylenes) correspond with the dibromethylenes in constitution.

The synthesis of anthracene from aluminium chloride, benzene, and acetylene tetrabromide, indicates that the mesocarbon-atoms in anthracene are probably linked together. The formation of dimethylanthracene from toluene, acetylene tetrabromide, and aluminium chloride, shows that the methyl-groups in dimethylanthracene, melting at  $225^\circ$ , are divided between the two benzene nuclei. Aluminium chloride not only removes but also transfers the side-chains of methyl-

and ethyl-benzenes from one molecule to another. Only the symmetrical tetraphenylethane is known.

In many aluminium chloride reactions, theoretical yields are obtained when carbon bisulphide is used as a diluent.

Symmetrical mesodimethylantracene hydride is formed, together with ethylbenzene and unsymmetrical diphenylethane, by the action of benzene and aluminium chloride on ethylidene bromide or chloride, or on vinyl bromide. Ethyltoluene, unsymmetrical ditolyethane, and tetramethylantracene hydride are formed by the action of aluminium chloride on ethylidene chloride and toluene. A new dimethylantracene is formed by heating the tetramethylantracene hydride with zinc-dust.

**Dehydrogenation by Means of Benzoic Peroxide.** By E. LIPPMANN (*Monatsh. Chem.*, **7**, 521—528).—Benzoic peroxide can react as a dehydrogenising agent, removing two hydrogen-atoms from two molecules of an aromatic hydrocarbon. Thus from toluene a hydrocarbon,  $C_{14}H_{12}$ , is formed; the hydrocarbon boils at 258—262°, is strongly refractive, and of aromatic odour, sp. gr. 1.0032; it is isomeric with stilbene and diphenylethylene, and as, on oxidation, it yields benzoic acid only, its constitution is probably expressed by the formula  $\langle \begin{smallmatrix} C_7H_6 \\ C_6H_4 \end{smallmatrix} \rangle CH_2$ , that of a benzylidenetoluene.

Similarly from xylene, a hydrocarbon,  $C_{16}H_{16}$ , is obtained as a refractive liquid, boiling at 260—270°, sp. gr. 998; as being isomeric with ditolyethylene and dimethylstilbene, it is named dixylylene.

V. H. V.

**Formation of Substituted Stilbenes.** By K. ELBS (*J. pr. Chem.* [2], **34**, 340—342).—On endeavouring to extend Strakosch's method of synthesis of stilbene-derivatives by the action of potash on benzyl-derivatives, the reaction with orthonitrobenzyl chloride was successful, but in the case of parabromobenzyl bromide the corresponding alcohol was obtained together with ethyl parabromobenzoate; the latter substance, the derivation of which in the above reaction is not satisfactorily explained, is a colourless viscid liquid, boiling at 236° under a pressure of 713 mm., of odour resembling pears, soluble in most menstrua with the exception of water, saponified only with difficulty.

V. H. V.

**Substituted Stilbenes.** By K. ELBS and F. BAUER (*J. pr. Chem.* [2], **34**, 343—347).—Paradinitrostilbene is not altered by potassium permanganate; on oxidation with chromic acid in acetic acid solution, it is readily converted into paranitrobenzoic acid. With bromine, it forms *paradinitrostilbene bromide*,  $NO_2 \cdot C_6H_4 \cdot CHBr \cdot CHBr \cdot C_6H_4 \cdot NO_2$ , a white, crystalline powder melting above 300°, but decomposing even at 110° with evolution of hydrobromic acid and the formation of paradinitrotolane; it is sparingly soluble in most menstrua. When an acetic acid solution of paradinitrostilbene bromide is boiled with potassium acetate, ethyl paradinitrohydrobenzoin acetate,

is formed; this crystallises in small, yellow crystals, melting at 340°, moderately soluble in alcohol, ether, and acetic acid.

Paradinitrotolane,  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{C} : \text{C} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ , obtained as described above, and best purified by sublimation, crystallises in needles melting at  $288^\circ$ ; it usually separates from solvents in the amorphous form.

V. H. V.

**Euxanthone-group.** By C. GRAEBE and A. FEER (*Ber.*, 19, 2607—2614).—Spiegler (*Abstr.*, 1884, 1182) ascribed to benzophenone oxide the constitution  $\langle \text{C}_6\text{H}_4 \cdot \text{O} - \text{C}_6\text{H}_4 \cdot \text{CO} \rangle$ , as it reacts neither with hydroxylamine nor with phenylhydrazine. The authors suggest for

this compound the constitution  $\text{C}_6\text{H}_4 - \text{C} \begin{array}{c} \text{O} \quad \text{O} \\ \diagup \quad \diagdown \end{array} - \text{C}_6\text{H}_4$ ; this would account for the negative result with hydroxylamine, as well as for the fact that it yields dihydroxybenzophenone when fused with potash (Richter, *Abstr.*, 1884, 324).

Orthodihydroxybenzophenone (Richter, *loc. cit.*) boils at  $330\text{--}334^\circ$  with partial decomposition into water and benzophenone oxide. The potassium salt has the formula  $\text{CO}(\text{C}_6\text{H}_4 \cdot \text{OK})_2$ . The *phenylhydrazine* and *hydroxylamine-compounds* melt at  $152^\circ$  and  $99^\circ$  respectively. The methyl salt was found to melt at  $104^\circ$  (not  $98^\circ$ ); it undergoes no change when heated with alcoholic potash at  $150^\circ$ ; the *hydroxylamine-derivative* melts at  $188^\circ$ . The *ethyl salt* crystallises from alcohol in colourless needles melting at  $109^\circ$ ; the *phenylhydrazine-compound* melts at  $114^\circ$ . The acetyl-derivative melts at  $96^\circ$  (not  $83^\circ$ ). When paracresol salicylate is subjected to the same treatment as the phenyl salt in the preparation of benzophenone oxide (Siefert, *Abstr.*, 1885, 1058), the compound  $\text{C}_6\text{H}_4 \langle \text{CO} \rangle \text{C}_6\text{H}_5\text{Me}$  is formed; this is very readily soluble in hot alcohol and melts at  $105^\circ$ .  $\alpha$ -Naphthol salicylate yielded  $\alpha$ -naphthophenone oxide,  $\text{C}_{17}\text{H}_{10}\text{O}_2$ ; it melts at  $155^\circ$ , and dissolves very readily in hot toluene. The *picrate* is yellowish-red.  $\beta$ -Naphthophenone oxide crystallises in needles melting at  $140^\circ$ .

When euxanthonic acid is fused with potash, it is converted into quinol; it has therefore the constitution

An *ethyl salt* was obtained which reacts with hydroxylamine.

N. H. M.

**Preparation of Dinitronaphthylamine: Metanitrophenyl-azodimethylamidobenzene.** By R. MELDOLA (*Ber.*, 19, 2683—2684).— $\alpha$ -Naphthylamine is boiled for several hours with acetic acid; the theoretical amount of nitric acid (sp. gr. 1.5) diluted with glacial acetic acid is then gradually added to the warm solution of the acetone-naphthalide and the whole warmed until the reaction is finished. The product is then poured into cold water, filtered, and washed well with cold water. The precipitate whilst still moist, is mixed in small quantities with strong sulphuric acid and warmed; it is then poured into cold water, and the orange-red precipitate washed with water; it may be purified by recrystallisation from alcohol. The yield of crude substance is almost theoretical.

Metanitrophenylazodimethylamidobenzene (Staedel and Bauer, Abstr., 1886, 944) has already been fully described by the author (Trans., 1884, 120).  
N. H. M.

**Eurhodines and Laurent's Naphthase.** By O. N. WITT (Ber., 19, 2791—2796).—The *eurhodol*,  $C_{14}H_8 \begin{smallmatrix} \diagup N \diagdown \\ | \\ \diagdown N \diagup \end{smallmatrix} C_{10}H_5 \cdot OH$ , is obtained by fusing sodium diphenylenenaphthaquinoxalinesulphonate (Abstr., 1886, 889) with potash until the yellow colour suddenly changes to a pure cinnabar-red. When the product is diluted with water and treated with hydrochloric acid in excess, the *hydrochloride* separates as a cinnabar-red, insoluble powder. If acetic acid is used in the place of hydrochloric acid, the free eurhodol separates in orange-yellow crystalline flakes. It is insoluble in all solvents and can only be purified by recrystallising the hydrochloride from boiling phenol. When heated, it sublimes with partial decomposition. Sulphuric acid dissolves it with a pure deep blue colour which changes immediately on addition of very little water to a splendid carmine-red; when the blue solution is heated to a certain point it becomes successively violet, red, and yellow. The dry eurhodol is electric.

$\alpha$ - $\beta$ -Naphthaquinoxaline,  $C_{10}H_6 \begin{smallmatrix} \diagup N \diagdown \\ | \\ \diagdown N \diagup \end{smallmatrix} C_{10}H_6$ , is prepared by the action of  $\beta$ -naphthaquinone on orthonaphthylenediamine in acetic acid solution; it is purified by crystallisation from naphthalene. It forms yellow needles melting sharply at  $275^\circ$ . It dissolves in sulphuric acid, yielding a pure violet solution which becomes orange-yellow when diluted; when further diluted, the free base is precipitated. It sublimes readily in long, yellow needles, and when quickly heated distils as a yellow oil which soon solidifies. It is identical with Laurent's naphthase (*Annalen*, 9, 384; compare also Nietzki and Goll, Abstr., 1885, 545).  
N. H. M.

**Indoles from  $\beta$ -Naphthylhydrazine.** By A. SCHLIEPER (*Annalen*, 236, 174—184).—The  $\beta$ -naphthylhydrazine described by E. Fischer (Abstr., 1886, 555) unites with acetone, forming the compound  $C_{10}H_7 \cdot N_2H : CMe_2$ . This substance crystallises in prisms of a pale-yellow colour. It melts at  $65.5^\circ$ , and is freely soluble in alcohol, ether, benzene, acetone, and in (hot) light petroleum. *Ethylidene  $\beta$ -naphthylhydrazine*,  $C_{10}H_7 \cdot N_2H : CHMe$ , forms three-cornered plates, soluble in hot alcohol, benzene, and chloroform. It melts at  $128$ — $129^\circ$ .  *$\beta$ -Naphthylhydrazinepyruvic acid*,  $C_{10}H_7 \cdot N_2H : CMe \cdot COOH$ , forms yellow needles. This acid melts at  $166^\circ$ , and decomposes with evolution of carbonic anhydride. It dissolves in hot alcohol and acetic acid. The ethyl salt melts at  $131^\circ$ , and is freely soluble in alcohol, ether, benzene, and acetic acid. On fusion with zinc chloride,  $\beta$ -naphthindole is produced;  $\beta$ -naphthindolecarboxylic acid is formed as an intermediate product. After purification by conversion into the picrate,  $\beta$ -naphthindole,  $C_{10}H_6 < \begin{smallmatrix} NH \\ CH \end{smallmatrix} \geq CH$ , boils at  $222^\circ$  under 18 mm. pres-

sure, and above  $360^{\circ}$  under the ordinary atmospheric pressure. It dissolves in alcohol, ether, benzene, and acetic acid with fluorescence. Strong hydrochloric acid forms a crystalline compound with it.

*$\beta$ -Naphthindolecarboxylic acid*,  $C_{10}H_6<\begin{smallmatrix} NH \\ CH \end{smallmatrix}>C\cdot COOH$ , crystallises in colourless plates, soluble in alcohol and acetic acid. It melts at  $226^{\circ}$  with evolution of carbonic anhydride. The sodium and barium salts are sparingly soluble in cold water. The ammonium and potassium salts are much more soluble.

*Methylnaphthindole*,  $C_{10}H_6<\begin{smallmatrix} NH \\ CH \end{smallmatrix}>CMe$ , from acetone- $\beta$ -naphthylhydrazine, boils between  $314^{\circ}$  and  $320^{\circ}$  under a pressure of 223 mm. It is freely soluble in alcohol, ether, and benzene. The picrate melts at  $176^{\circ}$ . On reduction with nascent hydrogen, *hydromethyl- $\beta$ -naphthindole* is obtained as an oily liquid, boiling between  $190$  and  $200^{\circ}$  under 20 mm. pressure. It is a strong base, and with mineral acids, forms salts which are very soluble in water. W. C. W.

**Action of Monamines on Citric Acid.** By H. HECHT (*Ber.*, 19, 2614—2618).—*Citrotrimethylamide*,  $C_6H_5O_4(NHMe)_3$ , is prepared by adding a strong solution of methylamine to a concentrated solution of methyl citrate in absolute alcohol, and keeping the product over sulphuric acid for some time. It separates in prisms melting at  $124^{\circ}$ ; it is very readily soluble in cold water, and is not acted on by alkali or hydrochloric acid.

*Citrodinaphthylamide*,  $C_{10}H_7\cdot N : C_6H_5O_4\cdot NH\cdot C_{10}H_7$ , is formed when a mixture of citric acid (1 mol.) and  $\beta$ -naphthylamine (3 mols.) is heated at  $140$ — $150^{\circ}$  for several hours. It crystallises in six-sided plates melting at  $233^{\circ}$ . It is insoluble in water or hydrochloric acid, sparingly soluble in alcohol.

The *trinaphthylamide*,  $C_6H_5O_4(NH\cdot C_{10}H_7)_3$ , is obtained by heating the dinaphthylamide with naphthylamine (eq. mols.) at  $150$ — $160^{\circ}$ ; it forms microscopic, prismatic crystals readily soluble in alcohol, insoluble in water; it melts at  $215^{\circ}$ , and is very stable.

*Citrodinaphthylamic acid*,  $OH\cdot C_6H_5O_4(NH\cdot C_{10}H_7)_2$ , is prepared by heating the dinaphthylamide with an excess of concentrated ammonia for six hours at  $170^{\circ}$ . It crystallises from alcohol in slender, microscopic needles melting at  $172^{\circ}$ ; it is readily soluble in alkali, insoluble in water. The silver salt was prepared.

*Monobasic naphthylamine citrate*,  $C_6H_5O_8NC_{10}H_9$ , separates as a rose-coloured substance when a hot, concentrated alcoholic, solution of citric acid (1 mol.) is mixed with  $\beta$ -naphthylamine (1 mol.) and cooled. It melts at  $89^{\circ}$ , dissolves readily in alcohol, ether, nitrobenzene, and water.

Compounds isomeric with the above were prepared from  $\alpha$ -naphthylamine in a similar manner. *Citrodinaphthylamide* is purified by precipitating the solution in glacial acetic acid with water; it crystallises from benzene in six-sided plates melting at  $194^{\circ}$ ; it is insoluble in hydrochloric acid. *Citrotrinaphthylamide*,  $C_6H_5O_4(NHC_{10}H_7)_3$ , crystallises in microscopic, rhombic prisms which melt at  $129^{\circ}$ . Boiling alkali solution and acids do not act on it. *Citrodinaphthylaminic acid*

crystallises in small groups of needles melting at  $149^{\circ}$ ; the alcoholic solution reacts slightly acid. The *silver salt* is sparingly soluble in water. N. H. M.

**Action of Ammonia on Ethyl Acetonedicarboxylate: Synthesis of Pyridine-derivatives.** By H. N. STOKES and H. V. PECHMANN (*Ber.*, 19, 2694—2717).—Ethyl  $\beta$ -hydroxamidoglutamate (Abstr., 1885, 1202) is readily soluble in hot water and in alcohol; the aqueous solution decomposes gradually, giving off ammonia. It gives a deep red coloration with ferric chloride.

The compound obtained by the action of alkalis on ethyl  $\beta$ -hydroxamidoglutamate and described as glutazine (*loc. cit.*), is shown to be a pyridine-derivative, probably having the constitution

It melts at about  $300^{\circ}$  with evolution of ammonia, is moderately soluble in hot water, almost insoluble in hot alcohol, and insoluble in other solvents. The neutral solution acquires a deep-red colour on addition of ferric chloride; on warming, the solution turns dark-green without becoming turbid. The *hydrochloride* (with 1 mol.  $\text{H}_2\text{O}$ ) crystallises in prisms readily soluble in alcohol; water decomposes it. The *sulphate* was prepared. The *sodium*, *ammonium*, and *barium salts* are very soluble.

Pentabromacetylacetamide (*loc. cit.*) melts at  $148^{\circ}$ ; at a higher temperature, it gives off bromine and hydrogen bromide. It is insoluble in water, readily soluble in alcohol, ether and glacial acetic acid, moderately in chloroform. When heated with water, it is converted into dibromacetamide, bromoform, and carbonic anhydride. Boiling alcoholic ammonia converts it into dibromomalonamide (melting at  $200.5^{\circ}$ ) and bromoform.

*Acetylglutazine*,  $\text{NH} < \begin{array}{c} \text{CO} \cdot \text{CH}_2 \\ \text{CO} \cdot \text{CH}_2 \end{array} > \text{C} : \text{N} \cdot \text{Ac}$ , is obtained by heating glutazine with acetic chloride at  $100$ — $120^{\circ}$ . It crystallises from water in small lustrous plates, which darken at  $230^{\circ}$  and melt at  $285$ — $290^{\circ}$ . When warmed with ferric chloride, it acquires a brilliant violet colour. The *ammonium* (with 1 mol.  $\text{H}_2\text{O}$ ), *silver*, and *barium salts* were prepared.

2, 4, 6 *Trihydroxypyridine* is prepared by boiling glutazine for 3—4 minutes with an excess of strong hydrochloric acid and then evaporating the solution in clock glasses as quickly as possible on a water-bath. The dry residue is extracted with cold alcohol and the solution quickly evaporated; the thick syrup so formed is mixed with a little water and a solution of caustic soda (0.3 gram to 1 gram glutazine) in twice its weight of water added, the whole being kept cool. The crystalline product is washed with a little water and dried. It forms yellow, microscopic needles which swell up when heated at  $220$ — $230^{\circ}$  and give off water. It dissolves readily in hot water, but is insoluble in other solvents. When treated with ferric chloride, it gives a deep-red coloration. Bromine-water converts it into pentabromacetylacetamide. It reacts strongly acid and decomposes carbonates. The salts

of the alkalis and alkaline earths are very readily soluble in water. When distilled with zinc-dust, it yields a small quantity of pyridine. Hydroxylamine hydrochloride reacts with trihydroxypyridine, yielding a *monoxime*,  $C_5NH_5O_2:N\cdot OH + H_2O$ . The latter is a heavy, sandy powder consisting of hexagonal plates; it melts at  $194-196^\circ$  with evolution of gas. It is rather soluble in hot water, less so in alcohol. When treated with strong soda solution, it becomes blue; with ammonia, it gives a yellowish-red colour which changes to intense purple when warmed. The oxime forms salts with acids. It is also formed by acting on glutazine with hydroxylamine. The *phenylhydrazine-compound* (obtained from both trihydroxypyridine and glutazine) forms plates readily soluble in hot alcohol; it melts at  $230^\circ$ .

When trihydroxypyridine is heated with ammonium acetate at  $120-140^\circ$ , it is converted quantitatively into glutazine.

*Trihydroxypyridine anhydride*,  $C_{10}H_8O_5N_2$ , is formed as the chief product in the decomposition of glutazine by boiling dilute sulphuric acid. It crystallises in flesh-coloured, microscopic prisms; it is very stable, and melts only at a high temperature. It is insoluble in all neutral solvents except water, which dissolves it slowly. It dissolves readily in an excess of alkali. The *hydrogen barium salt*,

forms yellow prisms insoluble in water and alcohol. The normal alkali and alkaline earth salts are readily soluble in water; they are not decomposed by carbonic anhydride. The *hydrochloride* crystallises in needles readily soluble in alcohol; it is decomposed by water. The *sulphate* crystallises from water in prisms. The anhydride can be converted into trihydroxypyridine by evaporating its aqueous solution.

The way in which glutazine is formed shows that the nitrogen of the pyridine-ring has the para-position to the side-chain containing nitrogen, and the ortho-position to both the oxygen-atoms. Hence the three oxygen-atoms in trihydroxypyridine must be symmetrical to one another and to the nitrogen, and trihydroxypyridine is therefore analogous to phloroglucinol. The analogy of the two compounds is seen in their yielding anhydrides and in their behaviour towards ammonia and hydroxylamine (compare Baeyer, Abstr., 1886, 350). It is probable that the pyridine-derivative exists in two forms, as shown in the following formulæ:—

3, 5 Dichloro-2, 6-dihydroxy-4-amidopyridine (*loc. cit.*) forms short flat needles melting at  $241.5^\circ$ ; it dissolves sparingly in hot water and alcohol, readily in alkali and dilute hydrochloric acid.

2, 4, 6 Trichloro-4-amidopyridine forms long colourless needles melting at  $157.5^\circ$ ; it is very readily soluble in alcohol, readily in dilute hydrochloric acid, and insoluble in alkali; it sublimes unchanged.

2, 3, 5 Trichloro-6-hydroxy-4-amidopyridine, melting at  $282^\circ$ , is very readily soluble in hot water, moderately in hot alcohol, sparingly in

ether and benzene. It is a monobasic acid, and decomposes carbonates. The *sodium salt* is rather soluble in water, sparingly in alcohol.

2, 3, 5, 6 Tetrachloro-4-amidopyridine melts at  $212^{\circ}$ , and sublimes unchanged. It is insoluble in water, soluble in alcohol and benzene. It can be boiled with strong sulphuric acid without decomposition. When heated with fuming hydriodic acid at  $200^{\circ}$ , black crystals of an *iodine-derivative* melting below  $80^{\circ}$  are formed. This, by solution in dilute sulphuric acid and precipitation with alkali, is converted into what is probably *dichloramidopyridine*; it melts at  $158^{\circ}$ . When the tetrachloro-compound is boiled with sodium ethoxide and alcohol, 2, 3, 5 *trichloro-6-ethoxy-4-amidopyridine* is formed; this crystallises in needles which melt at  $83^{\circ}$ . It distils with steam, is insoluble in water, alkali, and dilute acids, very readily soluble in alcohol, ether, benzene, &c. Dilute hydrochloric acid converts it (at rather above  $100^{\circ}$ ) into trichlorhydroxyamidopyridine (m.p.  $282^{\circ}$ ) and ethyl chloride. *Dichloro-diethoxy-3-amidopyridine*,  $C_5N_2H_2Cl_2(OEt)_2$ , and *dichloro-2-hydroxyethoxy-4-amidopyridine*,  $C_5N_2H_2Cl_2(OH) \cdot OEt$ , are formed by heating tetrachloramidopyridine with excess of sodium ethoxide and alcohol at  $190^{\circ}$ . The former crystallises in long needles melting at  $98^{\circ}$ ; it is very readily soluble in alcohol and ether, insoluble in water, alkalis, and dilute acids, and distils with steam. The latter crystallises from very dilute alcohol in flat needles which melt at  $161.5^{\circ}$ . It dissolves readily in alcohol, ether and alkalis, and is insoluble in dilute acids. The two compounds are also formed from trichlorhydroxyamidopyridine and from the diethoxy-compound by the action of sodium ethoxide and alcohol at  $190^{\circ}$ . N. H. M.

**Correction.** By A. LADENBURG and C. F. ROTH (*Ber.*, 19, 2586; compare Abstr., 1885, 994).—The authors state that in the mixture of bases of high boiling point from animal oil examined by them, aniline was present and accumulated in the fraction  $174-176^{\circ}$ , from which they separated the supposed new lutidine. A repetition of the experiments has not yet been possible owing to a difficulty in obtaining the material. W. P. W.

**Derivatives of Picolinic and Nicotinic Acids.** By E. SEYFFERTH (*J. pr. Chem.* [2], 34, 241-263).—At the outset, unsuccessful experiments are described, made with a view of obtaining hexahydropicolinic acid from the acid itself by the action of various hydrogenising agents. But in each case either the acid was not acted on or was decomposed with formation of picoline and its hydro-derivatives.

*Chloropicolinic acid*,  $C_5NH_3Cl \cdot COOH$ , is obtained by boiling chloropicoline trichloride,  $C_5NH_4Cl \cdot CCl_3$  (from picolinic acid and phosphoric chloride), with 80 per cent. sulphuric acid, and pouring the product into water. It crystallises in needles and prisms, often showing twinning. It melts at  $180^{\circ}$ , is sparingly soluble in cold water, readily soluble in hot water, alcohol and chloroform. It has strongly acid properties and does not form salts with dilute mineral acids. Its *calcium salt* crystallises with  $1H_2O$  in transparent prisms, and its *barium salt* in nodular aggregates. Both salts are sparingly

soluble in cold, but readily in hot water; its *silver* salt is a voluminous, flocculent precipitate. With reducing agents, it yields picoline and picolinic acid.

*Chlorohydroxypicolinic acid*,  $\text{OH}\cdot\text{C}_5\text{NH}_2\text{Cl}\cdot\text{COOH}$ , formed simultaneously with the above, crystallises in clusters of needles, melts above  $315^\circ$ , is sparingly soluble in cold, readily in hot water, alcohol, and ether. Like the above acid, it does not combine with mineral acids.

These acids are not identical with those obtained by Ost (Abstr., 1883, 794). With phosphoric chloride, nicotinic acid yields an oil containing chlorine, and this, when boiled with sulphuric acid, is converted into chlorhydroxy- and dichloro-nicotinic acids, together with trichloropyridine. The first of these acids crystallises in monoclinic prisms and needles, melting at  $302^\circ$ , sparingly soluble in cold, readily in hot water and alcohol. The aqueous solution gives with silver nitrate a white, flocculent precipitate, soluble in ammonia, and with ferric chloride a dirty red precipitate. Its barium salt crystallises in transparent rhombic prisms.

*Trichloropyridine*,  $\text{C}_5\text{NH}_2\text{Cl}_3$ , crystallises in colourless needles, melting at  $64^\circ$ , insoluble in water, soluble in alcohol, ether and benzene.

*Dichloronicotinic acid* crystallises in small, white, grouped needles, melting at  $138^\circ$ ; its *ethyl* salt forms colourless needles, melting at  $50^\circ$ , sparingly soluble in water, but soluble in alcohol, ether, and chloroform.

V. H. V.

**Bromoquinoline.** By A. CLAUS and F. COLLISCHONN (*Ber.*, 19, 2763—2769).—It was previously mentioned (this vol., p. 60) that when quinolinepropiobromide dibromide is heated, the hydrobromide of a new monobromoquinoline is formed. The bromo-compound is heated at  $170^\circ$  for some time, and then at  $190^\circ$ ; a crystalline residue is thus obtained without carbonisation. The bromoquinoline is separated from the quinoline that may be present by distilling with steam: the hydrobromide of the bromo-compound is decomposed, the free base going over with the steam, whilst the quinoline salt remains behind. It is a slightly yellow oil, having an odour resembling that of quinoline; it boils at  $273\text{--}274^\circ$  (uncorr.). The *hydrobromide* forms characteristic envelope-shaped crystals, which dissolve sparingly in cold water with partial decomposition, more readily in alcohol, and is almost insoluble in chloroform. When carefully heated at about  $190^\circ$ , it sublimes without having melted. The *hydrochloride* sublimes readily without melting. The *platinochloride*,  $(\text{C}_9\text{NH}_6\text{Br})_2\cdot\text{H}_2\text{PtCl}_6$ , crystallises from dilute hydrochloric acid in slender, orange-coloured needles. The *nitrate* and *sulphate* melt respectively at  $180^\circ$  and  $182\text{--}183^\circ$  (uncorr.). The *dichromate* crystallises in flat, short prisms, which melt at  $144\text{--}145^\circ$  with decomposition. The *compound*  $(\text{C}_9\text{NHBr})_2\cdot\text{AgNO}_3$  melts at  $172\text{--}173^\circ$ , and detonates at a high temperature with evolution of red vapour. The same bromoquinoline is obtained when an ethereal solution of bromine is added to a solution of quinoline in ordinary ether (containing alcohol); a yellow precipitate is formed. The latter crystallises from chloroform in lustrous, garnet-coloured crystals, melting at  $88^\circ$  (uncorr.). Analysis points to the formula  $\text{C}_9\text{NH}_7\cdot\text{HBr}\cdot\text{Br}_2$ . When exposed to air it gives off bromine. The *hydrochloride*,

$C_9H_7, HCl, Br_2$ , forms small, orange-coloured crystals melting at  $100-105^\circ$ . When the hydrobromide of the quinoline dibromide is heated at  $180^\circ$ , it is converted with evolution of hydrobromic acid into bromoquinoline hydrobromide.

When bromoquinoline is oxidised with potassium permanganate, Friedländer and Ostermayer's oxalylanthranilic acid (Abstr., 1882, 732), melting at  $210^\circ$  (not  $200^\circ$ ), and *bromopyridinedicarboxylic acid*,  $C_5NH_2Br(COOH)_2$ , are obtained. The latter forms yellowish crystals, readily soluble in water, alcohol, ether, &c.; it melts at  $165^\circ$  with evolution of carbonic anhydride and formation of *bromonicotinic acid*, melting at  $183^\circ$  (uncorr.).

The bromoquinoline described above is identical with that obtained by La Coste (Abstr., 1881, 741) by brominating quinoline hydrochloride.

N. H. M.

**Synthetical Experiments with Ethyl Acetoacetate.** By L. KNORR (*Annalen*, 236, 69—115).—The action of ethyl acetoacetate on aniline at different temperatures has already been investigated by the author (Abstr., 1884, 334). The anilide of acetoacetic acid, previously described as  $\beta$ -phenylamido- $\alpha$ -crotonic acid, melts at  $85^\circ$  and decomposes on distillation, yielding symmetrical diphenylcarbamide. On the addition of bromine to a solution of the anilide in chloroform, an unstable additive product is formed, which decomposes when the mixture is warmed, yielding the *anilide of monobromacetoacetic acid*,  $COMe \cdot CHBr \cdot CO \cdot NHPh$ . This substance crystallises in plates, and melts at  $138^\circ$  with decomposition. *Isonitrosoacetoacetic anilide*,  $COMe \cdot C(NO) \cdot CO \cdot NHPh$ , crystallises in prisms, and is freely soluble in alcohol, ether, acetic acid, and light petroleum. It melts at  $99-100^\circ$ . On reduction with zinc and acetic acid, a crystalline compound, melting between  $212^\circ$  and  $215^\circ$ , is obtained.

The formation of *hydroxylepidine* ( $\gamma$ -methylcarbostyryl),

by the action of dehydrating agents on acetoacetic anhydride, has been already described (Abstr., 1884, 334 and 1198), and this substance has been described under the names of hydroxymethylquinoline and hydroxyquinaldine. On distillation with zinc-dust, it is converted into  $\gamma$ -*lepidine*, and it yields chlorolepidine when treated with phosphoric chloride (Abstr., 1885, 274). *Chlorolepidine*,  $C_9NH_5MeCl [Me : Cl = 2' : 4']$ , melts at  $59^\circ$  and boils at  $296^\circ$  (corr.); it yields  $\gamma$ -methylquinoline when reduced with hydriodic acid, and also when decomposed by water at  $200^\circ$ .

*Methoxylepidine*,  $C_9NH_5Me \cdot OMe$ , formed by the action of potassium methoxide on chlorolepidine, is an oily liquid boiling at  $275-276^\circ$ . It forms a crystalline platinochloride. *Ethoxylepidine* melts at  $51^\circ$  and boils at  $250^\circ$  under 342 mm. pressure. Chlorolepidine reacts with aniline, forming *phenylepidinamine*, a crystalline compound melting at  $129-130^\circ$ . The platinochloride melts at  $235^\circ$ .

*Methylepidone* or *dimethylpseudocarbostyryl*,  $C_6H_4 \langle \begin{smallmatrix} CMe : CH \\ NMe \cdot CO \end{smallmatrix} \rangle$ , has already been described by the author as dimethylpseudoquinoxyl

(Abstr., 1885, 274). It can be prepared by the action of methyl iodide on hydroxylepidine, by the condensation of methylaniline and ethyl acetoacetate, and also by heating methoxylepidine at  $280^{\circ}$ . Methyllepidone melts at  $130-132^{\circ}$ , and sublimes without decomposition. It boils at  $290^{\circ}$  under 250 mm. pressure. It is a strong base, forming salts which are not decomposed by water. The platinumchloride,  $(C_{11}H_{11}NO)_2 \cdot H_2PtCl_6 + 3H_2O$ , decomposes at  $214-215^{\circ}$ . Nascent hydrogen converts methyllepidone into a sparingly soluble crystalline compound, which melts at  $258^{\circ}$ . With bromine-water, methyllepidone forms *bromomethyllepidine*,  $C_{11}H_{10}NOBr$ . This compound crystallises in needles and melts at  $172^{\circ}$ . It is insoluble in water and alkalis, but dissolves in dilute acids and forms a crystalline platinumchloride. On the addition of bromine to a solution of methyllepidone in chloroform, a dibromo-additive product appears to be formed. It is decomposed by warm water, forming monobromo-methyllepidone.

The properties of methyllepidone, methoxylepidine, and lepidine are seen in the following table:—

|                           | Methyllepidone.                          | Methoxylepidine.                  | Lepidine.                    |

W. C. W.

**Metaquinolinecarboxylic Acid.** By Z. H. SKRAUP and P. BRUNNER (*Monatsh. Chem.*, 7, 519—520).—It is here shown that the seventh quinolinecarboxylic or the metaquinolinebenzocarboxylic acid, recently obtained by Tortelli from  $\alpha$ -amidophthalic acid by means of the glycerol reaction, is also formed in small quantities, together with its isomeride, from meta-amidobenzoic acid, by means of the same reaction. In previous experiments, its formation was overlooked (Abstr., 1882, 71).

V. H. V.

**Synthesis of Active Conine.** By A. LADENBURG (*Ber.*, 19, 2578—2583).—Further experiments on a larger scale, and with pure materials, have confirmed the author's previous results (Abstr., 1886, 478).  $\alpha$ -Allylpyridine boils at  $187.5-192.5^{\circ}$ , and is a strongly refracting liquid of sp. gr. 0.9595 at  $0^{\circ}$ , sparingly soluble in water, and having a distinct conyryne-like odour. The platinumchloride,  $(C_3H_5 \cdot C_5H_4N)_2 \cdot H_2PtCl_6$ , melts at  $185-186^{\circ}$ , and crystallises in needles sparingly soluble in water. The aurochloride melts at  $135-136^{\circ}$ ; the mercuriochloride and cadmio-iodide are also described. By the action of sodium on an alcoholic solution at the boiling point,  $\alpha$ -allyl-

pyridine is reduced almost quantitatively to  $\alpha$ -propylpiperidine. This base has a sp. gr. 0.8626 at 0°, and boils at 166—167°; its hydrochloride crystallises in white, silky needles, melting at 203—205°. In smell, solubility, specific gravity, and physiological action,  $\alpha$ -propylpiperidine resembles conine, and not only are the platinochlorides, aurochlorides, and cadmio-iodides similar, but when  $\alpha$ -propylpiperidine is converted into conyryne by Hofmann's method, a blue fluorescence is obtained just as with conine. This fluorescence is due to an accompanying product, for if the fluorescent base after separation from unaltered conine be converted into the platinochloride, the conyryne regenerated from it is no longer fluorescent. Conyryne platinochloride from conine crystallises in monoclinic forms:  $a : b : c = 1.0614 : 1 : 1.5374$ ;  $\beta = 87^\circ 8'$ ; and the crystals from the synthetical base give practically the same values on measurement.

$\alpha$ -Propylpiperidine, however, in addition to the lower melting point of its hydrochloride, is optically inactive, and must be regarded as a physical isomeride of conine. To effect a separation into two optically active bases, a sterilised nutritive solution containing 0.5 per cent. of the tartrate was seeded with *Penicillium glaucum*, but without result. The active base, however, was obtained by introducing a crystal of the salt into a very concentrated solution of  $\alpha$ -propylpiperidine hydrogen tartrate; a slow separation of crystals took place, which yielded a dextrorotatory base, whose specific rotation was  $[\alpha]_D = 13^\circ 87'$ , compared with  $[\alpha]_D = 13^\circ 79'$  for conine. The hydrochloride of the synthetical active base melts at 217.5°, that of conine at 217.5—218.5°.

From the mother-liquor, a lævorotatory base was obtained, but it contained a large proportion of the dextrorotatory modification, which could not be further separated by the crystallisation method. However, on converting this lævorotatory mixture into the cadmio-iodide, it was found that after crystallisation, the crystallised salt yielded a base which was less lævorotatory than before, whilst from the mother-liquor a base was obtained, which in a 50 per cent. alcoholic solution gave a rotation of  $-3^\circ 30'$  in a decimetre tube, compared with  $3^\circ 10'$  for conine under the same conditions. W. P. W.

**Reduction of Nicotine.** By A. LIEBRECHT (*Ber.*, 19, 2587—2598).—The author gives reasons for regarding nicotine as a  $\beta\beta$ -hexahydrodipyridyl, in which one of the pyridine nuclei has taken up two, and the other four atoms of hydrogen. The author not having succeeded in obtaining dipyridyl by the oxidation of nicotine, has examined the complete reduction product obtained from its solution in absolute alcohol by the action of sodium (comp. Abstr., 1886, 161).

*Dipiperidyl*,  $C_{10}H_{20}N_2$ , is a colourless, oily liquid, solidifying at a low temperature, and having an odour like that of piperidine. It has a sp. gr. = 0.9561 at 4°, is lævorotatory, boils at 250—252° without decomposition, and is volatile to some extent with steam. In water, alcohol, and ether, it is readily soluble, and on exposure to light or the air it turns slowly yellow. Contrary to expectation, dipiperidyl acts only as a feeble poison. Dipiperidyl is a bi-acid base: its simple salts are very soluble and do not readily crystallise, although some

of the double salts crystallise well. The *hydrochloride* is very deliquescent; the *periodide*,  $C_{10}H_{20}N_2 \cdot 2HI \cdot 2I_2$ , crystallises in brown needles, which lose iodine on drying in the air. The *platinochloride*,  $C_{10}H_{20}N_2 \cdot H_2PtCl_6$ , forms small, red prisms, which on rapid crystallisation, separate either singly or in staurolite-like groups: it melts at  $202-203^\circ$ . The *aurochloride*,  $C_{10}H_{20}N_2 \cdot 2HAuCl_4$ , crystallises in yellow laminæ, melting at  $131-132^\circ$ , and is sparingly soluble in water. A mercuriochloride,  $C_{10}H_{20}N_2 \cdot 2HCl \cdot 5HgCl_2$ , crystallises in small sparingly soluble tables. Carbon bisulphide combines with dipiperidyl, forming a yellow salt, easily soluble in water and alcohol, less soluble in benzene and insoluble in ether. It readily becomes resinified, and when its alcoholic solution is boiled with mercuric chloride, the odour of allylthiocarbimide is evolved.

*Diacetodipiperidyl*,  $C_{10}N_2H_{18}Ac_2$ , is prepared by heating the base with acetic anhydride at  $170^\circ$  for six hours. It is a yellow, oily liquid, boiling at  $400-410^\circ$  with slight decomposition, and does not solidify in a freezing mixture.

The action of methyl iodide results in the formation of the hydriodides of two bases, dimethyl- and trimethyl-dipiperidyl, of which the former is readily soluble, whilst the latter is insoluble in water.

*Dimethyldipiperidyl*,  $C_{10}N_2H_{18}Me_2$ , is an oil boiling at  $230-332^\circ$ , soluble in water in all proportions, and slightly volatile with steam. Its salts, with the exception of the *mercuriochloride*,

are readily soluble, and can scarcely be crystallised; the *platinichloride*,  $C_{10}H_{18}Me_2N_2 \cdot H_2PtCl_6$ , forms small dark red crystals.

*Trimethyldipiperidyl*,  $C_{10}H_{17}Me_3N_2$ , is obtained as a yellow oil of repulsive odour resembling that of methylamine, boiling at  $205-212^\circ$ ; it is insoluble in water, and is not volatile with steam. The salts are very easily soluble and seem to be uncrystallisable, the *platinochloride*,  $C_{10}H_{17}Me_3N_2 \cdot H_2PtCl_6$ , is insoluble in alcohol and ether. The action of methyl iodide does not appear to yield a higher methylated base than trimethyldipiperidyl.

W. P. W.

**Sparteine.** By E. BAMBERGER (*Annalen*, **235**, 368-376).—Sparteine was discovered by Stenhouse (this Journal, 1851, 213), and its compounds were afterwards investigated by Mills (this Journal, 1862, 1). The author has re-examined these bodies, and his results in many cases differ from the observations of Mills. Sparteine boils at  $311-311.5^\circ$ , under a pressure of 723 mm. The *sulphate*,  $C_{15}H_{25}N_2 \cdot H_2SO_4$ , forms large, transparent prisms, which are very soluble in water. The hydriodide,  $C_{15}H_{26}N_2 \cdot HI$ , forms glistening, four-sided plates, which probably belong to the rhombic system. It is freely soluble in alcohol and in hot water. When aqueous hydriodic acid acts on sparteine, a resinous mass is formed, from which the dihydriodide can be obtained in silky needles, by boiling the alcoholic solution with animal charcoal.

The compound  $C_{15}H_{27}N_2EtI_2$ , which Mills obtained by the action of ethyl iodide and alcohol on sparteine at  $100^\circ$ , is decomposed by

sodium hydroxide solution, forming an oily liquid, which can be separated into sparteine and sparteine ethiodide, by means of ether. *Sparteine ethiodide*,  $C_{15}H_{26}N_2, EtI$ , is formed by the action of ethyl iodide on sparteine. It crystallises in thick prisms, and dissolves freely in water and alcohol. Sparteine methiodide crystallises in rhombic plates;  $a : b : c = 0.8989 : 1 : 1.6009$ . The methyl hydroxide is a deliquescent substance, with a strongly alkaline reaction. The carbonate crystallises in needles. When sparteine is oxidised with potassium permanganate, the chief product is oxalic acid; acetamide is also formed, together with a small quantity of a pyridine-derivative.

W. C. W.

**Pseudomorphine.** By O. HESSE (*Annalen*, **235**, 229—232).—When potassium hydroxide (2 mols.) and potassium ferricyanide (1 mol.) are added to a solution of pure morphine hydrochloride dissolved in 40 parts of water, pseudomorphine is deposited; 100 parts by weight of morphine yield 88.4 parts of pseudomorphine. This result shows that the reaction takes place according to the equation  $2C_{17}H_{19}NO_3 + 2KOH + 2K_3FeCy_6 = 2C_{17}H_{18}NO_3 + 2H_2O + 2K_4FeCy_6$  (the yield is theoretically 99.6 per cent.); not according to the following reaction:  $2C_{17}H_{19}NO_3 + 2KOH + 2K_3FeCy_6 = C_{17}H_{17}NO_3 + C_{17}H_{19}NO_3 + 2H_2O + 2K_4FeCy_6$  (the yield is only 49.65 per cent. of the morphine employed). This shows that the formula for pseudomorphine is  $C_{17}H_{18}NO_3 \cdot C_{17}H_{18}NO_3$ , as proposed by Polstorff (*Abstr.*, 1889, 405), instead of  $C_{17}H_{17}NO_3$ , as formerly proposed by the author (*Abstr.*, 1884, 616).

W. C. W.

**Papaverine.** By G. GOLDSCHMIEDT (*Monatsh. Chem.*, **7**, 485—505).—In this paper derivatives of papaveraldine, and the most convenient method for its preparation, are described.

The *nitrate*,  $C_{20}H_{19}NO_5 \cdot HNO_3$ , crystallises in citron-yellow needles; the *picrate*, in needles grouped together in voluminous aggregates; the *oxime*,  $C_{20}H_{20}N_2O_5$ , in flat, white needles melting at  $245^\circ$ ; the *methiodide*, in golden prisms melting at  $135^\circ$  with decomposition; and the *ethobromide*, in large prisms melting at  $270^\circ$ .

Papaveraldine, if heated only for a short time with potash, yields veratric acid together with small quantities of a dimethoxyquinoline, the constitution of which is at present uncertain.

With tin and dilute hydrochloric acid, papaverine yields a tetrahydro-derivative,  $C_{20}H_{25}NO_4$ , which crystallises in small, white prisms melting at  $200^\circ$ , soluble in benzene and acetone, sparingly soluble in ether and petroleum. Its *hydrochloride* crystallises in transparent prisms of the monoclinic system, melting with violent decomposition at  $290^\circ$ ; when injected internally, it causes albuminuria with inflammation of the kidneys. The *acid sulphate* forms acicular, and the *acid oxalate* prismatic crystals; the *dichromate*, glistening prisms; and the *picrate*, lemon-yellow needles. The *platinochloride* crystallises in minute yellow needles, and the *stannochloride* in concentrically grouped needles.

In an additional note, the author defends the formula  $C_{20}H_{21}NO_4$  for papaverine, as against  $C_{21}H_{21}NO_4$ , that proposed by Hesse, Beckett,

and Wright, and others; exception is also taken to a statement of Hesse relative to the existence of an alkaloid, pseudopapaverine.

V. H. V.

**Papaverine Salts.** By R. JAHODA (*Monatsh. Chem.*, **7**, 506—516).—As a further proof of the formula  $C_{20}H_{21}NO_4$ , proposed for papaverine, a number of its salts have been prepared and analysed; the results attained afford a strong confirmation of the above view.

The neutral *succinate* forms large tabular crystals melting at  $171^\circ$ , soluble in hot water; the *benzoate*, triclinic crystals ( $a : b : c = 0.459 : 1 : 0.680$ ;  $\eta = 95.27^\circ$ ), melting at  $145^\circ$ , soluble in alcohol, insoluble in water; the *salicylate*, monoclinic crystals ( $a : b : c = 1.161 : 1 : 1.685$ ;  $\eta = 102.39^\circ$ ), melting at  $130^\circ$ ; the *diodide* of the *hydroiodide*,

purple crystals of the monoclinic system.

The hydrochloride gives with halogen salts of the metals double crystalline salts, of which the following are described:—The *cadmiochloride*,  $(C_{20}H_{21}NO_4, HCl)_2CdCl_2$ , small crystals, of the tetragonal system;  $a : a : c = 1 : 1 : 0.646$ , melting at  $176^\circ$ ; the *cadmio-bromide* and *-iodide*, white precipitates, melting at  $150^\circ$  and  $180^\circ$  respectively; and the *zinciodide*, crystallising in small leaflets.

V. H. V.

**Constitution of Cinchonine.** By Z. H. SKRAUP (*Monatsh. Chem.*, **7**, 517—518).—The author criticises the view of Bischoff and Rach that cinchonic acid is  $\beta$ - $\gamma$ -dicarboxyl- $\delta$ -valerolactone (*Abstr.*, 1886, 1012); a study of the syrupy oxidation product of cinchonine and quinine has indicated the presence of an amorphous acid,  $C_8H_{13}NO_4$ , a base of the formula  $C_9H_{17}NO_2$ , difficult to obtain in the free state, although its salts form well-developed crystals, as also of a base of the formula  $C_9H_7NO$ , probably identical with kynurine, and an amorphous substance of the supposed composition  $C_{13}H_{13}NO_2$ , and of doubtful origin.

V. H. V.

**Specific Rotatory Power of Piperidine Bases.** By A. LADENBURG (*Ber.*, **19**, 2584).—The results obtained in a previous paper (this vol., p. 160) are in accordance with Le Bel-Van't Hoff's hypothesis, since  $\alpha$ -propylpiperidine contains an asymmetric carbon-atom in its constitutional formula. As this is true of all  $\alpha$ -alkyl-derivatives of piperidine, the author has examined  $\alpha$ -pipercoline and  $\alpha$ -ethylpiperidine, and by converting them into their dextro-tartrates has succeeded in obtaining optically active modifications of each. Dextro-rotatory  $\alpha$ -pipercoline has a specific rotatory power of  $21^\circ 8'$ .

W. P. W.

**Action of Bromine on Dimethylpiperidine; New Synthesis of Piperidine-derivatives.** By G. MERLLING (*Ber.*, **19**, 2628—2632).—The author previously obtained (*Abstr.*, 1884, 1385) by the action of bromine on dimethylpiperidine, two compounds—bromodimethylpiperidineammonium bromide and a hydrobromide. The latter is now shown to be dibromodimethylpiperidine hydrobromide. When the free base is warmed with alcohol, the alkaline solution becomes neutral, and characteristic crystals of monobromodimethylpiperidine-

ammonium bromide separate. These reactions can be explained by the constitutional formula assigned by Ladenburg to dimethylpiperidine:  $\text{CH}_2\cdot\text{CH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{NMe}_2$ . The constitution of dibromodimethylpiperidine and the ammonium bromide would then be

The formation of the hydrobromide of dibromodimethylpiperidine is probably due to 2 mols. of the free base reacting with one another; this view was strengthened by the discovery of a base free from bromine in the last mother-liquor from dibromodimethylpiperidine hydrobromide.

N. H. M.

**Hæmin Crystals.** By K. BIKFALVI (*Chem. Centr.*, 1886, 499).—Blood free from chlorine yields no hæmin (chlorohæmatin) crystals when heated with glacial acetic acid. The author finds, however, that if NaCl, NaBr, KBr,  $\text{NH}_4\text{Br}$ , NaI, or KI be first added to the blood, crystals resembling chlorohæmatin are formed.

L. T. T.

**Diastase.** By C. J. LINTNER (*J. pr. Chem.* [2], **34**, 378—394).—The author has examined the different methods proposed for the preparation of pure diastase, and determined the diastatic activity of the substances obtained. He adopts Kjeldahl's law of proportionality (*Abstr.*, 1880, 562), and uses the modification of Kjeldahl's method for determining diastatic activity, described in a former paper (*Abstr.*, 1886, 386). In place of his former method for preparing soluble starch, he now recommends the following:—A quantity of pure potato-starch is mixed with a sufficient quantity of 7·5 per cent. hydrochloric acid to cover it; it is then allowed to remain for seven days at the ordinary temperature or for three days at  $40^\circ$ , when the starch has lost the power of gelatinising. The structure of the starch, however, remains unaltered. It is then well washed with cold water until every trace of acid is removed, and dried in the air. So obtained it is soluble in hot water to a bright and limpid solution. A 2 per cent. solution will remain clear for some days, but 10 per cent. solutions set to a jelly-like mass on cooling. The acid used must not exceed 7·5 per cent. as 10 per cent. acid causes the gelatinisation of the starch; with sulphuric acid, however, it requires at least 15 per cent. acid digested at  $40^\circ$  to effect the conversion into soluble starch. Lintner uses a 2 per cent. solution of this soluble starch instead of that prepared by the method previously given.

The diastatic activity of the precipitated diastases is expressed as 100, when 3 c.c. of a solution of 0·1 gram diastase in 250 c.c. water added to 10 c.c. of a 2 per cent. starch solution produces in one hour, at the ordinary temperature, sufficient sugar to reduce 5 c.c. of Fehling's solution. Diastase is best prepared from green malt or from air-dried malt. Lintner examined the preparation obtained from these malts by extraction with water and glycerol and subsequent precipitation with alcohol, both before and after heating at  $70^\circ$ , and obtained, in all cases, a substance with a comparatively slight diastatic activity. As the result of his experiments, he recommends the following method of preparation:—1 part of green malt or sifted air-dried malt is extracted with 2 to 4 parts of 20 per cent. alcohol for 24 hours. The filtered

extract is mixed with  $2\frac{1}{2}$  volumes absolute alcohol; the precipitate quickly settles, and is washed on a filter with absolute alcohol; it is then transferred to a mortar, well mixed with absolute alcohol, thrown on a filter, and thoroughly washed with absolute alcohol and ether. Finally, it is dried in a vacuum over sulphuric acid. So obtained it is a light, yellowish-white powder with great diastatic activity. It is purified by repeated solution in water and precipitation with alcohol, and finally by dialysis. Loew's method of purification by means of precipitation with lead acetate is not to be recommended, since diastase loses three-fourths of its activity in the process. By purification, both the percentage of nitrogen and the diastatic activity are increased, whilst the amount of ash, which consists entirely of normal calcium phosphate, is diminished. A preparation obtained from green malt contained 8.3 per cent. nitrogen and diastatic activity = 96. After two precipitations the nitrogen = 9.06 per cent., and the activity = 100. This submitted to dialysis had the percentage of nitrogen raised to 9.9, and the percentage of ash diminished from 10.6 to 4.79. These and other analyses show that the diastatic activity increases with the amount of nitrogen. A purified diastase gave the following numbers on analysis, calculated on the ash-free substance. For the purpose of comparison the analyses of other soluble ferments are given:—

|                    | C.    | H.   | N.    | S.                   |
|--------------------|-------|------|-------|----------------------|
| Diastase.....      | 46.66 | 7.35 | 10.42 | 1.12 (Lintner).      |
| Pancreatic ferment | 46.57 | 7.17 | 14.95 | 0.95 (Hüfner).       |
| Invertase .....    | 43.9  | 8.4  | 9.5   | 0.6 (Barth, Donath). |
| Emulsin .....      | 43.5  | 7.0  | 11.6  | 1.3 (Bull).          |

Diastase gives all the reactions for the albuminoids, but not the characteristic biuret reaction for peptones; it gives, however, a characteristic blue coloration with tincture of guaiacum and hydrogen peroxide, which is soluble in ether, benzene, chloroform, and carbon bisulphide, but not in alcohol. This reaction is given by no other soluble ferment or protein substance. G. H. M.

*Note.*—Lintner appears to have overlooked the fact that O'Sullivan (this Journal, Trans., 1884, 2) described an almost identical method of preparing pure diastase. G. H. M.

**Action of Diastase and Invertin.** By H. MÜLLER (*Ann. Agronom.*, 12, 481—482).—The author has studied the action of these ferments under conditions such as prevail in the plant-cell, with a view to elucidate their physiological importance. Both ferments are active at 0°, but the activity increases until the neighbourhood of 50° is reached: the temperatures being 0°, 10°, 20°, 30°, 40°; the energy of diastase is expressed by the numbers 7, 20, 38, 60, 98, and that of invertin by the numbers 9, 19, 36, 63, 93.

Under ordinary conditions, cell-sap contains much carbonic anhydride, and is exposed to a pressure of several atmospheres. Both of these circumstances accelerate the activity of the ferments. Even at the ordinary pressure, saturation of the liquid with carbonic anhydride may have the effect of tripling the energy of diastase, and in presence

of carbonic anhydride diastase has the power of acting on starch which has not been boiled to a paste. Between the limits of 2 and 20 per cent., concentration of a sugar solution has little effect on the action of invertin, which is a little more feeble in strong solutions than in weak ones, but the accumulation of invert sugar is strongly opposed to the continuance of the reaction. J. M. H. M.

## Physiological Chemistry.

**Natural and Artificial Digestion.** By T. PFEIFFER (*Zeit. physiol. Chem.*, 11, 1—24).—The author has previously criticised the work of Stutzer on this subject (see Abstr., 1886, 1053). Additional experiments on pigs are now brought forward, and from them the following results are drawn:—

1. A comparison of the method of natural digestion of the nitrogenous constituents of the food combined with the investigation of the products of metabolism, with the method of artificial digestion of the food-stuff by pepsin and trypsin as devised by Stutzer, shows that there is an almost absolute agreement between the two.

2. By the help of Stutzer's method, the digestibility of the nitrogenous constituents of the food can be estimated with sufficient accuracy. This always gives results which agree more closely than those obtained with the method hitherto used, in which the products of nitrogenous metabolism in the fæces are not investigated.

W. D. H.

**Glycogen in the Liver of New-born Dogs.** By B. DEMANT (*Zeit. physiol. Chem.*, 11, 142—144).—In the intra-uterine condition, the liver is stated to be very poor in glycogen. Hoppe-Seyler states the opposite to be the case. The present research investigates the matter in the case of the dog; the glycogen was estimated by Brücke's method, and the result found was that in the days following birth glycogen was present in exceedingly large quantities; this is illustrated by the following table:—

| Age of animal.    | Percentage quantity of glycogen in the liver. |
|-------------------|---|
| 1 hour .....      | 11·389  |
| 3½ hours .....    | 9·527   |
| 3 hours .....     | 5·443   |
| 4 days .....      | 2·627   |
| 11 „ .....        | 2·792   |
| 12 „ .....        | 3·664   |
| Fully grown ..... | 1·661   |

W. D. H.

**Lactic Acid in Animals.** By A. HIRSCHLER (*Zeit. physiol. Chem.*, 11, 41—42).—Lactic acid has been described as occurring in the grey matter of the brain, and in the parenchymatous juices of the spleen, thymus, lymphatic glands, &c. Which variety of lactic acid this is,

has not yet been investigated. The present research is concerned with this question in relation to the spleen and lymphatic glands of the ox. Lactate of zinc was obtained by Hoppe-Seyler's method, with the modification that the finely chopped organ was extracted by 0.5 per cent. sulphuric acid instead of by cold water; in this way, more lactic acid is obtained. By estimation of the water of crystallisation of the zinc salt, and of the hydrogen and carbon, the conclusion is drawn that both in the spleen and lymphatic glands it is sarcolactic acid which is present.

W. D. H.

**Pigments of Melanotic Sarcomata.** By K. A. H. MÖRNER (*Zeit. physiol. Chem.*, **11**, 66—140).—The name *melanin* has been hitherto used for the pigments occurring in the eye, hair, and skin, in pathological new growths, and also for the decomposition products of chromogens in urine. The black pigment of the retina has been investigated by Berzelius, who found it contained a small quantity of iron, by Scherer who found no iron, and also by Rosow and Sieber. The percentage composition obtained by the various observers shows great discrepancies, and this, with their methods of preparing the pigment, renders it probable that they were not dealing with a pure substance. Concerning the black pigment of the skin of negroes and of the hair, still less is known, and although some few percentage estimations have been made by Sieber, the result cannot be described as a convincing one.

The pigment of melanotic tumours was first investigated by Heintz, who found that it was soluble in alkalis with difficulty, and that it contained no iron. An elementary analysis gave the following figures: C = 53.40, H = 4.02, and N = 7.10 per cent. Dressler made a similar investigation, and found in the pigment a small quantity of iron. Berdez and Nencki named the pigment *Phymatorusin*; they found it to be insoluble in water, alcohol, and ether, easily soluble in solutions of fixed alkalis or their carbonates, and in ammonia; from such solutions it was precipitable by acids, but was somewhat soluble in excess. The preparation contained carbon, hydrogen, oxygen, and nitrogen, sulphur in large amount (10.67 per cent.), but no iron, phosphorus, or chlorine. In horses, they found in melanotic tumours a pigment with somewhat different properties, which they called *hippomelanin*.

In the urine of some of these patients, a pigment has been found which according to some is an excess of the ordinary urine pigments, and according to others is the same pigment that occurs in the tumour. It is turned a dark-brown colour by the action of nitric acid; and in some cases a similar change occurs after mere exposure. The uncertain and contradictory statements of previous observers cannot but render uncertain which of the above statements is correct. Again, in other cases of these tumours, particles of a brown pigment are found in the blood, the corpuscles having the normal shape and colour; similar granules have been occasionally described in the urine and urinary passages.

The present research was undertaken with the material supplied by a patient, the full particulars of whose case are given. During life, the urine showed the peculiar coloration above-mentioned; after

death, the tumour itself was investigated. Its situation was the shoulder; secondary growths were present in the liver, but none in the kidney substance. The blood, except for a low percentage of hæmoglobin, was normal. The colouring matter did not give any absorption-bands, but produced a general dimming of the spectrum, especially towards the violet end. The methods by which the pigment was investigated were: first, by the spectrophotometer to determine the extinction coefficients in different parts of the spectrum; and, secondly, by elementary analysis. Although the quantity of material at hand was small, and therefore some results are incomplete, and others put forward with reserve, yet certain definite conclusions were arrived at. The pigment was found to contain iron, which also was estimated spectrophotometrically, as well as by the usual methods; the spectrophotometric method consisted in converting the iron of the ash into ferric thiocyanate, and comparing its extinction coefficients with those obtained from a solution of ferric chloride of known strength similarly treated. Iron was present in small quantities; the failure of some previous observers to obtain the proof of its presence is accounted for by their having used hydrochloric acid in the preparation of the pigment. It is found that this acid dissolves out nine-tenths of the iron from the pigment.

Baryta-water causes a precipitate in the urine, and this carries down with it a good deal of the pigment; this is filtered off. In the filtrate, the remaining portions of the pigment are carried down with the precipitate caused by lead acetate. For the method adopted for separating the pigment from the tissues of the tumour, the original paper must be consulted. The pigment obtained from these three sources is a brownish, amorphous powder when dry. It is partly soluble in acetic acid, and partly insoluble.

The following table represents the percentage composition, and the relative absorption for the region wave-length = 562, for these different preparations:—

|   | C.           | H.   | N.    | S.   | Fe.   | Absorp-<br>tion. |
|---|--------------|------|-------|------|-------|------------------|
|   | Percentages. |      |       |      |       |                  |
| <i>A. Pigment insoluble in acetic acid—</i> |              |      |       |      |       |                  |
| 1. From the tumour.....                     | 55·72        | 6·00 | 12·30 | 7·97 | 0·072 | 0·00038          |
| 2. From the baryta precipitate.             | 55·76        | 5·95 | 12·27 | 9·01 | 0·20  | 0·00039          |
| 3. From the lead precipitate ..             | —            | —    | —     | 8·30 | 0·25  | 0·00029          |
| <i>B. Pigment soluble in acetic acid—</i>   |              |      |       |      |       |                  |
| 3. From the tumour.....                     | —            | —    | —     | 5·90 | 0·21  | 0·00094          |
| 4. From the baryta precipitate.             | —            | —    | —     | —    | 0·19  | 0·00114          |
| 5. From the lead precipitate ..             | 58·07        | 8·03 | 11·08 | 4·75 | 0·20  | 0·00056          |

There are thus two pigments, although perhaps it may be that the

two are produced from a mother-substance by the action of the acid. They differ from one another in percentage composition, and in absorptive power. They resemble one another in solubilities, except with regard to acetic acid, and in colour to the naked eye. The high percentage of sulphur in the pigment insoluble in acetic acid agrees with the similar condition in phymatorusin. An important point brought out is the identity of the tumour pigment with that in the urine; it is probably brought to the urine by the blood, in which feebly alkaline liquid it is slightly soluble. It is not the same pigment as occurs in normal urine; that gives quite a different spectrophotometric chart.

W. D. H.

**Cobra Poison.** By C. J. H. WARDEN (*Chem. News*, **54**, 197—199; 209—211).—Two samples of air-dried snake-venom contained respectively 16.26 and 15.43 per cent. of water. Fresh venom yields 25—50 per cent. of solid residue. For the author's experiments, the solution of the dried venom in distilled water was injected under the skin of the back of white or piebald China mice. A dose of 0.012 gram of anhydrous venom was fatal in four minutes, and the rapidity of action decreases as the quantity of poison administered is diminished; with 0.000016 gram, the animal may live three hours, whilst 0.000008 gram is not fatal. Very large and very small doses cause convulsions, intermediate doses do not. In the case of white mice, the fatal ratio of poison to body weight appears to be about 1 : 10,000,000. Heating the solution of the venom soon produces marked coagulation, but it is only after heating for some time that the toxic activity is reduced, hence prolonged heating at a moderate temperature is more effective for such a purpose than short periods at higher temperatures. Similar remarks apply to the action of picric acid, which causes an abundant precipitate in solutions of the poison, and in some experiments a marked reduction in the toxic action when the filtered solution was employed.

D. A. L.

**Urine of the Tortoise.** By T. W. MILLS (*J. Physiol.*, **7**, 453—457).—The urine of the tortoise is liquid, ranging in colour from colourless to light amber, and is of an acid reaction. In some cases, it is green from admixture with bile in the cloaca. Albumin is invariably present; although probably this is derived from the intestine, *viâ* the cloaca. On allowing the urine to stand, the albumin having been removed, a deposit of uric acid crystals, of an orange colour occurs. On many occasions uric acid crystals were found in the urine without any treatment; these were always colourless. By Heintz's hydrochloric acid method, the amount of uric acid in the urine was estimated, and found to be several times greater than in human urine. Urea is altogether absent. The inorganic constituents do not differ in kind from those found in the urine of man.

## Chemistry of Vegetable Physiology and Agriculture.

---

**Reduction of Copper Sulphate during Alcoholic Fermentation.** By H. QUANTIN (*Compt. rend.*, 103, 888—889).—In experiments on a small scale, it is found that copper existing in the form of copper sulphate to the extent of 0.05 gram per litre, is completely precipitated in the form of copper sulphide during alcoholic fermentation. On a large scale, doubtless a still larger quantity would be removed, but the quantity given is greater than would ever be introduced into the wort as a result of the use of copper sulphate as a remedy for mildew. Since moist copper sulphide is readily oxidised, it is important to avoid any aëration of the lees containing it. The sulphide is the only salt of copper which is insoluble in the must of grapes.

C. H. B.

**Alcoholic Fermentation of Dextrin and Starch.** By U. GAYON and E. DUBOURG (*Compt. rend.*, 103, 885—887).—The authors have met with a species of *Mucor* which has the power of converting dextrin and starch into sugar, and then fermenting the sugar but, like *Mucor circinelloides*, it has not the power of inverting cane-sugar, and transforming it into alcohol. Other non-inversive ferments, on the other hand, have not the power of fermenting dextrin and starch. In beer wort or solutions of glucose, this mucor develops rapidly in large, spherical, ferment cellules. In dextrin or starch, it at first forms mycelial tubes, which soon swell up, divide, and form themselves into globular masses. In yeast-water containing sugar, the mucor forms only a bulky, unicellular mycelium.

The fermentation of dextrin takes place somewhat slowly, and that of starch requires still longer. The dextrin existing in beer is readily saccharified by this mucor and converted into alcohol, if the alcohol already in the beer is expelled before adding the ferment.

*Eurotium oryzae*, used in the manufacture of "koji," secretes a diastase which converts rice into a true malt, and this plant also inverts cane-sugar, but it cannot carry fermentation any further.

C. H. B.

**Method of Preventing Secondary Fermentations.** By U. GAYON and G. DUPETIT (*Compt. rend.*, 103, 883—885).—The addition of tannin in quantities of 0.5—1.0 gram per litre gives good results, but does not prevent the development of *Mycoderma aceti*.

Salts of bismuth, even in small quantities, completely prevent secondary fermentations. The addition of 0.1 gram of basic bismuth nitrate per litre almost entirely prevents any increase in the acidity of the wort, and by keeping the yeast pure produces a distinct increase in the proportion of alcohol. The character of the results is seen from the following table. The first column in each set of experiments shows the behaviour of the wort containing the bismuth salt, and the second column shows the behaviour of the ordinary wort:—

|                                     | A.       |          | B.    |      | C.    |      |

C. H. B.

**Is Free Nitrogen formed during Putrefaction?** By A. EHRENBURG (*Zeit. physiol. Chem.*, **11**, 145—179).—Considering the important part that nitrogen plays in the organisms of plants and animals, many researches have been undertaken to determine, first, whether the atmospheric nitrogen takes any part in the nutrition of organisms, especially low organisms like bacteria, or whether as a result of decomposition, nitrogen in the free state is formed; the conclusions drawn by various workers are most contradictory. The present research is devoted only to the investigation of the question as to whether nitrogen is formed in putrefactive processes. The author intends to pursue the subject further in relation to nitrification. By means of an apparatus, which is described and figured, the use of caoutchouc stoppers is dispensed with, as diffusion takes place through these; wherever a stopcock is necessary, it is immersed in a trough of mercury. The gases formed by various putrefying mixtures were analysed. The method of gas analysis is preferable to that of nitrogen estimations, since certain nitrogenous compounds, formed by putrefaction (*e.g.*, of the quinoline and pyridine groups), undergo dissociation at a high temperature. The substances investigated were dried blood moistened with cow's urine, cow's urine alone or mixed with calcium carbonate, and the dung of horses and cows. These substances were mixed with some liquid in which putrefaction was taking place, and the investigation carried out in the presence of pure oxygen, so that only the aerobic organisms could act; carbonic anhydride was formed, but no nitrogen. In other experiments carried out in the absence of oxygen on a mixture of broth, sugar, peptone, sodium phosphate, sodium chloride, and sodium nitrate, it was also found that no nitrogen was formed. These experiments were carried out in an atmosphere of carbonic anhydride, in which only the anaerobic bacteria would be able to act. It was also found that during the slow combustion of organic materials no nitrogen was formed.

W. D. H.

**Absorption of Carbonic Anhydride by Leaves.** By P. P. DEHÉRAIN and MAQUENNE (*Ann. Agronom.*, **12**, 526—534).—The authors cite determinations which confirm the conclusions already arrived at by them, namely, that the absorption of carbonic anhydride

by vegetable tissues is a true phenomenon of solution, varying with the temperature, as in all cases of absorption of gas by an inert solvent, and which, consequently, when the leaf respire in an atmosphere kept at constant pressure, gives rise to a supersaturation comparable with that of a mass of water into which calcium carbonate and hydrochloric acid have been introduced simultaneously.

This absorption of carbonic anhydride by leaves is extremely rapid, at any rate when the leaves are in a vacuum, in consequence of the large surface exposed.

J. M. H. M.

**Ripening of Seeds.** By A. MUNTZ (*Ann. Agronom.*, 12, 399—400).—Unripe rye grain contains a notable proportion of synanthrose, a sugar analogous to cane-sugar, and only found up to the present in the roots or tubercles of certain *Synantheraceæ*. The synanthrose in the dry grain was on May 25th 45 per cent. to 21·55 per cent. starch, and on July 12th 6·85 per cent. to 68·78 per cent. starch. There is still some synanthrose in the ripe grain after being kept for months. The unripe grain of wheat also contains synanthrose, which, however, does not persist, but is gradually replaced by cane-sugar; wheat also contains an inverting ferment capable of transforming synanthrose into reducing sugars. 200 grains of wheat weighed after desiccation at 9 A.M. 10·042 grams; after exposure to the sun for 12 hours they weighed 8·648 grams, the loss being due to slow combustion. The young colza seed contains cane-sugar and a reducing sugar having the rotatory power of invert sugar; at maturity, cane-sugar alone remains. By determining from time to time the sugar, starch, fat, and nitrogenous matter in a constant number of colza seeds during an increase in weight from 121 mgrms. to 498 mgrms., the author finds that the glucose diminishes gradually and disappears, the cane-sugar increases, the starch, always present in small quantity, gradually diminishes, the nitrogenous and fatty matters constantly increase. It, therefore, appears that the seed itself does not contain the carbohydrates which undergo transformation into oil; but analyses of the pod or silqua at various dates show that sugar and starch constantly flow there, and disappear after a short sojourn, thus probably furnishing the material out of which the oil of the seed is elaborated.

J. M. H. M.

**So-called Soluble Starch.** By J. KRAUS (*Ann. Agronom.*, 12, 540—541).—Janis and Schenk have found in the epidermis of *Ornithogalum* and of *Gagea* a substance dissolved in the cell sap which strikes a blue colour with iodine. Nägeli has shown that it is not starch, and believes it to be an albuminoid. The author, having met with this same substance in the epidermis of some *Arums*, has come to the conclusion that it is allied to the tannins. Chloriodide of zinc colours it rose, ferric chloride and ferrous sulphate strike a brownish-green; on the other hand, potassium dichromate and Gardiner's reagent give no reactions. The substance behaves like a tannin in being developed under the influence of light, and in persisting without alteration in dead or dying leaves. That iodine should strike a blue colour with a tannin is not surprising, since Giessmayer has shown that a solution of tannin gives with a weak solution of iodine, in feebly

alkaline water, a bright red colour, and Nasser has recognised that tannic and gallic acids and pyrogallol, in the presence of neutral salts or acids, are coloured red-purple by iodine. J. M. H. M.

### Substances contained in the Roots of *Hydrastis Canadensis*.

By M. FREUND and W. WILL (*Ber.*, 19, 2797—2803).—Perrins (*Pharm. J. Trans.* [2], 3, 546) obtained from the root of *Hydrastis*, berberine and another alkaloid to which he ascribed the name hydrastine. The authors found that the latter is best obtained by extracting the finely powdered roots with ether. It melts at 132° and crystallises in the rhombic system;  $a : b : c = 0.8461 : 1 : 0.3761$ . The solution in chloroform (1.2759 gram to 50 c.c.) has a rotatory power  $[\alpha]_D = -67.8^\circ$ ; in aqueous hydrochloric acid,  $[\alpha]_D = +127.3^\circ$ . Analyses of the compound confirm the formula  $C_{22}H_{23}NO_6$ , ascribed to it by Mahla (*Amer. J. Sci.* [2], 36, 57). It reacts with methyl iodide, yielding the compound  $C_{22}H_{23}NO_6, MeI$ . This crystallises from alcohol or water in needles melting at 208°. When hydrastine is dissolved in hydrochloric acid and treated with potassium permanganate, it is converted into opianic acid. Nitric acid acts on hydrastine, yielding a base melting at 115°, very readily soluble in chloroform, alcohol, and ether. Hydrastine is not changed when fused with potash. These experiments show that great analogy exists between hydrastine and narcotine.

Another compound was isolated from the roots of the *Hydrastis*; it crystallises well and melts at 100°. It does not contain nitrogen. It dissolves unchanged in hot strong hydrochloric acid and in warm aqueous potash, and appears therefore to be a lactone.

N. H. M.

**Valuation of Manures.** By P. P. DEHÉRAIN (*Ann. Agronom.*, 12, 436—444).—The author expresses the value of a manure or manurial constituent for a particular soil or crop in the following manner. If R is the yield per hectare on the manured plot, and R' that on the unmanured plot, V the price of the produce, and P the weight of manure used, then the value of the unit of weight of the manure for that soil and crop is  $\frac{(R - R')V}{P}$ . In the case of nitrogenous manures, if N, the weight of nitrogen in the manure, be substituted for P in the above expression we get as quotient the value of the unit of nitrogen in that particular form and case. Applying this method to the results of field experiments at Grignon, the author shows the different values that the unit of nitrogen may have in different forms and under different circumstances. Thus with green maize in 1879—

|   |  | fr. | c. |
|---|--|-----|----|
| The kilo. of nitrogen in farmyard manure was worth...         |  | 6   | 60 |
| "          "      nitrate of soda                  "      ... |  | 2   | 34 |
| "          "      flesh manure (large dressing) ..            |  | 0   | 88 |
| "          "      "          "      (small      "      ) ..   |  | 1   | 43 |

The experiments with oats from 1875—1879 yield the following values:—

|                                   | fr. | c. |           |
|-----------------------------------|-----|----|-----------|
| Nitrogen in farmyard manure ..... | 3   | 26 | per kilo. |
| „ nitrate of soda .....           | 3   | 68 | „         |
| „ mixture of the two .....        | 4   | 17 | „         |

J. M. H. M.

**Production of Farmyard Manure.** By A. MUNTZ and C. GIRARD (*Ann. Agronom.*, 12, 429—436).—By exact experiments, the authors have sought to establish the proportions of the total manurial elements in the food consumed which become stored up in the increase of live-weight, recovered in the manure, and lost. The food given was weighed and analysed, the increase of live-weight or the quantity of milk yielded during the duration of the experiments noted, and the manure carefully collected and analysed. The following results were obtained: 32 sheep kept in a fold with asphalt floor so as to prevent loss of manure, gave the following results:—

|                          |        |        |                  |
|--------------------------|--------|--------|------------------|
| Nitrogen consumed .....  | 21·817 | kilos. |                  |
| „ converted into flesh.. | 4·300  | „      | = 21·7 per cent. |
| „ recovered in manure.   | 5·588  | „      | = 19·72 „        |
| „ lost .....             | 12·129 | „      | = 55·58 „        |

Some of this great loss of nitrogen is due to escape into the air of ammonium carbonate; the air of the fold was found to contain about 0·008 gram ammonia per cubic metre, or 400 times as much as normal air.

Two Normandy cows were each fed daily with 53½ kilos. of lucerne and 49 kilos. of water, and each furnished 33 kilos. of solid excreta and 18 kilos. of urine. The weight of the animals increased by 15 kilos. during the experiment, and they furnished 361 litres of milk.

|                          |        |                           |   |
|--------------------------|--------|---------------------------|---|
| Nitrogen consumed .....  | 14·146 | kilos.                    |   |
| „ assimilated as flesh.. | 0·544  | } 3·104 = 21·95 per cent. |   |
| „ „ in milk..            | 2·560  |                           |   |
| „ in manure .....        | 7·461  | = 52·75                   | „ |
| „ lost .....             | 3·581  | = 25·30                   | „ |

The loss is much less than in the case of the sheep, probably because the fermentation being less active, less ammonium carbonate is formed.

*Quantity of Fertilising Matter supplied to the Soil by Grazing Sheep.*—With a ration of green lucerne and straw litter, 2·230 kilos. of manure were produced for 4·085 kilos. of lucerne consumed and 0·9 kilo. of water drunk. The sheep increased in weight 30 kilos.

The phosphoric acid in the forage was 2·952 kilos., and in the manure 2·955 kilos.; the potash in the forage 13·002 kilos., and in the manure 15·280 kilos., there was therefore no loss of these fertilising constituents; the distribution of the nitrogen was as under:—

|                            |        |         |           |
|----------------------------|--------|---------|-----------|
| Nitrogen consumed .....    | 14·548 | kilos.  |           |
| „ assimilated as flesh.... | 1·089  | = 7·50  | per cent. |
| „ in manure .....          | 6·349  | = 43·64 | „         |
| „ lost .....               | 7·110  | = 48·87 | „         |

With an earth litter the loss of nitrogen was much less, as the following figures show:—

|                                 | kilos.                  |
|---------------------------------|-------------------------|
| Nitrogen consumed.....          | 13·707                  |
| „ fixed by animal .....         | 1·379 = 10·06 per cent. |
| „ in manure .....               | 9·042 = 65·96 „         |
| „ lost .....                    | 2·376 = 23·98 „         |
| Phosphoric acid in fodder ..... | 2 820                   |
| „ „ manure.....                 | 3·260                   |
| Potash in fodder .....          | 13·235                  |
| „ manure.....                   | 12·017                  |

The advantage of earth litter over straw litter, and of the custom of folding on the soil instead of stabling, is demonstrated by these experiments.

With lucerne hay and straw litter, the following results were obtained.

|                         | kilos.                 |
|-------------------------|------------------------|
| Nitrogen consumed.....  | 23·011                 |
| „ fixed by animal ..... | 1·670 = 7·25 per cent. |
| „ in manure .....       | 8·899 = 38·67 „        |
| „ lost .....            | 12·442 = 51·08 „       |

J. M. H. M.

**Manurial Value of Basic Steel Slag.** By J. WRIGHTSON and J. M. H. MUNRO (*Ann. Agronom.*, 12, 488—495).\*—The basic steel cinder or Thomas slag employed in these experiments had the following composition:—CaO, 41·54; MgO, 6·13; Al<sub>2</sub>O<sub>3</sub>, 2·60; FeO, 14·66; F<sub>2</sub>O<sub>3</sub>, 8·64; MnO, 3·81; V<sub>2</sub>O<sub>3</sub>, 0·29; SiO<sub>2</sub>, 7·40; P<sub>2</sub>O<sub>5</sub>, 14·32; SO<sub>3</sub>, 0·31; S, 0·23; total 99·93. Side by side with this were tried ground Cambridge coprolites containing 25·1 per cent. P<sub>2</sub>O<sub>5</sub>; mineral superphosphate of ordinary quality containing 12·0 per cent. soluble P<sub>2</sub>O<sub>5</sub>; rich (Curaçoa) superphosphate containing 20·1 per cent. soluble P<sub>2</sub>O<sub>5</sub>; and also precipitated phosphate of lime prepared from basic cinder by Scheibler's process. This precipitated phosphate contained 30·89 per cent. P<sub>2</sub>O<sub>5</sub>, with CaO, 29·91; Fe<sub>2</sub>O<sub>3</sub>, 3·62; SiO<sub>2</sub>, 7·53; water, 18·72; the P<sub>2</sub>O<sub>5</sub> in this product is practically all soluble in ammonium citrate. The experiments were made in duplicate on a thin, light, chalky soil at Downton (Wilts), and on a stiff clay nearly destitute of lime at Ferryhill (Durham), with plots  $\frac{1}{10}$  acre in area. Duplicate plots of each dressing were employed at both stations; there were 35 plots in each series, and they were so arranged as to permit a comparison of every manured plot with one or more *adjacent* unmanured plots; the special comparisons between the different manures were also obtained from *adjacent* plots. Swedes were grown at Downton, and yellow Aberdeen turnips at Ferryhill; the mean yield of the six *unmanured* Downton plots was 2360 roots, weighing 6 cwts. 0 qr. 14 lbs., and that of the six *unmanured* Ferryhill plots was 362 roots, weighing 2 cwts. 2 qrs. 7 lbs. On the unmanured plots at Ferryhill, most of the young

\* "Report of Experiments made to ascertain the manurial value of Basic Cinder produced at the works of the North Eastern Steel Co., Limited," Middlesborough, 1886.

plants were unable to withstand the attack of the fly, on the manured plots, failure from this cause did not take place. The following table shows the *mean* increases over the unmanured plots obtained both at Downton and Ferryhill with the different manures :—

|                                   | lbs. $P_2O_5$ . | Increase per plot $\frac{1}{10}$ acre. |      |      |            |      |      |

| 17 lbs. precipitated phosphate .. | 5.3             | 3                                      | 3    | 13   | 9          | 0    | 21   |
| 78½ lbs. basic cinder .....       | 11.2            | 2                                      | 3    | 5    | 10         | 1    | 15   |
| 45 lbs. ground coprolites .....   | 11.2            | 0                                      | 1    | 2    | 8          | 2    | 0    |

At Downton, on a thin, chalky soil, it will be seen that 4 cwts. per acre of basic cinder was a little inferior to an equal weight of superphosphate, but vastly superior to the same quantity of ground coprolites. If dressings of these manures containing equal weights of phosphoric acid are compared, it is found that the unit of  $P_2O_5$  in basic cinder is a little inferior in efficiency to that in superphosphate, inferior also to that in precipitated phosphate, but decidedly superior to the unit of phosphoric acid in ground coprolites. Making the same comparisons at Ferryhill on this clay soil, deficient in lime, it is found that *soluble* phosphoric acid loses a great deal of its superiority over the insoluble forms. 4 cwts. per acre of basic cinder is actually a better manure than an equal weight of superphosphate, and but very little inferior to a dressing of superphosphate containing an equal weight of phosphoric acid; in fact, on this soil, soluble phosphate, cinder phosphate, and precipitated phosphate are very near each other in efficiency, with coprolite phosphate a little way behind. At Downton, a heavy dressing of basic cinder gave the best result, at Ferryhill, a dressing of 4 cwts. per acre was almost as efficacious as one of 20 cwts. per acre. The general conclusion deducible from these experiments is that phosphoric acid exists in basic cinder in a condition to be easily assimilated by plants, and that in this respect it resembles soluble phosphoric acid and precipitated phosphoric acid much more than the insoluble phosphoric acid of ground mineral phosphates, hence Thomas-slag is likely to occupy an important position as a phosphatic manure. In the two years 1884 and 1885 there were no signs of injury to the crop even from the heaviest dressings of basic cinder, namely, 1 and 2 tons per acre. Besides the precipitated phosphate prepared from basic cinder, two other patented preparations were included in the series of experiments, but in view of the very striking results obtained with

the raw ground cinder, these proposals lose much of their interest. According to one of these patents (Munro and Wrightson, No. 250, A.D. 1885), ground basic cinder is used as a precipitating agent for the soluble phosphoric acid of rich superphosphate, and by mixing the two substances in suitable proportions, a manure of moderate richness is obtained, free from any excessive proportion of oxides of iron, and containing phosphoric acid in three highly assimilable forms,—soluble, “precipitated,” and cinder phosphoric acid. The plots on which this manure was tried show that the efficacy of the soluble phosphoric acid was not weakened by partial precipitation, and that the cinder phosphoric acid in the compound manure exercised a manurial effect over and above that due to the phosphoric acid of the superphosphate. The manufacture of a superphosphate from basic cinder itself has also been tried and patented (Munro, No. 7740, A.D. 1885). When treated with the proper quantity of sulphuric acid, basic cinder is converted into a light green, dry, friable, and very open substance containing a large proportion of calcium sulphate, soluble phosphate of lime, and about 12 per cent. of crystallised ferrous sulphate. (A portion of the phosphoric acid exists as soluble ferrous phosphate.) In view of the recent experiments of Griffiths, it was thought that the ferrous sulphate contained in this manure might exert a beneficial effect on vegetation, instead of being, according to the common belief, an absolute poison. The effect of ferrous sulphate on vegetation seems to depend on the dose, a small quantity being sometimes beneficial, and a large one invariably noxious. On the experimental plots to which the “dissolved cinder” was applied, the effect of the ferrous sulphate appeared to be uniformly disadvantageous. The dissolved cinder in all cases had *some* manurial value, giving increases over the unmanured plots, but these increases were less than were obtained with the same quantity of cinder not dissolved by acid, so that the sulphate of iron appears to have neutralised a part of the benefit derived from the phosphoric acid. J. M. H. M.

**Influence of the Ferrous Oxide in Basic Cinder on the Growth of Plants.** By J. M. H. MUNRO (Middlesborough, 1886).—This report contains experiments supplementary to those which formed the subject of the preceding Abstract. Seeds of various sorts—barley, white turnips, clover, white mustard, garden cress—were sown in mixtures of garden soil with basic cinder, in order to ascertain whether the large proportion of ferrous oxide in the basic cinder exercises any unfavourable influence on germination or growth. In order to put this question to the severest test, enormously exaggerated doses of basic cinder were employed, namely, 10 per cent. of the mixed soil, 25 per cent., 50 per cent., and pure basic cinder without any soil. Most of the seeds tried germinated even in the pure basic cinder, and some of the plants lived until starved for want of nitrogenous food. All the other mixtures produced plants which flowered and seeded in due course—the barley plants in the mixture of equal parts of basic cinder and garden soil were actually better than those grown in garden soil alone, and produced full ears of grain of unimpaired germinating power. Since basic cinder is an alkaline substance containing free

lime, it is only natural that in the three strongest mixtures fewer seeds germinated than in the three weaker mixtures or in garden soil alone. The conclusion arrived at is that the ferrous oxide contained in basic cinder is without injurious influence on germination or growth.

## Analytical Chemistry.

---

**Apparatus for Gas Analysis.** By O. PETTERSSON (*Zeit. anal. Chem.*, 25, 479—484).—The principle on which the measurements are made is similar to that employed for air analysis (this vol., p. 180). The standard volume of air is, however, contained in a special bulb connected with the eudiometer through the differential manometer. The gas is introduced by a side tube from a bell-glass inverted in a mercury trough. The absorptions take place in Orsat tubes connected with the eudiometer by stopcocks. There are also wires for explosions.

M. J. S.

**Universal Spectroscope for Qualitative and Quantitative Chemical Analysis.** By G. KRÜSS (*Ber.*, 19, 2739—2746).—A modified form of Bunsen and Kirchhoff's spectroscope is described with sketches.

**New Volumetric Method for Determining Fluorine.** By F. OETTEL (*Zeit. anal. Chem.*, 25, 505—511).—The fluorine is measured as silicon fluoride in a special form of eudiometer. The decomposition vessel is a stoppered flask with the neck above the stopper enlarged into a cup for holding mercury. A tube branching from the neck is ground into the top of the eudiometer, the joint being also covered with mercury. The eudiometer is connected at its lower end with a mercury tube like that of the nitrometer. The graduation begins 10 c.c. below the top of the eudiometer, and 10 c.c. of sulphuric acid are introduced above the mercury. To obtain sulphuric acid suitable for the decomposition, ordinary acid is heated with sublimed sulphur until it begins to fume, then poured off from the fused sulphur and evaporated to two-thirds of its volume. The fluoride (which if decomposable by cold acid may be enclosed in a tube sealed by a drop of fused acid potassium sulphate) is placed in the flask with ignited quartz-powder. After reading the mercury level and temperature, 50 c.c. of acid is added and the stopper inserted. The acid is slowly heated to boiling, whilst the pressure is kept below that of the atmosphere, to prevent leakage. When decomposition is complete, the whole is allowed to cool and the volume of the gas read off. A correction of 1.4 c.c. is added for the solubility of silicon fluoride in sulphuric acid. The results are equal in accuracy to those obtained by Fresenius' method, and the whole determination requires only three hours, of which two are occupied by the cooling.

M. J. S.

**Air Analysis on a New Principle.** By O. PETTERSSON (*Zeit. anal. Chem.*, 25, 467—478).—The principle of this method of determining the moisture and carbonic anhydride in atmospheric air consists in performing all the operations in a closed system, in which the influence of barometric variations and changes of temperature is eliminated by adjusting the pressure of the gas undergoing measurement to equality with that of a constant quantity in one part of the apparatus.

The apparatus consists of a pipette with its lower tube graduated, and connected with an adjustable mercury reservoir by a flexible tube. There is a stopcock at its upper end for the introduction of the air for analysis. Below this stopcock are branched in the upper tubes (furnished with stopcocks) two rather larger pipettes filled respectively with phosphoric anhydride and strongly dried soda-lime. The lower tubes of these two pipettes are connected (by stopcock tubes) with the two ends of a sensitive differential manometer, which is a horizontal tube slightly curved and containing as index a drop of coloured sulphuric acid or high-boiling petroleum. The pipettes are all immersed in the same vessel of water. The whole apparatus having been filled with the air for analysis, the mercury having been adjusted to the zero of the graduated stem, and equality of pressure having been established by opening for a moment all the stopcocks, the measured volume of air is compressed into the phosphoric anhydride pipette by admitting mercury until it fills the measuring tube. In 20 minutes all the moisture will have been absorbed. The dried air is re-expanded into the measuring tube; the stopcocks to the manometer are opened, and the level of the mercury is adjusted till the pressure is again equal in all the pipettes. Since the quantity of gas in the soda-lime tube has remained unaltered it serves as a standard volume, although external pressure and temperature may have varied, and the reading of the mercury in the graduated tube at once gives the volume of the aqueous vapour absorbed. The same process is repeated with the soda-lime pipette, in which the carbonic anhydride is absorbed, and now the air in the phosphoric anhydride pipette is employed as the standard volume.

M. J. S.

**Assay of Iron Pyrites for Sulphur Available for Sulphuric Acid Manufacture.** By J. C. WELCH (*Analyst*, 11, 209—213).—In one method, the pyrites is mixed with calcium hydroxide and heated in a tube in a current of oxygen; the contents of the tube are dissolved in hydrochloric acid and boiling water, and precipitated with barium chloride; the presence of lime and iron in solution is perhaps objectionable. The results are only approximate. In the second method, which answers very well indeed, the pyrites is heated in a current of oxygen, the issuing gases are passed through bromine dissolved in hydrochloric acid and water, and the liquid is then boiled and precipitated with barium chloride. The second method is better than the method depending on heating with fuming nitric acid, even in the case of lead sulphide.

D. A. L.

**Volumetric Determination of Sulphuric Acid.** By H. WILSING (*Zeit. anal. Chem.*, **25**, 560—561).—A measured excess of barium chloride is added to the neutral solution, and the excess is then determined by titration with sodium carbonate, using phenolphthaleïn as indicator. The liquid is to be boiled while titrating. Substances precipitable by soda must first be removed. M. J. S.

**Volumetric Determination of Sulphates.** By H. QUANTIN (*Chem. News*, **54**, 233—234).—The solution of the sulphate under examination is well mixed with a hydrochloric acid solution of barium chromate to precipitate the sulphuric acid; it is then neutralised with ammonia to remove the excess of barium chromate. The filtrate, containing chromate equivalent to the original sulphate, is acidified with sulphuric acid and titrated with ferrous sulphate, using potassium ferricyanide as indicator. Various necessary precautions are noted. D. A. L.

**Determination of Nitric Acid by Absorption of Nitric Oxide in Standard Potassium Permanganate Solution.** By H. N. MORSE and A. F. LINN (*Amer. Chem. J.*, **8**, 274—280).—The nitric acid is reduced by ferrous chloride and hydrochloric acid in a current of carbonic anhydride. As ordinary marble contains air that cannot be removed by boiling with water, the author uses a saturated solution of sodium hydrogen carbonate containing a quantity of the same salt in suspension. The nitric oxide and carbonic anhydride pass through an empty tube and a set of potash bulbs, the latter containing a strong solution of potassium carbonate to arrest all acid vapours. The washed gases are absorbed in two, long, slanting tubes containing a measured quantity of potassium permanganate. When the absorption is complete, the tubes are emptied and the contents decolorised by dilute sulphuric acid and a measured quantity of oxalic acid, the excess being titrated back with standard permanganate solution; the tubes are cleaned by rinsing with a portion of the sulphuric and oxalic acids. The method yields very accurate and concordant results.

H. B.

**Lawrence Smith's Plan for Estimating Alkalis in Silicates.** By P. HOLLAND (*Chem. News*, **54**, 242—243).—The author's results indicate, firstly, that when carefully performed as directed, practically all the alkali is extracted at one operation; secondly, that the form of crucible recommended by Smith minimises the loss of salts by volatilisation. D. A. L.

**Analysis of Silicates.** By W. M. HUTCHINGS (*Chem. News*, **54**, 173—174).—The following method is recommended for mineral determinations in silicates. Alkalis are determined by flame colorations, metallic oxides by blowpipe tests, alkaline earths, alumina, and their approximate quantitative relation to one another and to iron by the following method:—A small quantity of the finely-powdered mineral is gently fused with seven times its weight of ammonium fluoride, the fluorides obtained are mixed with sodium carbonate and used in small quantities at a time in a platinum-wire loop before a

very hot flame, the beads are powdered and treated with water, alumina passes into solution, whilst iron and the alkaline earths remain undissolved. A mixture of cuprous iodide and sulphur in connection with the aluminium plate forms a very delicate test for small quantities of bismuth and lead. Both this mixture and Turner's flux keep good for many years. Glycerol is of more general use for boric acid testing than Turner's flux; in presence of copper for example.

D. A. L.

**Separation of Zinc from Iron, Cobalt, and Nickel.** By P. v. BERG (*Zeit. anal. Chem.*, **25**, 512—519).—Hampe has published (*Chem. Zeit.*, **9**, 543) a process for precipitating zinc from a solution containing the above metals, by converting them into formates and treating with hydrogen sulphide. He, however, found a large quantity of free formic acid necessary to completely prevent the simultaneous precipitation of the other metals. The author shows that by diluting the solution until it contains only about 0.1 per cent. of zinc oxide, a much smaller quantity of formic acid (1 per cent. of 1.2 sp. gr.) ensures a practically complete separation, except in the case of cobalt, which requires a double precipitation.

Monochloroacetic acid is still more efficient, a single precipitation being sufficient even with cobalt. To the dilute solution, heated to 50—60°, as much ammonia is added as is equivalent to the zinc present, then a small excess (about 2.6 grams to 450 c.c.) of monochloroacetic acid; hydrogen sulphide is then passed slowly through the liquid.

In either case, filtration must be commenced immediately the hydrogen sulphide is in excess, and the precipitate must not be allowed to dry on the sides of the beaker. It is washed with water containing hydrogen sulphide and a little of the organic acid. The test analyses communicated are satisfactory, but the conditions were not varied.

M. J. S.

**Aluminium Sulphate containing Aluminium Hydroxide and Free Sulphuric Acid.** By H. HAGER (*Arch. Pharm.* [3], **24**, 852).—If the neutral sulphate contains any hydroxide, the crystallised salt gives a more or less turbid solution with 2 parts of distilled water. To detect free sulphuric acid, Jorissen's test is applied thus:—A couple of drops of gurjun balsam is warmed with 3 c.c. of acetic acid. About 0.25 gram of the powdered aluminium sulphate is added and warmed gently. In the absence of free sulphuric acid, a whitish or yellowish mixture is formed; in the presence of free acid, a blue coloration appears within a few minutes.

J. T.

**Determination of Aluminium in Presence of a Large Proportion of Iron.** By R. T. THOMSON (*Chem. News*, **54**, 252—253).—The methods depending on boiling with a caustic alkali and subsequent precipitation, or on direct precipitation by sodium thiosulphate, were found to be ineffectual, therefore the following methods of treatment are recommended for getting rid of the great bulk of the iron; the first works best except when much manganese is present, therefore under such circumstances the second method should be used. 1st method:

Reduce the iron to the ferrous state by means of a current of sulphurous anhydride, and boil off the excess, when cool add phosphoric acid or ammonium or sodium phosphate, in excess of that required to precipitate all the alumina, then ammonia until a faint permanent cloudiness is formed, finally excess of ammonium acetate. Should the precipitate contain much iron (it always retains a little), it is washed, redissolved in hydrochloric acid, and again treated with sulphurous anhydride, &c. 2nd method: Add ammonia to the reduced iron solution until a slight cloudiness forms, then excess of ammonium acetate, boil, and if the precipitate contains much iron repeat the reduction and precipitation. In either case, when a satisfactory precipitate is obtained, it is dissolved in hydrochloric acid, boiled with a little nitric acid, nearly neutralised with caustic soda, then boiled with large excess of the last reagent. The alumina is then precipitated as phosphate, the precipitate being washed with a hot 1 per cent. solution of ammonium nitrate, containing about 0.1 gram per litre of ammonium dihydrogen phosphate, and is weighed as  $\text{Al}_2\text{P}_2\text{O}_8$ . Test results are very satisfactory. The presence of titanium does not interfere with the process. D. A. L.

**Silica in the Estimation of Manganese in Pig-iron, and Estimation of Phosphorus in Pig-iron and Steel.** By L. M. DEANE (*Chem. News*, 54, 174—175).—When samples of pig-iron containing more than 2 per cent. of silicon are analysed by the ordinary method, an appreciable amount of silica escapes separation, and is finally precipitated with the manganese. The ignited oxide of manganese should therefore be treated with hydrochloric acid, and the silica mixed with it determined in the usual way. For the estimation of phosphorus, the substance is dissolved in nitric acid, evaporated to dryness, redissolved in hydrochloric acid, and again evaporated to dryness. The residue is dissolved in hydrochloric acid, the silica separated, the solution evaporated nearly to dryness, a few drops of nitric acid added, and the heating continued until all nitrous fumes have escaped. The cold solution is mixed with cold water, and the phosphoric acid precipitated and weighed as ammonium phosphomolybdate. D. A. L.

**Direct Separation of Manganese from Iron.** By L. BLUM (*Zeit. anal. Chem.*, 25, 519—520).—From a solution containing nickel, cobalt, zinc, manganous and ferric chlorides, with tartaric acid and excess of ammonia, potassium ferrocyanide throws down all the metals except the iron. A clear filtrate can be obtained after boiling, but the precipitate cannot be washed. A solution containing 0.00004 gram of manganese and 0.01 gram of ferric chloride per c.c. gives a distinct precipitate. M. J. S.

**Detection of Stannic Sulphide in Presence of Antimonious Sulphide.** By A. GRIFFITH (*Analyst*, 11, 164—165).—When a solution containing antimonious sulphide is shaken with ether, and allowed to remain at rest, the sulphide rises to the surface with the ether; stannic sulphide does not behave in this manner. Therefore, when a solution containing both these sulphides is shaken with ether in

sufficient quantity, the antimonious sulphide rises to the surface and exposes the otherwise obscured stannic sulphide. The test does not work with stannous salts.

D. A. L.

**Production and Measurement of Gold and other Minute Metallic Spheres to Determine their Weight.** By G. A. GOZDORF (*Chem. News*, 54, 231—232).—The minute quantity of pure gold obtained in the assay of very poor ores, &c., is dried on the aluminium plate and taken up by a red-hot boric acid bead in a platinum-wire loop; when heated before the blowpipe the gold is obtained as an almost perfect sphere. The boric acid is dissolved off, and the minute sphere of gold measured under the microscope. A sphere 0.024 mm. diameter = 0.000002178 of a grain of gold has been examined. The modes of calculating are explained. Silver spheres may be obtained and measured in a similar manner; but for copper, lead, and other metals, the boric acid is replaced by sodium carbonate, as the former would dissolve a perceptible amount of these metals.

D. A. L.

**Estimation of Carbon in the Organic Constituents of Water.** By A. HERZFELD (*Ber.*, 19, 2618—2621).—The method is a modification of that proposed by Degener. The substance is boiled with chromic acid in a flask provided with a reflux condenser, the upper end of which is connected with a chloride of calcium tube. In the middle of the calcium chloride is a layer of powdered antimony, which absorbs any chlorine evolved from the substance. The carbonic anhydride is estimated in an improved form of Rose's apparatus.

N. H. M.

**Estimation of Nitrates in Water by Means of Aluminium.** By S. HARVEY (*Analyst*, 11, 181—186).—The author has adopted the following plan, after considerable experience with the method:—70 c.c. of the water is mixed in a bottle with 30 c.c. of 10 per cent. aqueous soda, a strip of aluminium foil, about 0.75 gram, is put in, the bottle is closed with a stopper carrying an open tube filled with glass beads, and the whole placed under a bell-jar until the reaction (which is aided by warmth) is complete. The contents and washings are made up to a definite volume, and, if possible, Nesslerised directly, otherwise they must be distilled, &c. In cases where free ammonia has to be expelled from the original water, the 70 c.c. is only made slightly alkaline at first, the 30 c.c. of soda being added subsequently. After keeping some time, a reduction in the quantity of ammonia is observed in waters which have not been previously boiled, this is presumed due to a re-oxidation. Accurate results are obtained. Cane-sugar, or salts of iron, calcium, or magnesium, do not affect the result. Certain sources of error are indicated.

D. A. L.

**Estimation of Glycerol in Wines.** By M. BARTH (*Chem. Centr.*, 1886, 504—505).—100 c.c. of wine is concentrated to about 10 c.c., 1 gram of powdered quartz and about 3—4 c.c. of 40 per cent. milk of lime added, and the whole evaporated to dryness. The glycerol is

then extracted with alcohol and finally with ether, the alcohol and ether evaporated on the water-bath, and the glycerol weighed.

L. T. T.

**Assay of Carbolic Soap.** By A. H. ALLEN (*Analyst.*, **11**, 103—106).—In the method recommended, the hydrocarbons are removed by agitating the soap, dissolved in soda and water, with ether, and the fatty acids are precipitated by means of brine. An aliquot part of the resulting solution is acidified with sulphuric acid and titrated with bromine-water until the solution is permanently tinged of a faint yellow colour; the bromine-water is standardised immediately before or after use by a solution of phenol or cresol. The remainder of the solution may be used for preparing a larger quantity of the bromine-derivative for qualitative purposes.

D. A. L.

**Estimation of Invert Sugar.** By A. HERZFELD (*Chem. Centr.*, 1886, 603).—In the method described by the author (*Chem. Centr.*, **85**, 604), the time taken in the preliminary heating of the liquid influences the result obtained. The tables given were constructed from experiments wherein this preliminary heating occupied four minutes.

The author recommends the following precautions:—An asbestos plate with a circular opening of 6.5 cm. diameter is placed on the wire gauze, and the flask placed on that, the Bunsen burner being placed at such a height that the flame plays over the whole of the exposed part of the flask, and heats the liquid to boiling in from  $3\frac{1}{2}$  to  $4\frac{1}{2}$  minutes. With these precautions, the results are very constant.

L. T. T.

**Titration with Fehling's Solution.** By E. BECKMANN (*Zeit. anal. Chem.*, **25**, 529—530).—Many persons find a difficulty in recognising the point at which the blue colour disappears. This seems to be due to an optical illusion which causes the colourless liquid to appear complementary in colour to the yellowish-red cuprous oxide. It may to some extent be obviated by adding a drop of zinc chloride, which promotes the separation of the cuprous oxide, but the safest way is to filter and test for copper, which is easily done by placing two thicknesses of filter-paper together, touching one side with the turbid fluid and testing the liquid which soaks through to the other. With diabetic urine, however, it is still necessary to rely on the disappearance of the blue colour.

M. J. S.

**Detection of Salicylic Acid.** By C. O. CURTMAN (*J. Pharm.*, [5], **14**, 523—524).—To 4 c.c. of liquid (wine, beer, &c.) is added 2 c.c. of methyl alcohol, or failing this, the same amount of ethyl alcohol, and then, with care, 2 c.c. of pure sulphuric acid. After mixing, the liquid is heated for about two minutes, allowed to cool for eight or ten minutes, then heated just to boiling, when, if salicylic acid is present, a distinct odour of oil of wintergreen is perceptible. If only traces of acid be present, it may be necessary to allow the liquid to stand, and to heat a third time especially if methyl alcohol has been replaced by ethyl alcohol. Although other ethereal salts are

formed in contact with beer and wine, besides methyl salicylate, the odour of the latter is the most characteristic and the most easily perceived. In examining condensed milk, fats, or other solids and semi-solids, the sample is digested in dilute alcohol at 20–30° for some hours, with frequent agitation. After filtration and concentration, methyl alcohol and sulphuric acid are added as before described; 0.001 part of salicylic acid in a food, &c., can be thus detected.

J. T.

**Specific Gravity and some other Characters of Waxes and Allied Substances.** By A. H. ALLEN (*Analyst*, **11**, 223–228).—Methods are described for obtaining fragments of wax, &c., free from air bubbles, for specific gravity determinations; also a method of taking gravities of waxes, &c. (heated by a suitable arrangement to 98–99°), by means of a Westphal balance and glass-rod plummet. The observed gravities indicate that waxes are denser than fats or glycerides in the solid state, but that the reverse is the case with the melted substances. Sperm and bottle-nose oil are shown to be different in composition from spermaceti. Evidence is adduced in support of the glyceride as opposed to the wax-like character of Japan wax (see also next Abstract). The relation of high gravity to high melting point in paraffin is noted.

D. A. L.

**Saponification of Fixed Oils.** By A. H. ALLEN (*Analyst*, **11**, 145–147).—The author has collected, grouped, and tabulated results obtained by various investigators in the examination of a large variety of fatty substances by Koettstorfer's saponification method. Oils consisting of olein mixed with comparatively small quantities of stearin or palmitin, whether of animal or vegetable origin, neutralise about the same quantity of potash—from 18.93 to 19.66 per cent. Oils from cruciferous plants require 17.02 to 17.9 per cent. of potash to neutralise them. Vegetable drying oils require 18.7 to 19.6 per cent. These numbers are not characteristic, but show that linoleic acid must have a higher atomic weight than is generally supposed. With marine animal oils, also, the numbers obtained are not characteristic, varying from 18.51 in cod-liver oil to 21.88 in porpoise oil, which contains much valeric acid; marine waxes, however, require only from 12.30 to 14.74, much less than the marine oils. The butter class contains—butter-fat requiring 22.15 to 23.24, cocoa-nut oil 24.62 to 26.84, palm-nut oil 22.00 to 24.76 per cent. of potash. The various mixtures of palmitin, stearin, and olein require from 19 to 20 per cent. of potash for their neutralisation. Beeswax requires 9.2 to 9.7; Chinese wax 6.5; castor-oil 17.6 to 18.15; Japan wax 21.01 to 22.25.

D. A. L.

**Adams' Method for Milk Analysis.** By A. H. ALLEN and W. CHATTAWAY (*Analyst*, **11**, 71–73); and W. THOMSON (*ibid.*, 73–75; compare also Abstr., 1886, 583).—Allen rolls up a piece of string with the paper to keep the folds of paper from touching one another; hence ensuring exposure of a more extensive surface. He also ties a cap of filter-paper over the bottom of the coil. With this modified coil, suspended by a loop in the string, 5 c.c. of milk may be run direct from a pipette on to the coil without fear of loss, and then the objec-

tionable two weighings may be dispensed with. Thomson recommends distributing the 5 c.c. of milk on an extended strip of filter-paper, drying quickly, coiling and then extracting the fat in usual manner.

D. A. L.

**Separation of Morphine and Strychnine from Fatty Matters.** By FOCKE (*J. Pharm.* [5], 13, 360—361).—According to the author, the following method gives good results. Exhaust the suspected matter with hot alcohol charged with tartaric acid. Filter after cooling, and evaporate on the water-bath. Take up the residue with 10 times its weight of water and add an excess of baryta-water. After some hours, add a slight excess of sulphuric acid, allow to remain for some time, filter and remove excess of acid by means of barium chloride. Filter and evaporate again so as to completely expel the hydrochloric acid of the barium salt. The residue is taken up with absolute alcohol, and the solution is evaporated to dryness on the water-bath. The new residue, which is slightly acid, is dissolved in water and extracted with ether, which removes the fatty matter taken up by the water. The aqueous solution, after being made alkaline, is again treated with ether, the ethereal solution evaporated, and the residue treated with water acidified with hydrochloric acid, which only dissolves the alkaloïds.

J. T.

**Detection of Artificial Colouring in Red Wine (Claret).** By SAMUELSON (*Chem. Zeit.*, 10, 998).—When mixed with an aqueous solution of sodium nitrate, white wine remains clear, but the colour becomes darker. In genuine red wines, a precipitate forms and the supernatant liquid becomes yellow, sometimes only after some time; this is not the case with artificially coloured wines. In a mixture of red and white wines, the amount of precipitate formed is inversely proportional to the quantity of white wine present. White wines coloured red with bilberry, mallow, red poppy, or orseille colouring matter do not give any precipitate. Red wines mixed with coloured white wines yield, in addition to the precipitate, the following reactions: with *bilberry* or *mallow* colours, a violet liquid; with *orseille*, a cherry-red liquid; with *red poppy*, a bright red liquid. The addition of cider to white wine can be detected by sodium nitrate, as cider is coloured dark-brown by this reagent and after some time gives a slight precipitate.

D. A. L.

**Estimation of Tannin.** By H. DIEUDONNÉ (*Chem. Zeit.*, 10, 1067).—This simple and, when carefully conducted, accurate method for estimating tannin is based on reading very small differences of density with a very delicate hydrometer. The hydrometer indicates 1° Baumé, and is divided into hundredths; with this the solution, or extract of the substance to be examined, made with *distilled water*, is tested at 22°, both before and after treatment with powdered skin, the difference in the hydrometric readings is due to tannin. A table is given showing the quantity of tannin corresponding with solutions of densities varying from 1.5 to 105 of the centesimal Baumé degrees at 22°. The standard solutions used in constructing the table con-

tained 0.1 to 10 grams of tannin dissolved in 500 c.c. of water. The ordinary solutions are prepared by boiling and pressing the material four times; they are made up to a definite volume and to a gravity of 1° B. or less, then a measured quantity is shaken with powdered skin, and the next day is filtered, pressed, &c. It is important to use dry and assayed powdered skin as well as good instruments.

D. A. L.

**Peptones in the Blood and Urine.** By GEORGES (*J. Pharm.* [5], 13, 353—354).—All the methods hitherto proposed for the detection of peptones in urine are more or less defective. The author gives the preference to the two following:—

I. This has been recently employed by Wassermann for the detection of peptones in the blood. The blood is received in strong alcohol; the clot thrown on a filter is washed first with cold then with boiling water; the aqueous solution is concentrated to about double the volume of the blood taken, and then added to the alcoholic solution; sodium acetate and ferric chloride are now added to the liquid. After filtration and cooling, the last traces of albumin are removed by adding potassium ferrocyanide and acetic acid, filtered, the excess of ferrocyanide precipitated by copper acetate, filtered, excess of copper removed by hydrogen sulphide; filtered again, and heated on the water-bath to expel hydrogen sulphide and to concentrate the liquid. This method gives good results, especially if care be taken to neutralise, or even to add a slight excess of alkali on adding the sodium acetate and ferric chloride. It also serves very well for the investigation of peptones in urine, commencing by boiling to precipitate albumin coagulable by heat, and terminating as above.

II. The double iodide of potassium and mercury precipitates albumin and the peptones, and Tanret has shown that the albuminous precipitate is insoluble in boiling acetic acid, whilst the peptone precipitate dissolves completely. Employing these reactions, Georges has established a much more rapid method as follows:—Precipitate by heat all the coagulable albumin; treat the urine with acetic acid and the double iodide, wash the precipitate on a filter with cold water charged with acetic acid to the same extent as the urine; wash again with the same acidified water boiling, keeping the washings apart. The clear liquid obtained gives a precipitate on cooling if the least trace of peptonic precipitate has been dissolved. It is only necessary to neutralise in order to obtain a solution to which the double iodide test can be applied.

## General and Physical Chemistry.

---

**Actinometry.** By E. DUCLAUX (*Compt. rend.*, **103**, 1010—1012).—Oxalic acid in aqueous solution is converted into carbonic anhydride and water by the action of light in presence of oxygen, and this decomposition is not due to any rise of temperature resulting from absorption of the sun's radiation, but is brought about by the visible and ultra-violet rays. In order to secure sufficient contact with the oxygen of the air, the solution is placed in flat vessels and the same volume of liquid is always employed; also, in order to eliminate the somewhat considerable influence of the concentration of the solution, a dilute solution, containing 3 grams of oxalic acid per litre, is employed. The amount of change is determined by titrating with lime-water. If the solution of oxalic acid has been kept for about two months in the dark, it is found to be much more sensitive to the action of light than a freshly prepared solution—a fact which indicates that the two liquids have not the same molecular constitution. The change is analogous to the ripening of collodion. The same degree of sensitiveness can be imparted to a freshly prepared solution by exposing it to sunlight for a few hours, and if a concentrated solution is treated in this way and is then diluted to the strength given, the increased sensitiveness is transmitted to the dilute solutions—a fact which indicates that the alteration takes place in the molecules of the acid and not in those of the water.

The total quantity of acid decomposed when the same quantity of liquid is exposed during the whole day is much greater than the sum of the quantities decomposed when a fresh portion of solution is exposed during each hour, the difference varying from day to day. There is therefore a period of quiescence similar to that which is observed in many photographic and chemical reactions, and which Bunsen and Roscoe have termed photochemical induction in the case of hydrogen and chlorine.

C. H. B.

**Fluorescences of Manganese and Bismuth.** By L. DE BOISBAUDRAN (*Compt. rend.*, **103**, 1064—1068).—A mixture of 100 parts of yttrium sulphate with 2 parts of manganese sulphate shows a yellowish-green fluorescence, the spectrum of which consists of a broad band which begins at about 6500, attains its maximum brilliancy at 5640, and fades away gradually at 4890—4840. With 4 per cent. of manganese sulphate, the fluorescence is more intense, but its character is not altered. The fluorescence differs from that of calcium, and is not due to the presence of traces of this element. A mixture of 100 parts of yttrium sulphate with 2 parts of bismuth sulphate gives a red fluorescence, with a spectrum consisting of a band which begins at 6840, attains its maximum brilliancy at 6420—6400, and fades away at 5790—5770. This fluorescence is not due to the presence of magnesium.

Calcium sulphate mixed with small quantities of both bismuth and manganese sulphates gives a fluorescence which is yellow at the centre, and pale-green further from the electrodes. In the spectrum, the orange-red band of the calcium-bismuth fluorescence is very distinct. If the tube is heated, the fluorescence becomes rose-yellow, the red band is scarcely affected, and the brilliancy of the green is diminished. At a higher temperature, the fluorescence diminishes and again becomes green with a bluer shade than originally, and the red band is almost extinguished. In all cases, the fluorescence is much less brilliant than with calcium and manganese sulphates free from bismuth.

A mixture of magnesium sulphate with both manganese and bismuth gives a fluorescence due to the superposition of the magnesium-manganese and the magnesium-bismuth fluorescences.

Cadmium sulphate with small quantities of both manganese and bismuth gives the cadmium-manganese fluorescence, which is somewhat less brilliant than in the absence of bismuth. Strontium sulphate, on the other hand, under similar conditions, gives the strontium-bismuth fluorescence, the intensity of which is somewhat diminished by the presence of manganese.

A mixture of calcium oxide with small quantities of manganese and bismuth oxides gives the calcium-manganese fluorescence with somewhat diminished intensity.

A mixture of zinc and calcium sulphates, in varying proportions, with small quantities of manganese, gives a fluorescence in which the calcium-manganese fluorescence is much more prominent than that due to zinc-manganese. With only 5 per cent. of calcium sulphate, the effect of its presence is readily observed, and it is quite distinct with even 2 per cent. if the tube is heated. C. H. B.

**Effect of Manganese on the Phosphorescence of Calcium Carbonate.** By E. BECQUEREL (*Compt. rend.*, 103, 1098—1101).—The most highly phosphorescent crystals of Iceland spar, which show an orange phosphorescence, contain a somewhat high proportion of manganese, probably in the form of carbonate, with mere traces of iron. The less strongly phosphorescent varieties contain very little manganese.

Calcium carbonate, precipitated from a solution of calcium chloride containing 4 per cent. of manganese chloride, gives almost identical results. Calcium carbonate, formed on the surface of such a solution when exposed in an atmosphere charged with the vapour of ammonium carbonate, does not show the same phenomenon.

These results explain the author's earlier observation, that calcium carbonate precipitated from calcium chloride prepared from Iceland spar, always gives an orange phosphorescence, whilst that prepared from aragonite shows a green phosphorescence. Further experiments are necessary to determine whether manganese is the sole cause of the phenomenon.

The phosphorescence of Iceland spar is affected by lithium, bismuth, and antimony, and by various metallic sulphides.

C. H. B.

**Red Fluorescence of Alumina.** By L. DE BOISBAUDRAN (*Compt. rend.*, **103**, 1107).—Pure calcined alumina shows no red fluorescence when subjected to the action of the silent discharge in a vacuum, but the red fluorescence described by Becquerel ("La Lumière") is shown brilliantly if the alumina contains a small quantity of chromic oxide, and is visible even with so small a proportion as 0.001 per cent.

Alumina with 1 per cent. of manganese oxide shows a green fluorescence; with 1 per cent. of bismuth oxide, a lilac fluorescence in the cold, which becomes blue on heating. Magnesia with 1 per cent. of chromic oxide shows a red fluorescence, whilst the fluorescence of lime containing chromic oxide differs very slightly from that of pure lime.

C. H. B.

**Phosphorescence of Alumina.** By E. BECQUEREL (*Compt. rend.*, **103**, 1224—1227).—The alumina prepared by Boisbaudran (preceding Abstract) does actually show a feeble red phosphorescence, but after being heated to a very high temperature in a platinum crucible for 15 minutes, it shows the red phosphorescence brilliantly. It would seem, therefore, that Boisbaudran had not sufficiently dehydrated his product.

The author has repeated his earlier experiments, and confirms his former conclusion that pure alumina shows some phosphorescence, which is often greenish in colour, but if strongly heated it shows a brilliant red phosphorescence, the intensity of which is increased by the presence of small quantities of chromium and certain other substances. He points out that the exact character of a phosphorescence or fluorescence will depend on the agent by which the substance is excited and the conditions under which excitation takes place.

C. H. B.

**Molecular Refraction of Liquid Organic Compounds of High Dispersive Power.** By J. W. BRÜHL (*Annalen*, **235**, 1—106; see also *Ber.*, **19**, 2746).—In previous papers (Abstr., 1880, 293, 295, 685, 781; 1881, 15; 1882, 263, 445, 827, 829), the author has shown that the mode of union of atoms in a compound, independently of their mere number, has a special influence in raising the molecular refractive power. The present paper embodies a number of new and confirmatory observations, together with discussions of the validity of the several expressions for molecular refractive power, and of the possible connection between dispersion and refractive index or chemical constitution. Numerous references to the work of other physicists are given. The methods of investigation have been previously described.

The first part of the paper contains an account of the preparation and purification of 21 unsaturated compounds specially examined, together with determinations of their densities, refractive indices for the lines  $\alpha$ , D,  $\beta$ , and  $\gamma$ , their molecular refractive powers according to Dale and Gladstone's formula  $(\mu_a - 1) \cdot \frac{P}{d}$ , and the more recent or "new" formula  $\left( \frac{\mu_a^2 - 1}{\mu_a^2 + 2} \right) \cdot \frac{P}{d}$ , &c. The constants for these and

for 21 other unsaturated compounds previously examined are arranged in four tables, from which subsidiary tables are constructed to illustrate special points.

Gladstone and Dale's constant was found to be correct within moderate limits of temperature, and since it was applied chiefly to the saturated and feebly dispersive compounds of the fatty series, comparable results were obtained. More recently, H. A. Lorenz (*Ann. Phys. Chem.* [2], **9**, 641) and L. Lorenz (*ibid.*, **11**, 70) have proved by independent theoretical methods that the relation between the velocity of propagation of light and the density of the medium is contained in the formula  $\frac{n^2 - 1}{(n^2 + 2)d} = \text{constant}$ , when  $n$  = refractive index,  $d$  = density. This constant was proved by these authors, and by Nasini and Bernheimer, to vary much less with the temperature than the old one. Landolt, also (*Abstr.*, 1882, 909), by its aid has recalculated the molecular refractive powers of many compounds examined by various authors, and found not only that all the earlier established relations are equally well expressed, but that a closer agreement between theory and observation is attained by its use. There still remain, however, serious discrepancies between theory and experiment, especially in the case of substances of high dispersive power.

The question then presented itself: Is there any relation between dispersion and mean refractive index on the one hand, or chemical constitution on the other?

Dispersion may be measured either as  $\mu_\gamma - \mu_\alpha$ , or by the constant B in Cauchy's equation—

$$\mu = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} + \dots$$

(using only constants A and B), in which  $\mu$  = refractive index for wave-length  $\lambda$ , A = refractive index for infinite wave-length. In the saturated compounds of the fatty series, B is small (0.3 to 0.5); but in the unsaturated compounds tabulated in this paper B is very great, in the case of cinnamaldehyde reaching the enormous value 2.5. Calculating the constants A and B from observations of  $\mu_\alpha$  and  $\mu_\gamma$ , the author has applied Cauchy's equation to calculating  $\mu_D$  for the last-named substances, and he shows by a tabular statement that theory and experiment agree well for compounds of low dispersion, but that very serious discrepancies arise when the dispersive power is high. Cauchy's equation is therefore untrustworthy in these cases. No definite relation can be traced between dispersion and mean refractive index. (See also following Abstract.) Neither does any connection exist between dispersion and chemical constitution. This is shown by selected examples, in which  $\frac{B}{d^{20}}$  (dispersion at 20° for unit density) is seen to have very different values for compounds of analogous constitution, nearly equal density and equal refractive index; whilst, on the other hand, the dispersion may be the same for substances of very different chemical structure.

Enquiry is next made into the validity of the old and new formulæ.

Tables are given of the values of  $(\mu_a - 1) \frac{P}{d}$  and  $\frac{\mu_a^2 - 1}{\mu_a^2 + 2} \cdot \frac{P}{d}$  for the 42 substances, both experimental and calculated by the aid of the following table of atomic refractive powers:—

|                                     |     | $r_a$ . | $r_A$ . | $r'_a$ . | $r'_A$ . |
|-------------------------------------|-----|---------|---------|----------|----------|
| Singly-linked carbon .....          | C'  | 5.00    | 4.86    | 2.48     | 2.43     |
| Hydrogen .....                      | H   | 1.30    | 1.29    | 1.04     | 1.02     |
| Singly-linked oxygen .....          | O'  | 2.80    | 2.71    | 1.58     | 1.56     |
| Aldehydic oxygen .....              | O'' | 3.40    | 3.29    | 2.34     | 2.29     |
| Chlorine .....                      | Cl  | 9.87    | 9.63    | 6.02     | 5.89     |
| Bromine .....                       | Br  | 15.39   | 14.81   | 8.95     | 8.70     |
| Iodine .....                        | I   | 24.69   | 23.35   | 13.99    | 13.36    |
| Singly-linked nitrogen .....        | N'  | 5.75    | 5.35    | 3.02     | 2.87     |
| Equivalent of ethylene grouping...  | =   | 2.30    | 2.00    | 1.78     | 1.59     |
| Equivalent of acetylene grouping... | ≡   | 1.90    | 1.80    | 1.97     | 1.86     |

In this table  $r_a$  and  $r_A$  are the equivalents for the refractive index of  $\alpha$  (red hydrogen line), and  $A$ , index for infinite wave-length, using the *old* (Gladstone's) formula:  $r'_a$  and  $r'_A$  the similar equivalents for the new (Lorentz). This table has been calculated in part by the author, in part by Landolt.

From this table, it is seen that when the molecular refractive power is calculated by the old formula, the differences between theory and experiment in most cases exceed the possible limits of experimental error, and are especially great for substances of high dispersive power. Since all the differences are positive, it is evident that dispersion here tends to raise the molecular refractive power. When the latter is calculated by the new formula, the differences, although still positive, are both relatively and absolutely smaller. The disagreement is, however, well marked in the case of highly dispersive compounds.

To show the disturbing influence of dispersion more clearly, the author in a new table arranges the various substances in the order of ascending values of  $B$  (dispersion-coefficient), placing opposite each the differences between the observed and calculated refractions according to the old and new formulæ. When  $B$  is small, the discrepancies are relatively about the same for both; but as  $B$  increases, there is a rapidly growing inequality between them, the advantage being always with the new formula. The two formulæ are therefore of nearly equal value (as Landolt supposed them always to be) only for feebly dispersive substances. Yet even here the new gives the more concordant results, as the author shows by a new table, including only unsaturated but feebly dispersive compounds.

In the author's opinion, the defects of the new formula are mainly, but not altogether, traceable to dispersion. The general connection between them has been proved above; but it is pointed out that no arithmetical relation exists between the discrepancies and the dispersion-coefficient.

Although as a rule the dispersion is high in compounds containing many  $C\equiv C$  groups, some unsaturated compounds of low dispersive power exist. Certain striking examples are mentioned, for which the new formula nevertheless gives good results. These show also that there is no connection between dispersive power and chemical constitution.

Some little space is devoted to refuting Gladstone's theory (Abstr., 1882, 133), adopted by Nasini, namely, that the atomic refraction of carbon-atoms, which are united only to other unsaturated atoms, is higher than that of unsaturated atoms, which are not so united. Examples are given of compounds containing atoms of this kind, for which theory and experiment give concordant results. Moreover, there is no connection between dispersion and such atoms, as proved by the high dispersive power of many substances (aldehyde, furfuraldehyde, &c.) from which they are absent.

The highly important relationship of molecular refractive power to unsaturated carbon groups is next discussed. This has been denied by Nasini and others. (See also Thomsen, following Abstract.) The author rehearses the older arguments on which his views rest, and quotes three series of substances containing 1, 2, and 3 ethylene ( $C\equiv C$ ) groupings respectively. For these the mean excesses of observed molecular refractive power over that calculated for the empirical formulæ alone, are 1.79, 3.47, and 5.38 respectively. A fourth table shows the empirical refractive powers for a series of seven substances, each containing 4  $C\equiv C$  groupings. In this, the discrepancies range from  $4 \times 1.73$  for the feebly dispersive allyl phenoxide, to  $4 \times 2.03$  for the highly dispersive cinnamic alcohol.

It is remarkable that when hydrogen is removed from a hydrocarbon, so as to form a ring of singly-linked carbon-atoms, there is no undue increase in refractive power. For example, in *citrene*, *pinene*, and tetrahydroterpene, which according to Wallach contain 2, 1, and 0  $C\equiv C$  groupings, whilst all three contain rings, the excess of observed over empirical molecular refractive power amounts to  $2 \times 1.78$ ,  $1 \times 1.78$  and 0.

In a note, it is pointed out that these considerations speak strongly in favour of Kekulé's benzene formula, as opposed to the prismatic formulæ of Ladenburg and others. Thomsen's thermochemical researches (Abstr., 1880, 785; 1882, 721) lead to exactly opposite conclusions.

The final conclusion of this chapter is: that ethylene groups are effective in raising the molecular refractive power; and that where the increase is greater than can be thus accounted for, it is attributable to dispersion.

A question of practical importance is: how far may the molecular refractive power according to the new formula be safely applied to determining chemical *structure*? This is attacked by making a comparison between the observed and calculated (taking *structure* into account) powers for various substances, and the number of  $C\equiv C$  groupings in their molecules. The value of this grouping according to Landolt = 1.78; or rather the mean value, since it is not the same for all series. Many of the slighter discrepancies in the table

may be explained by this variability, the presence of impurities, or uncertainty as to chemical constitution. But of the 42 cases quoted, in only eight does the discrepancy amount to more than the value of an ethylene group; and all these are of substances of high dispersive power. Of the remainder, in only three does the discrepancy equal one-half of 1.78. In some cases even of highly dispersive bodies the difference is less than this. It is not possible to assign an exact limit beyond which dispersion becomes of importance; but, generally, conclusions as to chemical structure are insecure when the dispersion equals that of cinnamic alcohol ( $\mu_\beta - \mu_a = 0.0248$ ;  $\mu_\gamma - \mu_a = 0.0412$ ;  $B = 1.38$ ). In such a case efforts should be made to prepare less dispersive derivatives of the substance in question, which is very frequently possible.

In another chapter, the value of the acetylene,  $C\equiv C$ , grouping is discussed. A strong point in favour of the new formula is that here its value is *greater* than that of the ethylene grouping, whereas for the old formula it is *less*. But old and new values are to some extent variable with the dispersion. A fresh study of five compounds (three propargyl-derivatives, heptidene, and acetylenylbenzene) leads to the slightly increased mean value (see table above) 2.18. This and the value of the ethylene grouping agree remarkably well with those calculated by the author from Mascart's determinations of  $\mu_D$  for gaseous ethylene and acetylene (*Compt. rend.*, 86, 1182).

In Section III, the question is discussed to what extent are the discrepancies between theory and experiment removed by substituting for  $\mu_a$  in the new formula, the refractive index  $A$  for infinite wavelength calculated from Cauchy's formula, using firstly two, and secondly three, constants. An elaborate study of the results so obtained leads to the following general conclusions.

When  $A$  is calculated from Cauchy's equation with two constants ( $A$  and  $B$ ), the molecular refractive powers, although in better agreement with experiment, seldom differ much from, and always in the same sense as, those calculated from  $\mu_a$ . For feebly dispersive substances, in fact, little is gained by the substitution; but for compounds of high dispersive power the advantage is usually, but not always, very decided.

The values of  $A$  deduced from Cauchy's equation with two and with three terms are about the same when the dispersion is low. But for highly dispersive substances the values of  $A$  from the three-termed formula are always the greater; hence the molecular refractive powers calculated from them diverge still more from the observed powers. Here, in fact, the uses of  $A$  and of  $\mu_a$  lead to about the same results.

The author's conclusion is that Cauchy's formula is purely empirical, and without any physical significance. (See also next Abstract.)

CH. B.

**Experimental Examination of the Older and More Recent Dispersion-formulæ.** By J. W. BRÜHL (*Ber.*, 19, 2821).—The author has shown (preceding Abstract) that in calculating refractive power, the difficulty introduced by dispersion cannot be removed by

substituting for  $n$  (the refractive index for any particular wave-length) its value for a wave-length supposed infinite, deduced from Cauchy's well-known equation. In view of the great importance of the subject in its chemical aspect, the author here presents a critical inquiry into the trustworthiness of the various formulæ connecting refractive index with wave-length, which have been proposed from time to time.

Cauchy's original formula,  $n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} + \dots$ , as well as

later modifications of it, lead to the conclusion that the refractive index  $n$  diminishes constantly as the wave-length increases, reaching a definite minimum value when  $\lambda$  becomes infinite, a conclusion which is manifestly untrue in the case of substances showing abnormal dispersion. Of the more modern theories discussed, which embrace the phenomena of abnormal dispersion, only one, that of Lommel, implies a limiting value of  $n$  greater than unity. Others either do not give such a limiting value (Ketteler's), or give it only under special conditions (Helmholtz's).

In 1879, Mouton proved the untrustworthiness of Cauchy's formula in calculating the dispersion of the ultra-red rays of the spectrum of a specimen of heavy flint glass, when the constants  $A, B, C$ , were deduced from the observed values of  $n$  for the seven principal Fraunhofer lines. The differences of the observed from the calculated values of  $n$  ranged from 0.0023 for  $\lambda = 8.8$  to 0.0137 for  $\lambda = 21.4$ , amounts which greatly exceed possible experimental errors. Very similar differences existed between the observed values of  $n$  for the ultra-red rays of the ordinary and extraordinary spectra of quartz, and the values calculated by Briot's equation  $\frac{1}{n^2} = a + b\frac{n^2}{\lambda^2} + c\frac{n^4}{\lambda^4} + \dots$

which gives a limiting value of  $n = \sqrt{\frac{1}{a}}$  for  $\lambda = \infty$ . The constants here were calculated from some measurements by Mascart for the lines C, G, O. The results of these experiments are arranged by the author in tabular form, and prove that Cauchy's formula fails when used for calculating by extrapolation the refractive index for ultra-red rays, and *a fortiori* for rays of infinite wave-length. The same is true of Christoffel's modification of Cauchy's equation. All, however, are available for interpolation.

It might be supposed that the failure of Cauchy's formula in these cases was due to the narrow range of observations from which the constants were determined. The author has therefore made a comparison, based on a series of measurements by Langley, between the observed and calculated values of  $n$  from the beginning of the ultra-violet to far beyond the red in the spectrum of flint-glass. The constants ( $A = 1.5504$ ,  $B = 1.334171$ ,  $C = -6.982411$ ) were deduced from the values of  $n$  for  $\lambda = 3.97$  ( $H_1$ ),  $\lambda = 7.6$ , and  $\lambda = 18.1$  (ultra-red).

The tabulated results are remarkable; in fact Cauchy's formula is here as valueless for interpolation as it was before for extrapolation. The interpolated values in no case agree with the observed values, in

one case differing by so much as 0.0045, whilst the observed values of  $n$  for  $\lambda = 23.56$  (1.5478) and for  $\lambda = 28.0$  (1.5435) are considerably smaller than the calculated *minimum*,  $A = 1.5504$  for  $\lambda = \infty$ . The constant  $C$ , too, being negative, it can be shown that  $n$  should reach a *maximum* value ( $= 1.6141$ ) when  $\lambda = \sqrt{-\frac{2C}{B}} = 3.23$ ; whilst the observed index for  $\lambda = 3.44$  was 1.6266, that is, greater than this theoretical maximum.

The author next directs attention to Helmholtz's formula—

$$n^2 - 1 = Q \frac{\lambda^4}{\lambda^2 - \lambda_m^2} - P\lambda^2,$$

in which  $P$ ,  $Q$ , and  $\lambda_m^2$  depend on the nature of the medium. When  $P > Q$ , the refractive index must diminish as  $\lambda$  increases, until  $n^2$  becomes negative, that is, until total reflection occurs. When  $P = Q$ ,  $n$  reaches a minimum value for  $\lambda = \infty$ ; but when  $P < Q$ , this limiting value corresponds with a finite wave-length. A value of  $n$  independent of dispersion can only exist, then, when  $P = Q$ , in which case Helmholtz's formula reduces to Lommel's.

Ketteler's still more recent formula—

$$n^2 - 1 = \frac{A}{\lambda^2 - B} + \frac{C}{\lambda^2 - D} + \dots$$

gives  $n = 1$ , when  $\lambda = \infty$ , that is, the limiting value of  $n$  would be unity for all substances, and consequently there could be no index of refraction independent of dispersion.

The author's investigations have now shown that for calculations by interpolation Helmholtz's and Ketteler's equations give equally good results in the case of media of low dispersive power. No choice between them is possible. But when applied to highly dispersive media, Helmholtz's formula is inferior not only to Ketteler's (which contains an additional constant), but also to Cauchy's. Taking a series of measurements of  $n$  for oil of cassia (Baden-Powell), the constants for each formula were determined from observations extending to the extreme limits of the visible spectrum. Calculating the values of  $n$  for intermediate wave-lengths, the best results were usually obtained by Ketteler's formula. But with constants determined from lines between C and G, Cauchy's formula proved most trustworthy, especially for extrapolation. These conclusions are clearly set forth in a tabular statement.

An important result of this investigation is that  $Q$  in Helmholtz's equation is always found  $> P$ , which at once disposes of Lommel's theory. The refractive index should therefore be a minimum for some wave-length not infinite. According to the way in which the constants were determined, this minimum was either 1.59 for  $\lambda = 8.555$ , or 1.6002 for  $\lambda = 7.397$ ; whereas for the line A,  $n$  was observed  $= 1.5963$ , or less than the theoretical minimum.

In the foregoing comparisons, the constants were always determined for lines within the limits of the visible spectrum. With constants

determined over a much wider range, Wüllner has found Helmholtz's formula, and Ketteler his own formula, to give excellent results in the case of feebly dispersive substances, although, as the author points out, the two are fundamentally different, and cannot both be correct. From the author's calculations, it appears that both are equally insufficient when applied to highly dispersive media. In proof, a table is given of the differences between the observed values of  $n$  for the ordinary and extraordinary spectra of calcspar, and the values calculated by Helmholtz's and Ketteler's equations respectively. The observed values are by Mascart for lines from A to R, and by Sarasin for the ultra-violet (cadmium) spectrum. The constants were determined for lines over the whole spectrum.

The results show that for the extraordinary spectrum, in which the dispersion is low, Helmholtz's formula is satisfactory, Ketteler's somewhat better. But when applied to the ordinary spectrum, in which the dispersion is  $2\frac{1}{2}$  times greater, the discrepancies are very serious, extending in the case of Helmholtz's formula to the third place of decimals. Ketteler's equation proved somewhat better.

From his investigations, the author draws the following important conclusions:—That all the formulæ connecting wave-length and refrangibility hitherto proposed are of purely empirical character, and applicable only to media of low dispersive power: that at present it is not certain that the refractive index reaches a limiting value, unity or otherwise, either for  $\lambda = \infty$  or for any other wave-length; and, finally, that in investigations bearing on chemical constitution and refractive power, dispersion must either be taken into account, or be eliminated in some empirical way.

CH. B.

**Supposed Influence of Multiple Bonds of Union on the Molecular Refraction of the Hydrocarbons.** By JULIUS THOMSEN (*Ber.*, 19, 2837).—In 1862–64, Landolt (*Ann. Phys. Chem.*, 117, 122, and 123) proved beyond doubt that a connection exists between molecular refractive power and chemical composition, by showing that in any homologous series the refractive power increases from member to member by a constant amount, and is independent of isomerism and metamerism.

Since then Brühl (Abstr., 1880, 295, 781; 1882, 445, and preceding Abstract) has endeavoured, with apparent success, to establish a relation between molecular *constitution* and refractive power, by showing that the refractive power of a compound, although independent of the number of single bonds of union between carbon-atoms in its molecule, is decidedly influenced by double and treble bonds. The following considerations, however, make such an influence at least doubtful:—

Brühl's results are summed up in the formula—

$$n \cdot c + 2m \cdot h + \alpha V_1 + \beta V_2 + \gamma V_3 = R \quad . \quad . \quad . \quad [1]$$

in which R is the molecular refraction of a hydrocarbon  $C_nH_{2m}$ ,  $c$  and  $h$  the refractions of a carbon and hydrogen atom respectively,  $\alpha$ ,  $\beta$ , and  $\gamma$  the numbers of single, double, and treble bonds of union, and

$V_1$ ,  $V_2$ , and  $V_3$  the increments of refractive power due to them respectively.

Brühl now puts  $V_1 = 0$ ; but this assumption may be avoided, and  $V_1$  eliminated as an independent constant by combining equation [1] with the necessarily true relation  $2n - m - \alpha - 2\beta - 3\gamma = 0$ . Multiplying the latter by  $V_1$ , and adding, we get—

$$n(c + 2V_1) + m(2h - V_1) + \beta(V_2 - 2V_1) + \gamma(V_3 - 3V_1) = R, \quad [3]$$

and finally substituting  $x$ ,  $y$ ,  $p$ , and  $q$  for the constant quantities within brackets, we get—

$$n \cdot x + m \cdot y + \beta \cdot p + \gamma \cdot q = R, \quad . \quad . \quad . \quad . \quad [4]$$

which is of the same form as [1], and identical with it when  $V_1 = 0$ , but in which  $R$  is not necessarily independent of the number of single bonds of union between carbon-atoms. In either case,  $x + y = c + 2h + V_1$  represents the increase in refractive power for each addition of  $\text{CH}_2$ . Experimentally,  $x + y$  has been found to vary from 4.85 in the benzene series to 4.525 in the naphthalene-group. No values of  $x$  and  $y$  can therefore exist which will in all cases satisfy equation [4], and this must also be true of the constants  $p$  and  $q$ . The following example illustrates this:—

Taking the experimental value of the refraction of two molecules of benzene,  $51.86 = 12c + 12h + 6V_1 + 6V_2$ , and of one molecule of naphthalene,  $43.93 = 10c + 8h + 6V_1 + 5V_2$  and subtracting, we have  $2c + 4h + V_2 = 7.93$ . From this and the relation  $c + 2h + V_1 = 4.85$  or  $4.525$  we find  $V_2 - 2V_1 = \text{constant } p$  in equation [4]  $= -1.77$  or  $-1.12$ .

Now Brühl (preceding Abstract) has found the following values for the constants of equation [4]:—

$$x = 2.48, y = 2.08, p = 1.78, q = 1.97 \quad . \quad . \quad . \quad [5]$$

The above calculation shows the *negative* influence of  $p$  to be as great as Brühl assumes it to be positive.

Again the difference between the molecular refractions of naphthalene and benzene, calculated with Brühl's constants  $= 42.02 - 26.46 = 15.56$ , whereas the actual difference  $= 8.00$ . Brühl attributes the discrepancy to the greater dispersive power of naphthalene. The author rather attributes it to the incorrectness of Brühl's hypothesis, which he proceeds to show is unnecessary.

Assuming either that double and treble bonds of union have no influence on molecular refraction, or that  $V_2 = 2V_1$ ,  $V_3 = 3V_1$ , equation [3] reduces to  $R = nx + my$ . The author has now determined the constants  $x$  and  $y$  from the observed molecular refractions of a series of five hydrocarbons of the general formula  $\text{C}_8\text{H}_{2m}$ , containing 1, 2, 3, and 4 double bonds of union, and thus arrives at the equation  $R = n \cdot 4.014 + m \cdot 0.840$ . A table is then given showing the molecular refractions of these five hydrocarbons and of three others, containing from 0 to 5 double bonds, calculated by the author's formula and by equation [4] with Brühl's constants; and the agreement with experiment is seen to be much better in the former case (mean error  $= 0.37$ ) than in the latter (mean error  $= 0.8$ ).

The author therefore concludes that the mode of union of carbon-atoms has no influence on molecular refraction.

In the author's formula, the values of  $x$  and  $y$  can only be regarded as approximate. However, the range of variation is not great. A table is given of the values of  $x$  calculated for 22 hydrocarbons, roughly classified according to the number of double bonds in their molecules. Throughout  $y$  is taken = 0.84. In no case does the value of  $x$  differ much from the mean value given above. For one group only, of which hexahydronaphthalene may be considered typical, it falls as low as 3.75; but even here  $x + y = 4.59$  is within the observed limits of variation.

CH. B.

**Thomsen's Supposed Explanation of Molecular-refraction Relations.** By J. W. BRÜHL (*Ber.*, 19, 3103—3108).—A partial reply to Thomsen (*ibid.*, 19, 2837, see previous Abstract). The author points out that the constant  $y$  in Thomsen's formula for molecular refraction,  $R = nx + my$ , has been calculated from observations on a series of hydrocarbons of the formula  $C_8H_{2m}$ , in which the increments of refractive power for each addition of  $H_2$  are very variable, sometimes positive, sometimes negative, a variability which can only be attributed to chemical constitution. Like other empirical formulæ, Thomsen's is no doubt applicable to the observations from which it was deduced, and possibly to others besides. But in many cases (quoted by the author) it is seriously at fault, whilst the author's formula applies to all hydrocarbons except those having a high dispersive power, to which the author attributes a special influence.

Referring to his previous work (see preceding Abstracts) for a full discussion of the question, he here contents himself with quoting examples of isomeric compounds whose molecular refractive powers differ more or less. In all the compounds selected, the dispersive power is low. Inspection of the table shows that when isomerides are equally saturated, that is, contain the same number of doubly or trebly bound atoms (isovaleric acid, propylic acetate, methylic butyrate), their molecular refractive powers differ very slightly; but when the saturation is unequal (allyl ethyl ether and valeral, cymene and hexahydronaphthalene) the differences are considerable, and beyond the possible limits of experimental error. The influence of saturation on refractive power cannot therefore be ignored.

CH. B.

**Absolute Electrodynamometer.** By H. PELLAT (*Compt. rend.*, 103, 1189—1190).—A description of a new electrodynamic balance.

**New Apparatus for Electrochemical Investigations.** By N. v. KLOBUKOFF (*J. pr. Chem.* [2], 34, 539—547).—A description, with plates, of a "universal commutator" which fulfils the following conditions:—

That with a given large number of circuits in which the measurement of the strength of the currents has to be determined with one and the same measuring instrument, the making and breaking contact with the latter can be easily and quickly effected.

That the alteration of the strength of a given current caused by throwing the resistance of the measuring instrument out of circuit can be overcome in such a way that at the moment of breaking contact with the measuring instrument, a resistance can be automatically introduced equal to that of the instrument. G. H. M.

Silver affords a further illustration of the identity between the specific heats before and after fusion. Great care was taken to prevent

phosphate was added to the magnesium salt showed that the difference between the heats of formation of the colloidal and crystalline varieties of the double phosphate is greater than +12.4. These experiments gave a higher value than the first series for the heat of formation of this compound, and the combined results of both series give for the heat of formation of ammonium magnesium phosphate, colloidal, +29.3 cal.; crystalline, +41.9 cal. These values agree closely with the corresponding values for colloidal and crystalline trimagnesium phosphate.

When magnesium hydrogen phosphate is in the colloidal condition, the displacement of the third atom of hydrogen by magnesium develops only +3.7 cal., whilst the same substitution in the crystalline phosphate develops +14.4 cal. Similar phenomena are observed with calcium phosphate. In like manner, the action of ammonia on colloidal magnesium hydrogen phosphate develops only +4.1 cal., whilst its action on the crystallised salt develops +14.6 cal., a quantity higher than that developed by magnesium, and equal to that developed by sodium or potassium. It follows that ammonium in union with magnesium forms a base, the energy of which is comparable with the energy of sodium and potassium, as already observed in the case of the chlorides and sulphates. (This vol., p. 96.) It also follows that the action of ammonia on trimagnesium phosphate will produce only a very slight thermal disturbance.

Trimagnesium phosphate is rapidly altered by ammonia with production of ammonium magnesium phosphate, not because the heats of formation of the two phosphates for the colloidal condition are very different, but because the double salt more rapidly passes into the crystalline condition and thus develops heat. This result illustrates the fact that the more or less rapid formation of salts in the colloidal or crystalline condition depends on the order in which the reacting substances are brought together. Ammonia also acts on crystallised trimagnesium phosphate with development of +0.42 cal., but the reaction is not complete without the addition of ammonium chloride. When this salt is added, there is a slight additional development of heat owing to the formation of a small quantity of magnesium chloride; this fact explains the effect produced by the presence of ammonium chloride when magnesium salts are precipitated by sodium phosphate. This effect is only exerted in presence of at least three equivalents of base. Ammonium chloride alone has no action on magnesium phosphate.

These facts explain the difficulty which is experienced in displacing ammonia from ammonium magnesium phosphate by means of magnesia or lime. Lime tends to produce colloidal calcium phosphate, the heat of formation of which is less than that of the double phosphate. The heat of formation of crystallised trimagnesium phosphate is also somewhat less than that of the double compound. That decomposition takes place at all is due to the combined effect of the slight dissociation of the ammonium compound in the presence of water, especially if heated, and the volatilisation of the ammonia, which is thus removed from the sphere of action, the magnesium taking its place.

C. H. B.

**Saturation of Arsenic Acid by Magnesia: Formation of Ammonium Magnesium Arsenate.** By C. BLAREZ (*Comp. rend.*, **103**, 1133—1135).—The developments of heat accompanying the displacement of successive atoms of hydrogen by magnesium are +14·866 cal.; +11·464 cal.; +2·03 cal., giving for the total heat of neutralisation, +28·36 cal.

The heat developed by the neutralisation of arsenic acid by magnesium and ammonium is +37·645 cal., from which it follows that the displacement of the third atom of hydrogen by ammonium develops +11·30 cal.

C. H. B.

**Heat of Formation of Potassium Methoxide and Ethoxide.** By DE FORCRAND (*Compt. rend.*, **103**, 1263—1266).—Potassium methoxide is obtained by dissolving potassium in excess of anhydrous methyl alcohol and heating the solution in a current of pure dry hydrogen at 200°. Complex alcoholates similar to those formed by sodium are at first formed. The heat of solution at 12° is +11·74 cal.

|  |                       |
|--|-----------------------|
| $\text{CH}_3\cdot\text{OH liq.} + \frac{1}{2}\text{K}_2\text{O solid} = \text{CH}_3\cdot\text{OK solid} + \frac{1}{2}\text{H}_2\text{O solid} \dots\dots\dots$ | develops + 24·79 cal. |
| $\text{CH}_3\cdot\text{OH liq.} + \text{KHO solid} = \text{CH}_3\cdot\text{OK solid} + \text{H}_2\text{O solid} \dots\dots\dots$                               | „ + 4·30 „            |
| $\text{CH}_3\cdot\text{OK solid} + \text{H}_2\text{O liq.} = \text{CH}_3\cdot\text{OH liq.} + \text{KHO solid} \dots\dots\dots$                                | „ - 2·87 „            |
| $\text{CH}_3\cdot\text{OH liq.} + \text{K solid} = \text{CH}_3\cdot\text{OK solid} + \text{H gas} \dots\dots\dots$   | „ + 38·17 „           |
| $\text{CH}_3\cdot\text{OK solid} + n\text{CH}_3\cdot\text{OH liq.} = \text{CH}_3\cdot\text{OK diss. in } n\text{CH}_3\cdot\text{OH liq.} \dots\dots\dots$      | „ + 12·76 „           |

Potassium ethoxide is obtained in a precisely similar manner. A small quantity of crystals of the compound  $\text{EtKO} + 3\text{EtOH}$  was obtained. Heat of solution of the ethoxide at 12—15° = +14·70 cal.

|   |                       |
|---|-----------------------|
| $\text{C}_2\text{H}_5\cdot\text{OH liq.} + \frac{1}{2}\text{K}_2\text{O solid} = \text{C}_2\text{H}_5\cdot\text{OK solid} + \frac{1}{2}\text{H}_2\text{O solid} \dots\dots\dots$              | develops + 22·28 cal. |
| $\text{C}_2\text{H}_5\cdot\text{OH liq.} + \text{KHO solid} = \text{C}_2\text{H}_5\cdot\text{OK solid} + \text{H}_2\text{O solid} \dots\dots\dots$  | „ + 1·79 „            |
| $\text{C}_2\text{H}_5\cdot\text{OK solid} + \text{H}_2\text{O liq.} = \text{C}_2\text{H}_5\cdot\text{OH liq.} + \text{KHO solid} \dots\dots\dots$   | „ - 0·36 „            |
| $\text{C}_2\text{H}_5\cdot\text{OH liq.} + \text{K solid} = \text{C}_2\text{H}_5\cdot\text{OK solid} + \text{H gas} \dots\dots\dots$  | „ + 35·66 „           |
| $\text{C}_2\text{H}_5\cdot\text{OK solid} + n\text{C}_2\text{H}_5\cdot\text{OH liq.} = \text{C}_2\text{H}_5\cdot\text{OK diss. in } n\text{C}_2\text{H}_5\cdot\text{OH liq.} \dots\dots\dots$ | „ + 13·59 „           |

The values for the potassium compounds agree very closely with those obtained previously for the sodium compounds, and the values are practically the same with both ethyl and methyl alcohol. Moreover the values corresponding with the action of potassium and potassium hydroxide on the two alcohols agree closely with those corresponding with their action on water.

In the case of sodium the differences between the heat developed

by its action on the two alcohols respectively, and on water, are much greater than the corresponding differences in the case of potassium, and the absolute values of the quantities are higher with sodium, a result which is due to the fact that the tendency to form polyalcoholic alcoholates is much greater in the case of sodium. Moreover, the heats of formation of the hydrates of potassium hydroxide are much greater than those of the corresponding sodium compounds.

It follows that the alcoholates of potassium ethoxide or methoxide dissolved in the alcohols are practically in the same condition as potassium hydroxide dissolved in water, whilst the dissociation of sodium hydroxide in water is much greater than that of sodium methoxide and ethoxide in the alcohols.

C. H. B.

### Heats of Neutralisation of Glyceric and Camphoric Acids.

By H. GAL and E. WERNER (*Compt. rend.*, 103, 1199—1200).—*Glyceric Acid*,  $\text{OH}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{COOH}$ .—Heats of neutralisation by the first and second equivalent of potassium hydroxide respectively +11.334 cal. and +12.127 cal.; total +23.461 cal. The addition of a third equivalent of alkali causes no further thermal disturbance.

*Camphoric Acid*,  $\text{C}_8\text{H}_{14}(\text{COOH})_2$ .—Heats of neutralisation by the first, second, and third equivalents of sodium hydroxide respectively, +13.828 cal.; +13.253 cal.; +0.0 cal.; total +27.081 cal.

These results confirm the former conclusion that the total heat of neutralisation of hydroxy-acids is lower than that of acids into which the hydroxyl-group has not been introduced.

C. H. B.

### Heats of Neutralisation of Malic and Citric Acids and their Pyrogenic Derivatives.

By H. GAL and E. WERNER (*Compt. rend.*, 103, 1019—1022).

|                          | Heat of<br>neutralisation. | Heat of solution<br>at about 20°. |
|--------------------------|----------------------------|-----------------------------------|
| Maleic acid . . . . .    | $13.310 \times 2$          | — 4.438                           |
| Fumaric acid . . . . .   | $13.299 \times 2$          | — 5.901                           |
| Citraconic acid. . . . . | $13.511 \times 2$          | — 2.793                           |
| Mesaconic acid. . . . .  | $13.633 \times 2$          | — 5.943                           |
| Itaconic acid. . . . .   | $12.837 \times 2$          | — 5.923                           |
| Malic acid . . . . .     | $12.4 \times 2$            |                                   |
| Citric acid. . . . .     | $12.8 \times 3$            |                                   |

The heat developed by neutralisation is practically the same for each acid function of the same acid.

In all cases, with the exception of itaconic acid, the heat of neutralisation of the pyrogenic derivatives is about 2 cal. greater than that of the generating acid, a relation similar to that already observed in the case of monobasic acids and the corresponding hydroxy-acids (this vol., p. 96). The pyrogenic acids derived from malic acid by the loss of  $\text{H}_2\text{O}$ , and from citric acid by the loss of  $\text{CO}_2 + \text{H}_2\text{O}$ , no longer contain the hydroxyl-group.

C. H. B.

**Heat of Neutralisation of Meconic and Mellitic Acids.**

By H. GAL and E. WERNER (*Compt. rend.*, **103**, 1141—1142).—The heat developed by the action of successive equivalents of sodium hydroxide on meconic acid,  $\text{OH}\cdot\text{C}_4(\text{COOH})_3$  is +14.074 cal.; +13.611 cal.; +8.369 cal.; +1.328 cal. = 37.382 cal.

The heat developed by the action of sodium hydroxide on mellitic acid,  $\text{C}_6(\text{COOH})_6$ , is +15.040 cal.; +15.516 cal.; +15.294 cal.; +13.713 cal.; +12.793 cal.; +11.678 cal. = 84.034 cal.

The heat of neutralisation of meconic acid is less than that of mellitic acid, probably because the former is a hydroxy-acid. In both cases the heat of neutralisation diminishes as neutralisation becomes more complete. The values for mellitic acid show that if neutral sodium mellitate is evaporated with excess of hydrochloric acid, it will lose part of the base and yield an acid salt, and the same acid salt will be obtained, when mellitic acid is heated with a solution of an alkaline chloride. The values obtained for mellitic acid are analogous to those found for phosphoric, sulphuric, and other acids in which several hydroxyl-groups are united with the same radicle.

The numbers for the six acid functions of mellitic acid differ more widely than would have been expected from the symmetrical constitution generally assigned to this acid.

C. H. B.

**Temperature Regulator.** By G. W. A. KAHLBAUM (*Ber.*, **19**,

2860—2862).—An improvement on Andrea's form (*Ann. Phys. Chem.* [2], **4**, 164).

**Influence of Change of Atmospheric Pressure on Boiling**

**Point.** By G. W. A. KAHLBAUM (*Ber.*, **19**, 3098—3101).—With the exception of Broch's "Températures d'ébullition de l'eau pure" (*Trav. et Mém. Bureau Internat. des Poids et Mes.*, I., A., **43** (1881)), calculated from Regnault's observations (*Mém. Acad. Sci.*, **21** (1847)), accurate determinations of boiling point at regular intervals of pressure have not been made.

The author has made such a series of measurements for ether (sp. gr. 0.720). The ether was boiled in a platinum vessel, the heating being as uniform as possible; and to avoid possible change of the zero point of the thermometer, the latter was wrapped in wadding and transferred to a vessel of boiling ether after each observation. It was thus maintained at about the same temperature for a period of four months. The author strongly recommends this device. By graphic interpolation, the boiling points were calculated for each mm. of pressure from 721 to 750, and are given in tabular form. Only relative, not absolute, accuracy is claimed for them.

A comparison of this table with Broch's shows that within the ordinary limits of variation of atmospheric pressure, the curves of boiling point for water and ether are practically parallel. Assuming this to be true for other liquids whose boiling point may exceed 100° by as much as that of ether falls below it, the author gives a table of corrections of observed boiling point for each mm. pressure, for liquids boiling between 30° and 170°, of which the following is a condensed form—

|                                |                        |
|--------------------------------|------------------------|
| Between 720—730 mm. = + 0.038° | 750—760 mm. = + 0.037° |
| „ 730—740 „ = + 0.037          | 760—770 „ = - 0.036    |
| „ 740—750 „ = + 0.037          | 770—780 „ = - 0.036    |

or a mean of  $1^\circ$  for each 2.69 mm. This agrees with Kopp's result,  $1^\circ = 2.7$  mm. (*Annalen*, **34**, 266); Landolt's slightly higher figure,  $0.043^\circ = 1$  mm. (*Annalen*, Suppl. Bd. **6**, 175), was calculated for lower pressures.

CH. B.

**Boiling Points of the Fatty Acids,  $C_2H_4O_2$ — $C_5H_{10}O_2$ .** By G. W. A. KAHLBAUM (*Ber.*, **19**, 2863—2865).—The author compares his published results with those obtained by Ramsay and Young (*Abstr.*, 1886, 965), and by Richardson (*Trans.*, 1886, 761), and points out their close agreement for pressures varying between 5 and 50 mm. This he regards as sufficient answer to the criticisms of Ramsay and Young.

W. P. W.

**Vapour-tensions of Ethereal Solutions.** By E. RAOULT (*Compt. rend.*, **103**, 1125—1127).—The author has carefully measured the vapour-tensions of ethereal solutions of several organic compounds at different temperatures.

Between  $0^\circ$  and  $25^\circ$ , the difference between the vapour-tension of the ethereal solution and that of the ether is exactly proportional to the vapour-tension of pure ether at the particular temperature. For solutions containing from 1 to 5 mols. of the substance in 5000 grams of ether, the difference between the vapour-tension of the solution and that of pure ether is proportional to the amount of solid in solution. The relative diminution of the vapour-tension caused by the solution of 1 gram of the substance in 100 grams of ether depends on the nature of the substance. The molecular reduction of the vapour-tension  $k$  is obtained by the formula  $k = \frac{f + f'}{f} \times \frac{M}{P}$ , in which  $f$  is the vapour-tension of ether,  $f'$  the vapour-tension of the solution,  $M$  the molecular weight of the substance, and  $P$  the amount dissolved in 100 grams of ether. It is found that if a gram-molecule of any compound whatever is dissolved in 100 grams of ether, the vapour-tension of the ether is diminished by a constant fraction of its normal value. For all temperatures between  $0^\circ$  and  $25^\circ$ , the value of this fraction is 0.71.

C. H. B.

**Apparatus for Measuring the Tension of Vapours.** By G. W. A. KAHLBAUM (*Ber.*, **19**, 2954—2958).—The essential point in this apparatus is the maintenance of a uniform temperature by the circulation of a current of water heated in a vessel exterior to the jacket.

W. P. W.

**Dissociation of Salts containing Water of Crystallisation.** By W. MÜLLER-ERZBACH (*Ber.*, **19**, 2874—2876).—A continuation of the author's experiments (*Abstr.*, 1885, 952; 1886, 10) in which the relative vapour-tensions of the water in the salts and of pure water are compared. The following salts are examined:  $CaN_2O_6 + 4H_2O$ ,

p 2

relative tension = 0·06—0·07:  $\text{CaN}_2\text{O}_6 + 3\text{H}_2\text{O}$ , relative tension = 0·10—0·11; after the loss of 1 mol.  $\text{H}_2\text{O}$ , this fell to 0·04. The salt obtained by dissolving the latter in a fourth molecular proportion of water had a relative tension = 0·27—0·36; after 2 mols.  $\text{H}_2\text{O}$  had been removed, the tension fell to 0·08—0·07, and reached 0·04 before the last traces of water were removed. The author regards this variation in the tension required to separate the different proportions of the water from the solution as affording good evidence of the existence of a molecular compound in the liquid. With  $\text{SrN}_2\text{O}_6 + 4\text{H}_2\text{O}$ , the relative tension at  $12\cdot4^\circ$  was 0·61;  $\text{ZnN}_2\text{O}_6 + 6\text{H}_2\text{O}$ , relative tension = 0·18 at  $12\cdot1^\circ$ , after the loss of  $2\text{H}_2\text{O}$  this fell to 0·025, and became imperceptible when a salt containing 3 mols.  $\text{H}_2\text{O}$  was left.  $\text{BaH}_2\text{O}_2 + 8\text{H}_2\text{O}$  lost 1 mol.  $\text{H}_2\text{O}$  with a relative tension = 0·88—0·92, 5 more mols.  $\text{H}_2\text{O}$  were lost when it fell to 0·18—0·22, and a diminution to 0·10 to 0·12 accompanied the separation of a seventh mol.  $\text{H}_2\text{O}$ ; 1 mol.  $\text{H}_2\text{O}$  remaining combined with the salt.  $\text{SrH}_2\text{O}_2 + 8\text{H}_2\text{O}$  lost 1 mol.  $\text{H}_2\text{O}$  with a relative tension = 0·73 at  $17\cdot6^\circ$ , and a further 6 mols.  $\text{H}_2\text{O}$  with a relative tension = 0·27 at  $18\cdot5^\circ$ , 1 mol.  $\text{H}_2\text{O}$  remaining combined with the hydroxide.

W. P. W.

**Dissociation of Copper Sulphate.** By W. MÜLLER-ERZBACH (*Ber.*, 19, 2877—2879).—In this paper, it is pointed out that H. Lescœur, working with a different method and at higher temperatures, has arrived at results (this vol., p. 100) which agree exactly with those previously obtained by the author (*Abstr.*, 1886, 10). Lescœur, in his criticisms on the author's earlier experiments (*Abstr.*, 1884, 952), has overlooked these more recently published experiments on the dissociation of copper sulphate.

W. P. W.

**The Relation between the Efflorescence and Deliquescence of Salts and the Maximum Vapour-tensions of their Saturated Solutions.** By H. LESCEUR (*Compt. rend.*, 103, 1260—1263).—The presence of a few tenths of a per cent. of water over and above that which is actually combined with the salt, is sufficient to give the maximum vapour-tension of its saturated solution. In order that a salt may be deliquescent, the maximum vapour-tension of its saturated solution must be lower than that of the aqueous vapour in the atmosphere. The following table gives the vapour-tensions of the saturated solutions, and may be termed the scale of deliquescence at  $20^\circ$ :—

|                           |           |                       |         |
|---------------------------|-----------|-----------------------|---------|
| Potassium nitrate . . . . | 15 mm.    | Strontium bromide . . | 9·1 mm. |
| Potassium chloride ..     | 13·55 mm. | Potassium carbonate   | 6·9 "   |
| Sodium acetate (cryst.)   | 12·4 "    | Magnesium chloride    | 5·75 "  |
| Iodic acid . . . . .      | 11·6 "    | Calcium chloride ...  | 5·6 "   |
| Strontium chloride . . .  | 11·5 "    | Potassium acetate ..  | 3·9 "   |
| Sodium nitrate . . . . .  | 11·15 "   | Arsenic anhydride ..  | 2·3 "   |
| Sodium chromate . . . .   | 10·6 "    | Sodium hydroxide ..   | 1·0 "   |
| Calcium nitrate . . . . . | 9·3 "     | Potassium hydroxide   | 0·8 "   |
| Ammonium nitrate ..       | 9·1 "     |                       |         |

On the other hand, if the vapour-tension of a hydrated salt is greater than that of the aqueous vapour in the air, the salt will be efflorescent. The following table furnishes a scale of efflorescence at  $20^{\circ}$  :—

|   |          |
|---|----------|
| Sodium arsenate, $\text{Na}_2\text{HAsO}_4 + 12\text{H}_2\text{O}$ .....          | 16.0 mm. |
| „ sulphate, $\text{Na}_2\text{SO}_4 + 10\text{H}_2\text{O}$ .....                 | 13.9 „   |
| „ phosphate, $\text{Na}_2\text{HPO}_4 + 12\text{H}_2\text{O}$ .....               | 13.5 „   |
| „ acetate, $\text{NaC}_2\text{H}_3\text{O}_2 + 3\text{H}_2\text{O}$ .....         | 12.4 „   |
| „ carbonate, $\text{Na}_2\text{CO}_3 + 10\text{H}_2\text{O}$ .....                | 12.1 „   |

C. H. B.

**Density of Weak Aqueous Solutions of Certain Salts.** By J. G. MCGREGOR (*Chem. News*, 55, 3—6).—Experiments have been made to decide:—1. Whether or not there are solutions of salts, given volumes of which are less than the volumes of the water they contain. 2. How the density of very weak solutions varies with their strength. Anhydrous copper sulphate has already been shown to form weak solutions exhibiting the first property. Experiments with zinc sulphate, magnesium sulphate, and calcium chloride now show that these salts do not behave in this manner, but that the solutions they form are always of greater volume than the water they contain. The strength of the solutions examined, varied in the case of zinc sulphate from 0.186 to 2.895 per cent. of the salt; of magnesium sulphate from 0.191 to 1.132; of calcium chloride from 0.191 to 1.320 per cent. With regard to the density of the solutions: with the zinc and magnesium salt, the increase in density is nearly in direct proportion to the percentage of salt in solution, whereas with calcium chloride the rate of increase of density with concentration diminishes as the percentage of salt in solution increases. The mode of experimenting is fully described and the results are tabulated. D. A. L.

**Cohesion and Submersion Figures.** By C. TOMLINSON (*Chem. News*, 55, 1—2).—Referring to a paper by Ackroyd on this subject (*Abstr.*, 1886, 971), the author recalls the work of Rogers and his own work in the same direction. In 1864, he published papers on “Submersion Figures” produced by a large variety of liquids, and diagrams were given illustrating the formation and structure of these liquid “rolling rings,” and also of aerial “rolling rings.” Reference is also made to other work on the same subject, to the modes of exhibiting vortex rings at the lecture table, and to the author’s researches

on the action of nuclei and porous bodies in liberating vapour from boiling liquids. D. A. L.

**Weight of Drops and their Relation to the Constants of Capillarity and the Capillary Meniscus Angle.** By J. TRAUBE (*J. pr. Chem.* [2], 34, 515—538; compare this vol., p. 101).—From the results obtained with water and with solutions of alcohol of different strengths, the author concludes that the weight of drops and their capillary constants decrease with the increasing curvature of the surface of formation of the drops; this decrease does not, however, begin before a certain degree of curvature, which is different for different liquids. The decrease of the weight of drops in the case of different liquids is not proportional to the increase of curvature, but appears to be the greater the smaller the capillary constants of the liquid. He also finds that the edge-angle of the meniscus of drops of different liquids is equal or proportional to the meniscus angle of the same liquid in capillary tubes.

The author also made a series of determinations with solutions of alcohols and acids of different strengths, observing in each case the time which was necessary for the formation of a drop from a capillary tube and also the time necessary for the formation of a drop plus the curved surface of its meniscus; by working out the proportion between these, he found that the ratio of the time of formation between the curved surface of the drop-meniscus and the drop increases with the increasing radius of the tube; and that the drop-meniscus in general increases in proportion to the drop with increasing concentration of the solution; that is, with decreasing cohesion. The difference in the quotient  $\frac{T_w}{T_t}$  decreases with increasing concentration ( $T_w$  = time of formation of the drop-meniscus,  $T_t$  = that of the drop); therefore, curves constructed with the concentrations (as abscissæ) and these quotients are concave. With compounds of an homologous series, and equal concentration, the drop-meniscus increases with the molecular weight of the dissolved substance. The determination of the size of the drop-meniscus was made in order to see if any conclusion regarding the meniscus angle could be drawn from their respective sizes. The results showed that—1. The volume of the drop-meniscus and the top meniscus angle, which the tangential planes, formed by the last particles of the curved surface of the drop-meniscus, form with the horizontal tube wall, decreases with increasing concentration of the solution, like the meniscus angle in capillary tubes. 2. For substances of an homologous series, in solutions of equal strength, the volume of the drop-meniscus decreases with the increasing molecular weight of the dissolved substance, as do also the top edge of the angle of the drop-meniscus, and the meniscus in capillary tubes.

In conclusion, the author considers that Laplace's hypothesis, according to which the meniscus angle for wetting liquids is equal to 0, cannot be maintained in view of the results obtained by the direct measurement of the capillary meniscus at different temperatures, and by the measurement of drops; moreover, one of the most important

theories of capillarity can only be maintained if the finiteness of the meniscus angle is accepted.

Wilhelmy's important law of the constancy of the meniscus angle cannot be accepted in its universality, since the size of this angle appears to depend on the temperature of the liquid and the curvature of the walls of the tube. Moreover, the meniscus angle, which the surface of a drop forms with a horizontal glass surface, is not, as Quincke supposes, equal to that which is enclosed by the meniscus surface in tubes with a vertical partition. The one is perhaps the complement of the other.

**Volatilisation of Dissolved Substances during the Evaporation of the Solvent.** By P. M. DELACHARLONNY (*Compt. rend.*, 103, 1128—1129).—Concentrated solutions of sulphuric acid, sodium hydroxide, sodium carbonate, and ferric sulphate were heated at 65—70° in vessels closed by inverted funnels. In a few hours, the fact that some of the dissolved substance had been carried off in the vapour of the solvent was easily recognised by means of suitable test-papers which had been placed in the apex of each funnel. Even at the ordinary temperature, the papers had distinctly changed after four or five days.

Acid solutions of alum and of ferrous sulphate at the ordinary temperature gave similar results.

There is no evidence of the actual carrying off of solid particles; the colour of the test-papers was uniform, and not in streaks or patches.

C. H. B.

**The Periodic Law.** By W. SPRING (*Ber.*, 19, 3092—3093).—A question of priority with regard to Emerson Reynolds's illustration of this law (*Chem. News*, 54, 1).

## Inorganic Chemistry.

**Formation of Active Oxygen in the Atmosphere, and its Connection with the Electric Phenomena of the Air and the Production of Storms.** By C. WURSTER (*Ber.*, 19, 3208—3217).—Observations made by the author lead him to conclude that ozone is formed in the air by the action of sunlight on clouds. When clouds are continually formed from above, they all become laden with ozone, whilst when they form from below only the upper layer will contain much ozone. In the former case, the accumulation of ozone causes the clouds to become strongly negatively electric, and so gives rise to thunderstorms.

N. H. M.

**Formation of Active Oxygen in Paper.** By C. WURSTER (*Ber.*, 19, 3217—3218).—The yellow and brown colour acquired by some

papers is due to the action of active oxygen on the resin used in sizing the paper, or in some cases on the woody matter present in the paper. By means of dimethylparaphenylenediamine paper (this vol., p. 298), the presence and even the percentage amount of woody matter can be determined in a paper. When the moist dimethylparaphenylenediamine paper is pressed between paper containing wood, it acquires a deep red colour. Ordinary sized paper merely turns it a delicate rose colour.

N. H. M.

**Phosphorus Pentafluoride.** By H. MOISSAN (*Compt. rend.*, **103**, 1257—1260).—Perfectly dry phosphorus pentafluoride confined over mercury is not decomposed by the action of induction sparks 40 mm. in length, a result which agrees with Thorpe's earlier observation. With sparks 150—200 mm. in length, however, the gas is decomposed into phosphorus trifluoride and fluorine, the latter at once attacking the glass and the mercury.

Phosphorus pentafluoride yields no trifluoride when heated to dull redness with an excess of phosphorus. In this respect, its behaviour differs from that of the pentachloride. It is not affected by sulphur vapour at 440°, nor by iodine vapour at 500°. In presence of a minute trace of water, it attacks glass, with formation of silicon fluoride and phosphorus oxyfluoride, whilst the alkalis in the glass are converted into phosphates or fluorophosphates.

In order to analyse the gas, a measured volume was absorbed in water in a platinum vessel, treated with nitric acid and molybdic solution, and the phosphorus finally weighed as magnesium pyrophosphate. Another method consists in absorbing a measured volume in potassium hydroxide solution, which is mixed with some pure silica, evaporated to dryness, mixed with concentrated sulphuric acid, and heated until vapours of this acid begin to come off. The liquid is then diluted, made alkaline with ammonia, and the phosphorus precipitated as magnesium ammonium phosphate.

The results agree with the formula  $PF_5$ ; the first method is the most accurate.

C. H. B.

**Compounds of Selenious and Arsenious Anhydrides with Sulphuric Anhydride: Isolation of Sulphuric Anhydride.** By R. WEBER (*Ber.*, **19**, 3185—3190).—When selenious anhydride is warmed with very carefully purified sulphuric anhydride, it dissolves therein, and if the excess of sulphuric anhydride is distilled off at 60—70°, a crystalline compound,  $SeO_2 \cdot SO_3$ , is left. This substance is decomposed by a temperature of 100°, sulphuric anhydride being evolved. Water decomposes it with great violence.

In like manner, sulphuric anhydride dissolves arsenious anhydride. If the excess of sulphuric anhydride is distilled off at 60°, a compound of the formula  $As_2O_3 \cdot 6SO_3$  is left; if the distillation is continued at 100°, the residue has the formula  $As_2O_3 \cdot 3SO_3$ . These compounds are quite distinct from the compound  $As_2O_3 \cdot SO_3$  discovered by Reich in 1863 in the Freiberg smelting works.

The author states that the specimens of pure sulphuric anhydride previously obtained and described (this Journal, 1877, ii, 164) still

retain their original character, melting and resolidifying at  $15^{\circ}$ , and showing no signs of forming allotropic modifications. He is still of opinion that the various modifications of sulphuric anhydride are all due to the presence of traces of moisture. He describes further precautions for obtaining absolutely pure anhydride, and considers the best method to be to cohobate carefully purified sulphuric anhydride with phosphoric anhydride in a slight modification of the bent and sealed distilling tube previously described (*loc. cit.*). After continued cohobation, the sulphuric anhydride will remain liquid down to  $15^{\circ}$ , even in contact with the phosphoric anhydride. Finally the sulphuric anhydride may be distilled over into the opposite end of the distilling tube, and this then sealed off without the air being able to come in contact with the inside of the tube. Phosphoric anhydride forms a compound  $P_2O_5, 3SO_3$ , which crystallises out from the excess of sulphuric anhydride. This compound decomposes at the boiling point of sulphuric anhydride.

L. T. T.

### Behaviour of Iodine with Realgar and Arsenic Iodosulphide.

By R. SCHNEIDER (*J. pr. Chem.* [2], **34**, 505—514).—*Arsenious iodosulphide*,  $AsI_3, As_2S_3$ , is prepared by heating together either a mixture of realgar (1 mol.) and iodine (2 atoms) with the least possible access of air, or a mixture of 3 parts arsenious iodide with 1.6 parts of arsenic trisulphide. It forms an amorphous, vitreous mass with conchoidal fracture, and is of a dark red or reddish-brown colour. It is not acted on by the air at ordinary temperatures. When heated at  $100^{\circ}$ , it softens, and boils at a higher temperature without evolution of iodine vapour, but with partial decomposition into arsenious iodide and sulphide. It is insoluble in hot and cold alcohol, ether, carbon bisulphide, and chloroform. Hot water slowly decomposes it with formation of hydriodic acid. Boiling hydrochloric acid slowly decomposes it with evolution of iodine. When boiled with concentrated sulphuric acid, it gives off iodine, sulphur and sulphurous anhydride. Potassium and ammonium hydroxides dissolve arsenious iodosulphide to a colourless liquid, from which dilute acids precipitate arsenious sulphide, whilst the whole of the iodine and part of the arsenic remain in solution. When treated with an ammoniacal solution of silver nitrate, it is decomposed, forming silver iodide, sulphide, and arsenite. This reaction affords a means of determining the composition of the substance.

When realgar is shaken with a solution of iodine in carbon bisulphide, and iodine is added in small quantities until the whole of the realgar is dissolved (1 mol. realgar requires 6 atoms iodine), and the solution then evaporated, arsenious iodide separates, partly in hexagonal plates and partly in rhombohedrons, mixed with long prisms of sulphur. Also, when a mixture of realgar (1 mol.) with iodine (6 atoms) is heated, and the resulting mass is dissolved in carbon bisulphide, arsenious iodide and sulphur are formed.

G. H. M.

**Arsenic Pentasulphide.** By L. W. McCAY (*Chem. News*, **54**, 287).—When a solution of an alkaline arsenate strongly acidified with hydrochloric acid and saturated with hydrogen sulphide is

heated in a closed vessel at  $100^{\circ}$  for one hour, the arsenate is completely converted into pentasulphide. It contains no trisulphide, and if due precautions have been taken to exclude air, no free sulphur. Pure arsenic pentasulphide is lemon-yellow in colour, does not yield any sulphur to carbon bisulphide, and dissolves in ammonia without separation of sulphur. When the ammoniacal solution is agitated with silver nitrate and filtered, a clear filtrate is obtained, from which nitric acid precipitates silver arsenate. The formation of arsenic pentasulphide in this manner confirms Bunsen's results, he having obtained it by the action of hydrogen sulphide on hot solutions of arsenic compounds.

D. A. L.

**Carbonic Anhydride in the Atmosphere.** By R. BLOCHMANN (*Annalen*, **237**, 39—90).—The author gives an account of the various methods which have been used for the estimation of the carbonic anhydride in the atmosphere from the time of Saussure to the present day. It is pointed out that Pettenkofer's method yields too high results; the normal amount of carbonic anhydride in 10,000 volumes of air is 3, not 4 volumes. The author describes a modification of Pettenkofer's method, which permits of the baryta-water being filtered through asbestos and titrated without coming into contact with the air of the atmosphere. A double burette of special construction is required. Drawings of the apparatus are given in the original.

W. C. W.

**Bimetallic Phosphates.** By A. JOLY (*Compt. rend.*, **103**, 1129—1132).—The action of disodium hydrogen phosphate on solutions of metallic salts varies with the conditions, and with the nature of the metal. In some cases, with silver nitrate for instance, an amorphous precipitate of the tribasic phosphate is at once produced; in others, a gelatinous monophosphate is at first precipitated, and this gradually passes into a crystalline diphosphate. In the case of the alkaline earths and manganese, the first stage in the reaction is represented by the equation  $4\text{Na}_2\text{HPO}_4 + 4\text{M}''\text{Cl}_2 = \text{M}_3''(\text{PO}_4)_2 + \text{M}'\text{H}_4(\text{PO}_4)_2 + 8\text{NaCl}$ .

The monophosphates decompose in presence of water with a rapidity which depends on the nature of the metal and the concentration of the solution (*Abstr.*, 1884, 556).

In some cases, there is an intermediate reaction, the gelatinous monophosphate becoming crystalline. This is the final stage of the reaction if the conditions are such as to prevent the formation of a diphosphate. The diphosphates decompose at  $100^{\circ}$  into crystalline tribasic phosphates and the free acid, and at the ordinary temperature the reverse change takes place to a greater or less extent. These facts indicate that the intermediate phosphates described by various authors are in reality mixtures. The precipitation of silver phosphate may be regarded as taking place in two stages, the first products being the trisilver phosphate and the monophosphate, the latter immediately decomposing into the tribasic salt and the free acid, which limits the extent of the reaction. The formation of disilver phosphate is impossible under these conditions, since this salt is immediately decomposed by water (this vol., p. 215).

In the case of hypophosphoric acid, the precipitate is at first a gelatinous bibasic phosphate, which rapidly changes into a crystalline monobasic phosphate (Abstr., 1886, 200, 408, 593, 662).

C. H. B.

**Silver Phosphates and Arsenates.** By A. JOLY (*Compt. rend.*, 103, 1071—1074).—Precipitated and amorphous silver phosphate dissolve in phosphoric acid solution, the solubility increasing with the concentration of the acid and the temperature. If a liquid containing less than 38 parts of phosphoric anhydride to 100 parts of water is saturated with silver phosphate at  $80^{\circ}$  and allowed to cool, it deposits trisilver phosphate in pale-yellow, rhombic dodecahedrons modified by faces of the icositetrahedron. The mother-liquor deposits no more crystals on standing, but will dissolve a further quantity of amorphous silver phosphate if heated, and thus the same solution of phosphoric acid can be used for the crystallisation of an unlimited quantity of silver phosphate.

If the solution contains 40 parts of phosphoric anhydride to 100 parts of water, it deposits disilver hydrogen phosphate,  $\text{Ag}_2\text{HPO}_4$ , in colourless crystals derived from a hexagonal prism. They generally form long prisms with rhombohedral terminations. In contact with water or alcohol, they become yellow, and decompose into trisilver phosphate and phosphoric acid, but they are not affected by ether. If the concentration of the phosphoric acid solution differs much from the strength given, the product is a mixture of crystals very difficult to purify.

When the crystals of disilver hydrogen phosphate are heated to  $110$ — $150^{\circ}$ , they yield silver pyrophosphate,  $\text{Ag}_4\text{P}_2\text{O}_7$ , which can also be obtained by heating the syrupy solution of the silver phosphate to the same temperature. Hurtzig and Geuther obtained the same compound by adding ether to the solution which had been heated. The pyrophosphate is not, however, formed in the wet way as these authors supposed, since under the given conditions of concentration, the fused acid salt, and not its solution, is decomposed. The experiment simply shows that disilver hydrogen phosphate yields the pyrophosphate at a lower temperature than that at which phosphoric acid is converted into pyrophosphoric acid.

Silver arsenate is much less soluble than the phosphate in the free acid. If the solution contains less than 70 parts of arsenic anhydride to 100 parts of water, the solution saturated with amorphous silver arsenate at  $80^{\circ}$  deposits very brilliant, black, opaque crystals of trisilver arsenate, which are unmodified rhombic dodecahedra.

A solution of arsenic acid of the composition  $\text{H}_3\text{AsO}_4 + \text{H}_2\text{O}$ , when saturated with silver arsenate, yields white monoclinic crystals of silver dihydrogen arsenate, a compound which is very readily prepared. It is decomposed into trisilver arsenate and arsenic acid by a trace of water, and if heated to  $100^{\circ}$  yields silver metarsenate in the form of a white powder which absorbs water very slowly. Before losing water, the crystals of the acid salt become red, probably owing to the formation of arsenic acid and disilver hydrogen arsenate,  $\text{Ag}_2\text{HAsO}_4$ . In fact, if a solution from which silver dihydrogen arsenate will crystallise is saturated with silver arsenate at a tempera-

ture a little below  $100^{\circ}$ , it deposits orange-red hexagonal prisms with rhombohedral terminations. Their form agrees with that of disilver hydrogen phosphate, and indicates that they are disilver arsenate, but they could not be purified.

When a syrupy solution of silver arsenate in arsenic acid is heated above  $100^{\circ}$ , it yields a white granular powder similar in appearance to the compound  $\text{Ag}_2\text{O}, 2\text{As}_2\text{O}_5$ , described by Hurtzig and Geuther.

C. H. B.

**Solubility of Silver Chromate in Ammonium Nitrate.** By R. F. CARPENTER (*J. Soc. Chem. Ind.*, 5, 286).—It is found that on treating freshly precipitated silver chromate with a strong solution of ammonium nitrate, the solution instantly assumes a bright yellow colour in the cold. On warming, the rate of solution rapidly increases up to the boiling point; on cooling, the silver chromate crystallises out in needle-shaped crystals. In a paper by G. Biscaro (*Chem. News*, 53, 67) "On a Defect in the Volumetric Estimation of Chlorine by Mohr's Process," it was stated that "if nitrates, especially those of the alkalis and alkaline earths, are simultaneously present, the precipitation of the red silver chromate often takes place too late," a circumstance which the author considers to be fully explained by the above experiments. The subjoined table gives the results of some experiments made to determine the relative solubility of silver chromate in the nitrates of potassium, sodium, ammonium, and magnesium in cold and hot strong solutions:—

|                      | One-tenth normal silver nitrate added. |                 | Grains of silver chromate dissolved in hot solution. |
|----------------------|--|-----------------|--|
|                      | $10^{\circ}$ .                         | $100^{\circ}$ . |  |
| Pure water.....      | 0.05 c.c.                              | 0.25 c.c.       | 0.064  |
| Sodium nitrate ....  | 0.05 „                                 | 0.25 „          | 0.064  |
| Potassium nitrate .. | 0.10 „                                 | 0.75 „          | 0.192  |
| Ammonium nitrate.    | 0.07 „                                 | 1.25 „          | 0.320  |
| Magnesium nitrate..  | 0.35 „                                 | 1.00 „          | 0.256  |

50 grains of each of the above salts were dissolved in 100 c.c. of water, and the amount of decinormal silver nitrate solution taken to obtain the reaction with potassium chromate is given in the table. In the last three cases, the author has deducted the amount of silver chromate dissolved by the water alone, and has given the amount due to the solvent action of the respective nitrates. From all these, the silver chromate crystallised out again on cooling. D. B.

**Tetracalcium Phosphate and Basic Converter Slag.** By E. JENSCH (*Ber.*, 19, 3093—3101).—It has been generally assumed that the phosphoric acid in basic converter slag is present as tetracalcium phosphate. The author has endeavoured to prepare such a phosphate by heating tricalcium phosphate with calcium carbonate to a high temperature. He has failed to obtain a crystalline substance such as is frequently seen in the basic slag, but at the same time the properties of the tricalcium phosphate are so altered as to indicate some chemical change having occurred.

The following analyses of basic slag are quoted:—I. Mean results

for the slag of all German works (Hasenclever). II. Mean of 12 analyses of slag from the steel works at Friedenshütte. III. Mean of four analyses of slag from Witkowitz.

|      | P <sub>2</sub> O <sub>5</sub> . | CaO.  | MgO. | FeO. | Fe <sub>2</sub> O <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | MnO. | S.   | SO <sub>3</sub> . | SiO <sub>2</sub> . |
|------|---------------------------------|-------|------|------|----------------------------------|----------------------------------|------|------|-------------------|--------------------|
| I.   | 17.25                           | 48.29 | 4.89 | 9.44 | 3.78                             | 2.04                             | 3.91 | 0.49 | 0.22              | 7.96               |
| II.  | 18.93                           | 54.87 | 4.90 | 8.83 | 5.20                             | 3.51                             | 0.51 | 0.44 | —                 | 6.85               |
| III. | 16.86                           | 49.45 | 1.26 | 9.88 | 5.96                             | 2.17                             | 2.93 | 0.61 | 0.10              | 10.08              |

The author considers that II may be regarded as consisting of—

|                                       |  |  |                          |      |
|---------------------------------------|--|--|--------------------------|------|
| P <sub>2</sub> O <sub>5</sub> , 4CaO. | Mn <sub>2</sub> O <sub>3</sub> , 3CaO. | Fe <sub>2</sub> O <sub>3</sub> , 3CaO. | SiO <sub>2</sub> , 2CaO. | CaS. |
| 48.78                                 | 1.20                                   | 30.77                                  | 19.59                    | 0.99 |

With regard to the statement frequently made, that a large proportion of the phosphorus is present in the form of iron phosphide, the author's results show that at most only 1.5 per cent. can be present in this form, and that even this is rendered soluble in the soil.

A. J. G.

**The Determination of Water in the Hydrates of Strontium Oxide.** By C. SCHEIBLER (*Ber.*, 19, 2865—2868).—A controversial paper, in which the author rejects the deduction drawn by C. Heyer (this vol., p. 108), as evidence of the existence of a dihydrate of strontium oxide. It is also pointed out that Heyer's method for the determination of water in the dihydrate has only a limited value, since it is inapplicable to the monohydrates of the alkaline earths and to the dihydrate of barium oxide.

W. P. W.

**Action of Carbonic Anhydride on the Dihydrate of Strontium Oxide.** By R. FINKENER (*Ber.*, 19, 2958—2963).—The author finds that well moistened strontium hydroxide, kept for some time at 50° in an atmosphere of aqueous vapour having a tension of 16 mm., is converted into the dihydrate of strontium oxide. When exposed to a current of dry carbonic anhydride, the dihydrate is decomposed into the carbonate, but the product dried at 145° is deficient in carbonic anhydride and contains water. In opposition to Heyer's statement that carbonate alone is formed under these conditions, the author regards this fact as evidence that, in addition, a hydrated basic carbonate is also formed. The basic carbonate is a neutral compound which, in an atmosphere of carbonic anhydride, slowly absorbs that gas. It does not lose its water completely at 120°, but must be raised to incipient redness before complete dehydration occurs; no evolution of carbonic anhydride occurs at this temperature, but the product on moistening with water is strongly alkaline.

W. P. W.

**Estimation of Water in Strontia Dihydrate.** By C. HEYER (*Ber.*, 19, 3222—3224).—The author does not believe in the existence of a basic strontium carbonate, and ascribes the analytical results obtained by Finkener (preceding Abstract) to the use of too great an amount of substance (Finkener used over 5 grams), as not more than 0.5 gram should be used to ensure complete decomposition (compare this vol., p. 108).

N. H. M.

**Vapour-density of Zinc.** By J. MENSCHING and V. MEYER (*Ber.*, 19, 3295—3298).—In their paper, the authors describe the method used by them in the determination of the vapour-density of zinc, and give details of the furnace employed, with which a constant temperature of about  $1400^{\circ}$  was obtainable under the conditions of working. The porcelain experimental tube was filled with nitrogen carefully freed from every trace of oxygen by slow passage over red-hot copper turnings, and through chromous chloride and alkaline pyrogallate. Two experiments were made, one at a temperature lower than the maximum, the second at the maximum temperature of the furnace, and the numbers obtained for the density were 2.41 and 2.36 respectively, compared with 2.25, the theoretical density of monatomic (Zn) zinc vapour. Experiments were also made with magnesium, but so far without success, since it has not been found possible to volatilise the metal in hydrogen. W. P. W.

**Ammonio-mercuric Chromates.** By C. HENSGEN (*Rec. Trav. Chim.*, 5, 187—198).—On dissolving mercuric oxide in ammonium dichromate, Hirzel obtained a compound to which the formula  $(\text{NHg}_2\text{OH}_2)_2\cdot 4\text{HgCrO}_4$ , was ascribed, although based only on determinations of the mercury and chromium. In this paper, it is shown that mercuric oxide dissolves readily in a saturated solution of ammonium dichromate; golden, crystalline leaflets or needles separate out; these are insoluble in water, alcohol, and ether, very soluble in hydrochloric acid, but only sparingly soluble in dilute nitric or sulphuric acid. Analytical results showed the atomic ratio  $\text{Hg} : \text{N} : \text{Cr} = 1 : 2 : 2$ , and that three-fourths of the total nitrogen was in the form of ammonium and the remainder in an amido-group, results which point to the composition  $(\text{NHg}_2\cdot\text{H}_2\text{O})_2\cdot\text{Cr}_2\text{O}_3\cdot 3(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ . These crystals when treated with excess of ammonia yield a canary-yellow powder, which no longer contains nitrogen in the form of ammonium, and to which the formula  $(\text{NHg}_2\cdot\text{H}_2\text{O})_2\text{CrO}_4$  is ascribed. If mercury chromate be digested with a warm, concentrated solution of ammonium dichromate, a brown solution is obtained, from which, on pouring into an excess of cold water, a yellow powder is deposited; the composition of the substance is  $(\text{NHg}_2\cdot\text{H}_2\text{O})_2\text{CrO}_4$ , the analogue of the selenate  $(\text{NHg}_2\cdot\text{H}_2\text{O})_2\text{SeO}_4$ . V. H. V.

**Water of Crystallisation of Alums.** By E. MAUMENÉ (*Compt. rend.*, 103, 1140—1141).—Ordinary potassium-alum, containing according to the author 28.73 mols.  $\text{H}_2\text{O}$ , was dried for several months over sulphuric acid almost completely free from water. It never shows any condition of equilibrium corresponding with the formation of a hydrate containing 24 mols.  $\text{H}_2\text{O}$ . Towards the end of the operation, dehydration took place very slowly. The product contains 3.5 mols.  $\text{H}_2\text{O}$ , and seems to have attained a condition of equilibrium.

C. H. B.

**Chemical Composition of some Ancient Ceramics from Brandenburg.** By E. JENSCH (*Ber.*, 19, 2850—2853).—Fragments of urns from various ancient burying places were analysed. The following may be quoted as examples:—I. From the urn field between

Reichersdorf and Kuppen, Jessnitz N/L. II. Fünfeichen, Fürstenberg a/O. III. Platkow, Gusow, in the Lebus district.

The specimen II was taken from the sides, which were covered with a thin glaze, I and III were taken from the bottom of the urns. Specimen II was coarse-grained and porous. Dried at 105° the loss of weight varied between 0·6—5·3 mean 1·95 per cent., an additional loss of 1·5—9·4, mean 4·0,2 per cent., occurring when the temperature was raised to a red heat.

|      | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | CaO. | MgO. | Alkalis. |
|------|--------------------|----------------------------------|----------------------------------|------|------|------|----------|
| I.   | 62·46              | 27·27                            | 3·17                             | 0·44 | 1·21 | 0·89 | 2·93     |
| II.  | 61·32              | 36·57                            | 1·07                             | 0·33 | 0·18 | 0·24 | 0·13     |
| III. | 64·57              | 27·70                            | 1·77                             | —    | 2·83 | 0·28 | 0·69     |

|      | P <sub>2</sub> O <sub>5</sub> . | SO <sub>3</sub> . | MnO. | Total. |
|------|---------------------------------|-------------------|------|--------|
| I.   | 0·01                            | 0·11              | 0·23 | 98·73  |
| II.  | —                               | —                 | —    | 99·84  |
| III. | 0·75                            | —                 | 0·27 | 98·66  |

Owing to the unusual amount of phosphoric acid, analyses of five other fragments from the two urns containing the highest amount were made, with a result that a variation of 0·26—0·85 per cent., and 0·12—0·97 per cent. respectively were found. This is in all probability accounted for by imperfect admixture of bone-ash or some material rich in phosphorus with the red clay of the district which was most probably used in the manufacture of the urns. The clay accompanying the urn from Linderode had the composition SiO<sub>2</sub>, 62·67; Al<sub>2</sub>O<sub>3</sub>, 29·34; FeO and Fe<sub>2</sub>O<sub>3</sub>, 3·56; CaO, 1·17; MgO, 0·53; Alkalis, 2·02.

W. P. W.

**Heating and Cooling of Fused Steel.** By OSMOND (*Compt. rend.*, 103, 1135—1137).—Iron containing 0·16 per cent. of carbon shows a feeble perturbation at 749° (this vol., p. 14), but the modification of the iron takes place mainly at a higher temperature. In the cooling of the fused metal, there are in fact three points at which the rate of cooling diminishes. Between 863 and 820°, the maximum effect being observed between 845° and 839°; between 775° and 736°, the maximum being between 763° and 749°; and between 693° and 669°. The first change indicates the return of the iron from the  $\beta$  modification which is stable at high temperatures, to the ordinary modification stable at the ordinary temperature, this return being retarded by the presence of the small quantity of carbon. The first diminution in the rate of cooling corresponds with a development of +3·8 cal. and the second with a development of +1·3 cal., the total 5·1 agreeing closely with Pionchon's determination +5·3 cal. On reheating, the second and third perturbations become coincident.

With steel containing 0·57 per cent. of carbon, the two perturbations at the highest temperatures become merged into one which takes place at 736—690°, but is still quite distinct from recalescence. If the steel contains 1·25 per cent. of carbon, the temperature at which alteration takes place is still lower, and in fact coincides with recalescence at

704°. It is evident that during cooling the presence of the dissolved carbon retards the alteration of the iron the more completely the greater its quantity.

Steel containing 0.16 per cent. of carbon shows the same perturbations in an atmosphere of hydrogen as in nitrogen. Steel containing 1.25 per cent. of carbon when cooled in hydrogen from 800° shows much enfeebled recalescence, a result probably due to the fact that hydrogen, as Forquignon has shown, has a strong attraction for the carbon in steel, and thus diminishes the proportion of carbon which combines with the iron. In another experiment, however, cooling from 1100°, no anomalies were observed.

No noteworthy differences are observed in an atmosphere of coal-gas.  
C. H. B.

**Influence of Silicon on the Condition of Carbon in Cast-iron.** By F. GAUTIER (*Compt. rend.*, **103**, 1137—1140).—The author has repeated Stead and Wood's experiments in which white iron was converted into grey iron by melting with a certain proportion of iron rich in silicon. His results were precisely the same, and show that in presence of not less than 2 per cent. of silicon the combined carbon is almost completely changed into graphite. He points out that the reverse change takes place in the Bessemer process. About half the silicon is removed before the amount of carbon has appreciably diminished, and it is then found that the iron has become white. The presence of manganese interferes with the conversion of combined carbon into graphite, owing to the tendency of the manganese to combine with carbon.

Grey iron prepared indirectly in this way is more homogeneous and has greater tenacity than grey iron obtained in the ordinary way.  
C. H. B.

**A New Class of Cobaltic Salts.** By F. KEHRMANN (*Ber.*, **19**, 3101—3103).—*Potassium cobaltic oxalate*,  $K_6Co_2(C_2O_4)_6 + 6H_2O$ , is obtained by mixing cobaltic hydroxide, potassium oxalate, oxalic acid, and water to a thick paste, and allowing the mixture to remain 14 to 21 days. After recrystallisation, &c., the salt is obtained in nearly black, well-formed, seemingly monosymmetric crystals, which in thin lamellæ show distinct dichroism (dark blue and emerald-green).

When treated with cold saturated sodium chloride solution, the sodium potassium salt is obtained crystallising in beautiful pyramids. The barium salt crystallises in sparingly soluble, green needles. The solutions of these salts are stable in the cold, but quickly decompose on heating with evolution of carbonic anhydride and formation of cobaltous salts. Corresponding nickel compounds could not be obtained.  
A. J. G

## Mineralogical Chemistry.

**Occurrence of Free Iodine in a Mineral Water.** By J. A. WANKLYN (*Chem. News*, **54**, 300).—The water from Woodhall Spa, near Lincoln, is exceptionally rich in bromides and iodides, and, moreover, contains iodine in sufficient quantity to give it a brown tint. On agitating it with carbon bisulphide, the water is decolorised, the bisulphide becoming violet. D. A. L.

**Gold from Burmah.** By R. ROMANIS (*Chem. News*, **54**, 278—279).—The samples were found on the banks of the Meza, a tributary of the Irrawaddi, about 30 miles from the latter river, and to the westward of Katha. Sample A.—Large irregular fragments with quartz embedded in some of them. Iridosmine and crystals of chrome iron can be separated under a microscope. The composition is given below. The silver ore is a grey mineral which loses 49 per cent. on ignition. Sample B.—Fine smooth grains; about 17 per cent. insoluble in aqua regia, the insoluble matter consists of quartz, zircon, and about 7 per cent. of iridosmine in bright, flat grains mixed with a black mineral apparently a platinum ore.

D. A. L.

**Preparation of Crystallised Insoluble Carbonates.** By L. BOURGEOIS (*Compt. rend.*, **103**, 1088—1091).—0·5 gram of the amorphous carbonate is heated in a tube at 150—180°, with 20 c.c. of water and 2 grams of ammonium chloride, and then very slowly cooled. After the process of heating followed by slow cooling has been repeated four or five times, the carbonate becomes completely crystallised. The ammonium chloride is partially converted into carbonate, which decomposes into ammonia and carbonic anhydride. Part of the insoluble carbonate is thus dissolved, and separates in crystals during the slow cooling. When the heating is repeated, the

same changes take place, and the crystals gradually increase at the expense of the amorphous substance. Calcite is obtained in simple rhombohedrons without admixture with aragonite; strontianite is obtained in short, rhombic prisms; witherite in long, thin, fibrous needles; cerusite in long, striated needles, which are always mixed with a variable proportion of a hydrated carbonate in nacreous, hexagonal lamellæ, with negative uniaxial double refraction, which is probably identical with hydrocerussite. Cadmium carbonate crystallises in rhombohedrons similar to those of calcite.

Lithium, magnesium, zinc, manganese, iron, nickel, cobalt, and copper carbonates yield only amorphous precipitates or indistinct spheruliths.

Almost identical results are obtained by heating the carbonates at  $140^{\circ}$  with a solution of urea, which is converted into ammonium carbonate by hydration. In addition, copper yields small prisms, which seem to be identical with malachite. C. H. B.

**Occurrence of Iodine in Phosphorites and of Lithium in Psilomelane.** By F. SANDBERGER (*Jahrb. f. Min.*, 1887, 1, Mem., 95).—The author notes the remarkable manner in which elements occurring in rocks in very minute quantities become concentrated in certain products of the decomposition of the rocks. This is the case with iodine, which the author has detected in the staffelite from Brilon in Westphalia, separated out from decomposed diabase, and in the osteolite from the weathered basalts of the Kreuzberg on the Rhone.

Not less remarkable is the concentration of small quantities of lithium in psilomelane, a fact first observed in the Saxon Ore Mountains, but subsequently by the author in various places in the Black Forest. Lithium also becomes concentrated in the hexagonal variety of zinc sulphide, the so-called *schalenblende*. B. H. B.

**Nephrite from Alaska.** By A. B. MEYER (*Jahrb. f. Min.*, 1887, 1, Ref., 6—8).—The author describes two axes procured from the Indians of South-east Alaska. The smaller has a sp. gr. of 2.96, and contains some magnetite; the sp. gr. of the larger being 2.92. The hardness of the latter is somewhat less than is usual with nephrite; the material being no longer quite unaltered. Analysis of the latter gave the following results:—

| $\text{SiO}_2$ . | $\text{Al}_2\text{O}_3$ . | $\text{FeO}$ . | $\text{CaO}$ . | $\text{MgO}$ . | $\text{H}_2\text{O}$ . | Total. |
|------------------|---------------------------|----------------|----------------|----------------|------------------------|--------|
| 51.63            | 4.31                      | 4.82           | 10.45          | 22.36          | 4.84                   | 98.41  |

Under the microscope, it was found that this nephrite resembles most closely that from the river Kitoj in East Siberia. It differs from this, however, in the absence of all accessory constituents, except magnetite.

Green nephrite has been found *in situ* at the extreme north-west of Alaska. The raw material brought from Point Barrow in Alaska by Baird, proves on analysis to be neither nephrite nor jadeite, but pectolite. B. H. B.

**Prehnite from Silesia.** By A. BEUTELL (*Jahrb. f. Min.*, 1887, 1, Mem., 89—94).—1. *Prehnite from Striegau.*—Prehnite has recently been found in the granite of Striegau. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO.  | Loss on ignition. | Total. |
|--------------------|----------------------------------|----------------------------------|-------|-------------------|--------|
| 43·29              | 25·58                            | trace                            | 26·36 | 4·77              | 100·00 |

These results correspond with the formula  $\text{Si}_3\text{O}_{12}\text{Ca}_2\text{Al}_2\text{H}_2$ . The mineral usually occurs in the form of compact masses, isolated crystals being occasionally met with. Thin sections under the microscope present the optical anomalies observed by Des Cloizeaux and Mallard in the prehnites of Connecticut and Arendal.

2. *Prehnite from Jordansmühl.*—An analysis of prehnite from Jordansmühl has been published by B. Schubert (Abstr., 1883, 35). To this the author now adds the results of an exhaustive crystallographical and optical investigation. The axial ratio he finds to be  $a : b : c = 0.8420 : 1 : 1.1272$ .  
B. H. B.

**Porphyry from Horka in Prussia.** By V. STEGER (*Jahrb. f. Min.*, 1887, 1, Ref., 42).—The porphyry occurring at Horka in Prussian Upper Lausitz exhibits a grey to dirty yellow ground-mass, containing numerous reddish-brown, small crystals of orthoclase and white crystals of oligoclase. Quartz occurs but rarely. As accessory constituents, the rock contains hornblende and sillimanite. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO.               | MgO.              | P <sub>2</sub> O <sub>5</sub> . | K <sub>2</sub> O. |
|--------------------|----------------------------------|----------------------------------|--------------------|-------------------|---------------------------------|-------------------|
| 58·74              | 14·96                            | 8·75                             | 3·68               | 1·59              | 2·62                            | 3·60              |
|                    |                                  |                                  | Na <sub>2</sub> O. | Loss on ignition. | Total.                          |                   |
|                    |                                  |                                  | 3·22               | 2·87              | 100·03                          |                   |

In chemical composition, the Horka porphyry resembles most closely that from Vetakollen and Tyveholmen, near Christiania. It differs from these, however, in its percentage of phosphoric anhydride.  
B. H. B.

**Analyses of Persian Eruptive Rocks.** By E. DRASCHE (*Jahrb. f. Min.*, 1887, 1, Ref., 65—66).—No. 1. Augite andesite, from the Elburs, near Bumehin, containing plagioclase and augite in a reddish-brown ground-mass. No. 2. Olivine diabase from the same locality; pale brown augite forming small irregular patches between plagioclase needles. The olivine is for the most part altered. No. 3. Plagioclase basalt from Bumehin, exhibiting a porphyritic structure; augite, plagioclase, magnetite, and iron-glance, occurring in a colourless magma. The olivine originally present is entirely decomposed. No. 4. Black rock from Tschemerin Kuschkek, appearing under the microscope as a compact mass containing numerous granules, in which plagioclase, a chloritic mineral, and apatite have separated out.

**Investigations on Ore-veins.** By F. SANDBERGER (*Jahrb. f. Min.*, 1887, 1, Mem., 111—113).—To complete his investigations on ore-veins, the author has collected pure material in quantity sufficient to enable a dry silver assay to be made of the silicates. The substances employed did not contain a trace of intermixed sulphides. The mica from the gneiss of Schapbach was found to contain 0·001 per cent. of silver, and the augite from the granular diabase of St. Andreasberg in the Harz also contained 0·001 per cent. of silver. Nine years ago the author proved that lead, antimony, zinc, cobalt, copper, nickel, and arsenic were present in this augite. Consequently the elements of all the Andreasberg ores are shown to be present in it.

B. H. B.

**Recent Alluvial Deposits in the Ij and the Zuyder Zee.** By J. M. VAN BEMMELEN (*Rec. Trav. Chim.*, 5, 199—218).—In this paper, analyses are given of the recent deposits of eminently fertile clay in the Zuyder Zee and Ij, with especial reference to the proportion of chlorides, sulphates, magnesium and calcium carbonates, and phosphoric acid, together with the composition of the silicates. In some localities, there was a considerable accumulation of iron pyrites, especially on the small ancient islands, along the banks of lakes of brackish water, and in the soil in which plants have taken root and formed deposits of turf. The chemical changes which lead to this accumulation, consists in the simultaneous reduction of ferric oxide and sulphuric acid, accompanied by a slow disappearance of calcium carbonate. The ferrous sulphide thus formed is converted into pyrites as Bunsen has previously explained. Analyses of certain clays showed from 2 to 5 per cent. of pyrites. When these clays are dried and exposed to the action of the air, a contrary action takes place, the pyrites being reconverted into ferric sulphate, which is deposited in the form of a bright yellow, amorphous mould, this being ultimately converted by rain into a very basic insoluble sulphate. The paper is illustrated by numerous analytical results.

V. H. V.

**Mineral Waters from Java.** By S. MEUNIER (*Compt. rend.*, 103, 1205—1207).—Three springs from Kapouran, near Boghor, in the kingdom of Kouripan, were examined. The waters were found to contain the following proportions of solid matter in grams per

litre:—Great Green Spring, 15·87; Hot Spring, 27·00; High Platform Spring, 28·78.

The relative proportions of the constituents are practically the same in all three springs:—

|                                 |         |
|---------------------------------|---------|
| Calcium chloride.....           | 54·203  |
| Magnesium chloride .....        | 40·651  |
| Sodium chloride .....           | 2·860   |
| Potassium chloride .....        | 1·104   |
| Residue insoluble in water..... | 1·924   |
|                                 | <hr/>   |
|                                 | 100·742 |

The portion of the residue insoluble in water consists of minute crystals of calcium magnesium carbonate, resembling those of dolomite.

These springs are characterised by the absence of carbonates and the presence of a large proportion of calcium chloride. They belong to a hydrological group, representatives of which are found in the Cauquenès, Chili; Tinguiririca, Peru; Savu Savu, in the Fiji Islands; Berg Giefshubel, Saxony; and Pitkeathly, Scotland.

C. H. B.

## Organic Chemistry.

**Russian Petroleum.** By J. A. LE BEL (*Compt. rend.*, **103**, 1017—1019).—It is well known that American petroleum consists mainly of paraffins, whilst Bakû petroleum consists mainly of naphthenes,  $C_nH_{2n}$ , and naphthylenes,  $C_nH_{2n-2}$ . Boussingault has shown that Alsatian petroleum contains other hydrocarbons.

At Tiflis, a petroleum is obtained with a composition similar to that of the American oil, and in the Crimea heavy and light petroleum are obtained from neighbouring strata. The following table gives the sp. gr. of corresponding fractions of oil from different sources:—

|                          |                      | Sp. gr. |
|--------------------------|----------------------|---------|
| Pennsylvania .....       | 236—240 <sup>p</sup> | 0·81    |
| Bakû .....               | 240—241              | 0·83    |
| Alsace .....             | 235—245              | 0·86    |
| Tschungnelek (Crimea) .. | 235—245              | 0·89    |

The Crimean oil contains 87·4 per cent. of carbon and 12·5 per cent. of hydrogen. The differences in sp. gr. are greater than the differences in the amount of carbon, and these differences do not remain constant when the more volatile fractions are examined:—

|                       |        | Sp. gr. |
|-----------------------|--------|---------|
| Pennsylvania .....    | 92—94° | 0·690   |
| Bakû .....            | 90—95  | 0·738   |
| Bakû .....            | 90—91  | 0·747   |
| Tschungnelek .....    | 80—93  | 0·750   |
| Toluene hydride ..... | 96—97  | 0·758   |

The more volatile fractions of the Crimean oil are very similar to the corresponding fractions of the oil from Bakû, and differences only become evident with the fractions boiling above 150°. The sp. gr. of the Russian oils agrees with that of toluene hydride, with which Beilstein and Kurbatow regard them as identical. It may also be supposed that the Russian oil contains naphthenes belonging to the trimethylene series; in this case it should contain a term  $C_6H_{10}$ , boiling at 30—35°, with a sp. gr. about 0·04 higher than that of the corresponding fraction of American oil. If, on the other hand, these naphthenes are hydrides of the benzene series, the first term would be  $C_6H_{12}$ , boiling at 70°.

It is found that fractions of Bakû oil boiling at 30—35° have a sp. gr. which agrees closely with that of the same fraction of American oil, and also with that of pentane boiling at 30°. The differences only become evident with the fractions above 60°, and it may be taken that the Russian oils boiling above 60° contain no naphthenes, a result which confirms Beilstein and Kurbatow's conclusion as to their identity with the benzene hydrides.

C. H. B.

**Action of Heat on Ethylene.** By L. M. NORTON and A. A. NOYES (*Amer. Chem. J.*, **8**, 362—364; compare Abstr., 1886, 604 and 781).—Ethylene was slowly passed through a hard glass tube heated to dull redness, the escaping gases passed through condensing tubes, ammoniacal cuprous chloride and bromine, samples of the gases being ultimately collected. After a month, 15 c.c. of liquid had been condensed, and was found to contain benzene, naphthalene, and anthracene; only a very slight precipitate was formed in the cuprous solution. There were about 300 grams of bromides of unsaturated hydrocarbons, consisting largely of ethylene bromide; but methylene, propylene, and butylene bromides were also present, as well as a solid bromide.

The solid bromide is identical in composition and properties with the crotonylene tetrabromide obtained from coal-gas, from crotonylene from erythrol and from oil-gas, it is, therefore, divinyl,  $CH_2:CH:CH:CH_2$ . The escaping gases consisted of methane and ethane. The author believes that the aromatic hydrocarbons are formed directly from the ethylene without the intermediate formation of acetylene.

H. B.

**Reaction of Organic Bisulphides and Bisulphoxides with Potassium Sulphide.** By R. OTTO and A. RÖSSING (*Ber.*, **19**, 3129—3132).—When the bisulphides of ethyl, amyl, phenyl, paratolyl, or benzyl are treated with potassium sulphide in alcoholic solution, they are converted into the corresponding mercaptides according to the

equation  $X_2S_2 + 2K_2S = 2XSK + K_2S_2$ , the reaction thus seeming to be general for organic sulphides.

Potassium bisulphide seems to be without action on these bisulphides.

In like manner the thiosulphonates of the general formula  $RSO_2SR$  are decomposed by potassium sulphide into the potassium salts of the thiosulphonic acids and potassium mercaptides.

In a foot-note, the following boiling points are given:—Paratoluene hydrosulphide  $190\cdot2$ — $191\cdot7^\circ$ . Paratoluene bisulphide begins to boil at  $307^\circ$  (thermometer in liquid), but is in great part decomposed during the distillation. Phenyl bisulphide begins to boil at  $320^\circ$ , but is also in great part decomposed on distillation.

A. J. G.

**Action of Alcohols on Auroposphorous Chloride.** By L. LINDET (*Compt. rend.*, **103**, 1014—1017).—Triethyl chloraurophosphite,  $Et_3PAuClO_3$ , is obtained by allowing absolute alcohol to drop on a mixture of dry aurous chloride and phosphorus, both of which are immediately dissolved. The product is mixed with water, and the insoluble, oily ethereal salt is separated. Ethyl phosphite dissolves aurous chloride, and yields an oil identical in appearance with triethyl chloraurophosphite, but the product could not be purified. The ethereal salt is also obtained by dissolving aurous chloride in a solution of ethyl phosphite in alcohol, prepared by Railton's method of allowing phosphorus trichloride to drop into a large excess of absolute alcohol.

Triethyl chloraurophosphite is a liquid which solidifies to a white, crystalline mass at about  $-10^\circ$ . It is not volatile, and is stable when exposed to air at the ordinary temperature, but begins to decompose at  $100^\circ$ ; sp. gr. =  $2\cdot025$ . It is insoluble in water, but dissolves in alcohol, ether and benzene. Ammonia dissolves it readily, with formation of the compound  $Et_3PAuClO_3 + 2NH_3$ , which is obtained in somewhat deliquescent leaflets by evaporating the ammoniacal solution at  $40^\circ$ . This compound dissolves in water, and when the solution is acidified the ethereal salt is precipitated. Triethyl chloraurophosphite also dissolves in potassium hydroxide solution, and is reprecipitated on adding an acid. If the solution is concentrated on the water-bath, or in a vacuum at the ordinary temperature, the ethereal salt separates as an oil mixed with crystals of potassium hydroxide, but both dissolve on addition of water. At  $100^\circ$ , potassium chloride and potassium aurite are formed, but the ethereal salt is not completely decomposed unless evaporated to complete dryness in presence of excess of potassium hydroxide. Under these conditions, gold separates in the metallic state.

Propyl, butyl, and amyl alcohols yield similar products.

Trimethyl chloraurophosphite,  $Me_3PAuClO_3$ , is obtained by the action of pure methyl alcohol on aurous chloride and phosphorus. It forms slender, colourless needles, which melt at  $100$ — $101^\circ$ , alter slightly when exposed to air, and do not volatilise without decomposition. It is insoluble in water, and is somewhat less soluble than the ethyl-compound in alcohol, ether and benzene. It also dissolves in methyl alcohol.

C. H. B.

**Dextrorotatory Hexyl Alcohol from Essence of Chamomile.** By P. v. ROMBURGH (*Rec. Trav. Chim.*, **5**, 219—227).—By frequent fractional distillation of essence of Roman chamomile, a dextrorotatory alcohol (*methethopropyl alcohol*),  $\text{CHMeEt}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OH}$ , is obtained, boiling at  $154^\circ$ ; sp. gr. 0.829 at  $15^\circ$ ;  $[\alpha]_D = 8.2$  at  $17^\circ$ . On oxidation with chromic mixture, the alcohol yields a dextrorotatory caproic acid (*methethopropionic acid*),  $\text{CHMeEt}\cdot\text{CH}_2\cdot\text{COOH}$ , boiling at  $196$ — $198^\circ$ ; sp. gr. 0.930 at  $15^\circ$ ;  $[\alpha]_D = 8.92$ . Its calcium and silver salts crystallise in needles, and its amide in long needles melting at  $124^\circ$ , soluble in water. A hexyl caproate is formed as a subsidiary product of oxidation. This boils at  $233$ — $234^\circ$  with slight decomposition; sp. gr. 0.867 at  $15^\circ$ ;  $[\alpha]_D = 12.86$  at  $19^\circ$ . As both the alcohol, and also the acid obtained therefrom, are optically active substances, according to the hypothesis of Van't Hoff and Le Bel they must contain an asymmetrical carbon-atom. Of the three possible hexyl alcohols satisfying this condition, two have been identified by Lieben and by Zeisel and Silva. The alcohol now described must therefore have the remaining formula, that ascribed to it above. V. H. V.

**Thiodiglycol-compounds.** By V. MEYER (*Ber.*, **19**, 3259—3266).—Thiodiglycol is obtained by treating a concentrated aqueous solution of potassium sulphide with glycol chlorhydrin. The product is evaporated on a water-bath and extracted with alcohol. It is a syrup almost without odour.

*Thiodiglycol chloride*,  $\text{S}(\text{CH}_2\cdot\text{CH}_2\text{Cl})_2$ , is formed by gradually mixing phosphorus chloride with thiodiglycol (kept cool), and pouring the product into water. It is an oil having a slight, sweet, ethereal odour. When cooled in ice-water, it solidifies to long prisms. It boils at  $217^\circ$ , and is almost insoluble in water. It has very poisonous properties: a rabbit exposed to air previously passed over filter-paper saturated with the substance died in three days.

When ethylene bromide is heated to boiling for a long time with aqueous potassium sulphide, an amorphous, insoluble product is obtained, differing from the polymerised diethylene disulphide (formed by adding ethylene bromide gradually to a solution of potassium sulphide in alcohol). It remains unchanged when boiled for days with phenol. The polymeride, which is decomposed by boiling with phenol, can also be prepared by adding ethylene bromide to the sodium salt,  $\text{C}_2\text{H}_4(\text{SNa})_2$ , covered with a little alcohol; if 50 times the weight of alcohol is used, the whole well cooled, and the bromide gradually added, diethylene disulphide is obtained.

The author is making experiments with a view to synthesise the ethyl vinyl ether of thioglycol,  $\text{SEt}\cdot\text{C}_2\text{H}_4\cdot\text{S}\cdot\text{CH}:\text{CH}_2$ , in order to compare it with the product obtained by the reduction of diethylene disulphide ethyl iodide (Mansfeld, this vol., p. 122). N. H. M.

**Preparation of Derivatives of Carbohydrates.** By E. BAUMANN (*Ber.*, **19**, 3218—3222).—*Tetrabenzoyl dextrose*,  $\text{C}_6\text{H}_5\text{O}_6\text{Bz}_4$ , is prepared by mixing a solution of 5 grams of grape-sugar in 15 c.c. of water with 210 c.c. of a 10 per cent. soda solution, adding 30 c.c. of benzoic chloride, and shaking until the odour of the chloride disappears. It

is insoluble in water, readily soluble in ether, alcohol, and benzene; it melts at 60—64°. It is only slowly decomposed by boiling acids or alkalis. 0·001 or 0·002 gram of grape-sugar dissolved in 100 c.c. of water can be detected by shaking with 2 c.c. of benzoic chloride and the corresponding amount of soda solution; the benzoyl-derivative separates as a flaky precipitate.

*Hexabenzoyl saccharose*,  $C_{12}H_{16}O_{11}Bz_6$ , is obtained in a manner similar to the above compound.

*Tetrabenzoyl glucosamine*,  $C_6H_9NO_5Bz_4$ , is prepared by shaking a solution of 5 grams of glucosamine in 20 c.c. of water with 140 c.c. of 10 per cent. soda solution and 20 c.c. of benzoic chloride. It is readily soluble in chloroform, insoluble in water, sparingly soluble in alcohol, from which it separates in long needles melting at 197—198°. It is completely decomposed by boiling with alkali.

*Glycerol dibenzoate*,  $C_3H_5O_2Bz_2\cdot OH$ , crystallises from light petroleum in long, colourless needles melting at 70°; it is very readily soluble in alcohol, ether, and chloroform, insoluble in water. N. H. M.

**Formation and Composition of Humous Substances.** By M. CONRAD and M. GUTHZEIT (*Ber.*, 19, 2844—2850).—In their previous papers (*Abstr.*, 1885, 745; 1886, 138; this vol., p. 25), the authors have shown that when cane-sugar is inverted by dilute acids, the lævulose is more quickly and completely decomposed, and yields more humous substances than the dextrose. Ulmin is the chief product from lævulose, whilst from dextrose ulmic acid entirely soluble in aqueous potash is obtained. If a more concentrated acid is employed, the humous substances from dextrose are less soluble, and concentrated hydrochloric acid yields a product practically insoluble in cold aqueous potash. The authors draw the following conclusions from their experiments:—

(1.) That when saccharoses and glucoses are decomposed by dilute acids, the yield of humous substances stands in no direct relation to that of formic and acetopropionic acids. (2.) Saccharoses by the action of dilute acids first suffer hydrolysis, and the resulting glucoses, by the elimination of the elements of water, yield on the one hand formic and acetopropionic acids, and on the other humous substances. (3.) Saccharoses and glucoses, with the exception of lævulose, yield more humous substances by boiling with dilute (7—10 per cent.) hydrochloric acid than with sulphuric acid. (4.) The more concentrated the acid, the greater is the yield of humous substances. (5.) With dilute acids, lævulose yields more humous substances than dextrose. (6.) The percentage composition of the humous substances varies between 62·3—66·5 C and 3·7—4·6 H; those obtained by the action of concentrated acids containing the highest percentage of carbon.

The authors have confirmed Sestini's observation that air-dried humous substances when heated above 110° give off a vapour of acid reaction, and capable of reducing silver from solutions of its salts.

W. P. W.

**Arabinose.** By H. KILIANI (*Ber.*, 19, 3029—3036).—Arabinose is prepared by heating cherry gum (1 part) with 8 litres of 2 per cent. sulphuric acid for 18 hours in a water-bath; neutralising with hot,

saturated, aqueous baryta, and evaporating the solution (without filtering) to a small bulk; it is then shaken with much 96 per cent. alcohol. The clear solution is decanted, most of the alcohol distilled off, and the residue evaporated down; it is again shaken with alcohol, and the solution concentrated by distillation. On cooling, crystals separate; these are washed with alcohol and recrystallised from six or seven times their weight of alcohol (sp. gr. 0.825); the product is then pure.

Arabonic acid (Bauer, Abstr., 1885, 501) is prepared by shaking a solution of 20 grams of the sugar in 100 c.c. of water with 40 grams of bromine for an hour; the bromine is then removed by warming and the hydrobromic acid by means of silver oxide. Analytical results show that it is a tetrahydroxyvaleric acid,  $C_5H_{10}O_6$ , and not an acid of the formula  $C_6H_{12}O_7$  (Bauer, *loc. cit.*). The calcium salt,  $(C_5H_9O_6)_2Ca + 5H_2O$ , and the barium salt which forms microscopic plates were analysed. The acid could only be obtained as a syrup.

*Arabinosecarboxylamide*,  $C_7H_{15}O_7N$ , separates as a fine, white, crystalline powder, when a clear solution of arabinose (1 part) in water (1 part) is mixed with 60 to 70 per cent. hydrocyanic acid, and kept for eight days in a closed vessel. It dissolves readily in water, but is insoluble in strong alcohol and ether; when heated, it becomes yellow at  $130^\circ$ , and decomposes completely at  $160^\circ$ , with evolution of gas. Boiling water and hot alkali solutions decompose it with evolution of ammonia.

The lactone of *arabinosecarboxylic acid*,  $C_7H_{12}O_7$ , is prepared by dissolving the amide in the corresponding amount of hot baryta-water, evaporating until the odour of ammonia has disappeared, and precipitating the barium exactly with sulphuric acid. The filtrate is made clear by the addition of a few drops of hydrochloric acid, and evaporated. It crystallises from water in very lustrous prisms (probably rhombic), melting at  $145-150^\circ$ ; it is very sparingly soluble in alcohol. It has nearly the same rotatory power as the lactone of dextrocarboxylic acid;  $[\alpha]_D = -54.8$ . The *calcium* and *barium salts* are amorphous.

The mother-liquor from the preparation of arabinosecarboxylamide contained chiefly ammonium arabinosecarboxylate. N. H. M.

**Decomposition by Heat of the Nitrates of the Paraffinoid Amines.** By P. v. ROMBURGH (*Rec. Trav. Chem.*, 5, 246—251).—The decomposition of ammonium nitrate may be explained on the supposition that the nitrite is at first formed, on which the oxygen liberated acts to form an unstable combination,  $NH_2OH \cdot NO \cdot OH$ , which in its turn is decomposed into water and nitrous oxide. If this were the interpretation of the reaction, the nitrates of the paraffinoid amines should yield a nitrosamine as a product of their decomposition, thus:  $NMe_2H \cdot OH \cdot NO_2 = NMe_2H \cdot OH \cdot NO + O = NMe_2 \cdot NO + H_2O + O$ ; the liberated oxygen would partly oxidise either the salt or the nitrosamine formed.

Dimethylamine nitrate decomposes at  $150^\circ$ , with evolution of nitrogen and carbonic anhydride; and from the residue dimethylnitrosamine is obtained, the yield of which is 50—54 per cent. of that

required by the above theory. Similarly also diethylamine nitrate is decomposed when heated at  $170^{\circ}$ , and the reaction becomes violent with rise of temperature; carbonic anhydride and nitrogen together with an inflammable gas are evolved, and from the residue diethylnitrosamine may be obtained.

Experiments on the decomposition of methylamine, ethylamine, and tetrethylammonium nitrate were not so successful.

V. H. V.

**Action of Hydrogen Chloride on Mixtures of Aldehyde with Alcohols and Phenols respectively.** By A. CLAUS and E. TRAINER (*Ber.*, 19, 3004—3011).—When a mixture of aldehyde and methyl alcohol (1 vol. : 2 vols.) is treated with hydrogen chloride at a temperature below  $0^{\circ}$ , dried, and treated with sodium isobutoxide, the chief product is dimethylacetal; methylisobutylacetal (from chlor-ether contained in the original product) is also formed; it boils at  $124$ — $128^{\circ}$ . When equal mols. of aldehyde and methyl alcohol are used, dimethylacetal, methyl-isobutylacetal, and di-isobutylacetal are obtained; the last compound would be formed from  $\alpha$ -dichloro-ether in the original product.

Ethyl alcohol and aldehyde give a good yield of  $\alpha$ -chlor-ether together with diethylacetal and  $\alpha$ -dichlor-ether (compare Wurtz and Frapoli, *Annalen*, 108, 226).

Isoamyl alcohol and aldehyde (equal mols.) yielded  $\alpha$ -chlorethyl isoamyl ether; when 2 mols. of the alcohol are used, di-isoamylacetal,  $C_2H_4O_2(C_5H_{11})_2$ , alone is formed. It boils at  $209$ — $211^{\circ}$  (uncorr.). Isobutyl alcohol (1 mol.) gave a better yield of monochlorether than amyl alcohol, and in the reaction with 2 mols. of alcohol a small amount of  $\alpha$ -chlorethylisobutylacetal (boiling at  $155$ — $160^{\circ}$ ) could be isolated.

Ethylidene diphenyl,  $CHMe(C_6H_4.OH)_2$ , is obtained by passing hydrogen chloride through a mixture of aldehyde (1 mol.) with phenol (2 mols.). It is readily soluble in alcohol, ether, chloroform, &c., insoluble in water, benzene, and light petroleum; it could not be obtained in the crystalline state. It softens at  $100^{\circ}$ , and becomes viscous at  $125^{\circ}$ . Aqueous alkali dissolves it readily.

Ethylidene-di- $\alpha$ -naphthol is formed in a similar manner, and is completely analogous in its properties to the diphenyl-derivative.

When  $\beta$ -naphthol and aldehyde are treated with hydrogen chloride, a crystalline compound, melting at  $162$ — $163^{\circ}$ , is formed, having the formula  $C_2H_4O_2(C_{10}H_7)_2$ . It has none of the properties of a phenol, but corresponds with the acetals. The authors consider that this different behaviour of  $\alpha$ - and  $\beta$ -naphthol (the one behaving like a phenol and the other like a fatty alcohol) is fresh evidence in favour of his unsymmetrical naphthalene formula.

N. H. M.

**Acid Propionates and Butyrates.** By W. G. MIXTER (*Amer. Chem. J.*, 8, 343—346).—The following salts are described: *Acid barium propionate*,  $(C_3H_5O_2)Ba.C_3H_6O_2 + 3H_2O$ , forms tabular crystals that very slowly lose water and acid in dry air. *Acid strontium propionate*,  $(C_3H_5O_2)_2Sr.C_3H_6O_2 + 3\frac{1}{2}H_2O$ , forms long, thin

crystals, that lose acid on exposure to the air. *Acid calcium propionate*,  $2(\text{C}_3\text{H}_5\text{O}_2)_2\text{Ca}, \text{C}_3\text{H}_5\text{O}_2 + 5\text{H}_2\text{O}$ , forms long needles, that have an acid reaction and decompose on heating. *Acid barium isobutyrate*,  $(\text{C}_4\text{H}_7\text{O}_2)_2\text{Ba}, \text{C}_4\text{H}_7\text{O}_2$ , was obtained by heating a solution of the normal salt with the excess of the acid at  $100^\circ$  until constant.

H. B.

**Preparation of  $\beta$ -Iodopropionic Acid.** By V. MEYER (*Ber.*, **19**, 3294–3295).—The author finds that  $\beta$ -iodopropionic acid can be readily prepared from the glyceric acid obtained by the oxidation of glycerol with nitric acid, since the accompanying products neither form crystalline compounds with phosphorus iodide, nor interfere with the crystallisation of the iodo-acid. The syrup obtained by the oxidation of glycerol and subsequent removal of nitric acid, is diluted with water to a sp. gr. of 1.26, and 30 c.c. of the solution is then poured into a flask containing phosphorus iodide prepared from 50 grams of iodine and 6.5 grams of yellow phosphorus. A vigorous action takes place either in the cold or on gently warming, and the contents of the flask on cooling solidify owing to the separation of  $\beta$ -iodopropionic acid in large, colourless laminae, which after one crystallisation from water are quite pure.

W. P. W.

**Methylisopropylacetic Acid.** By P. v. ROMBURGH (*Rec. Trav. Chem.*, **5**, 228–239).—Köbig concluded that the caproic acid obtained by the oxidation of the hexyl alcohol from the essence of Roman chamomile was identical with that obtained by Markownikoff from the nitrile derived from methyl isopropyl carbinol. This view is not confirmed in the present paper, in which it is shown that methylisopropylacetic acid is not identical with the caproic acid obtained from the essence of chamomile. Two methods were used for the synthetical formation of methylisopropylacetic acid,  $\text{CHMePr}^\beta\text{COOH}$ , namely, the conversion of ethyl sodiomalonate into the isopropyl-derivative, and this into the ethereal salt of methylisopropylmalonic acid, from which the acid itself was obtained by hydrolysis; this, when heated, readily decomposed into carbonic anhydride, and the corresponding acetic acid; (ii) the conversion of ethyl acetoacetate into ethylic methylisopropylacetoacetate and the decomposition of this by alkalis into methylisopropyl acetone and methylisopropylacetic acid. Of these methods, the former is preferable.

The acid boils at  $189\text{--}191^\circ$ ; sp. gr. = 0.928 at  $15^\circ$ ; its silver salt crystallises in delicate needles, and its amide in micaceous scales.

*Methylisopropylacetone*,  $\text{CHMePr}^\beta\text{COMe}$ , boils at  $135\text{--}140^\circ$ , has a strong odour resembling menthol; sp. gr. = 0.815 at  $20^\circ$ ; it does not seem to react with sodium hydrogen sulphite or with phenyl hydrazine.

*Methylisopropylmalonic acid*,  $\text{CHMePr}(\text{COOH})_2$ , is crystalline, melts, though not very definitely, at  $124^\circ$ ; its silver and calcium salts are sparingly soluble; its ethyl salt is a colourless liquid boiling at  $221^\circ$ ; sp. gr. = 0.990 at  $15^\circ$ ; it has an agreeable odour. As a subsidiary product, isopropylmalonic acid was obtained, a substance previously described by Conrad and Bischoff.

V. H. V.

**Derivatives of Erucic and Brassic Acids.** By C. L. REIMER and W. WILL (*Ber.*, 19, 3320—3327).—Erucic acid is best obtained by saponifying rape oil with alcoholic potash, distilling off the alcohol, and dissolving the acid liberated on addition of sulphuric acid in three times its volume of 95 per cent. alcohol; on cooling to 0° crystals of erucic acid separate in an almost pure condition. The melting point of the acid was found to be 34°. *Ethyl erucate*,  $C_{22}H_{41}O_2Et$ , is a colourless, odourless oil, boiling above 360° without decomposition; its vapour-density, however, could not be determined. The *anhydride*,  $C_{44}H_{82}O_3$ , is prepared by heating erucic acid and phosphorus trichloride in molecular proportions. It is an oil crystallising in a freezing mixture to a mass of scales, and is very readily soluble in ether, benzene, and chloroform, sparingly soluble in alcohol. The *amide*,  $C_{22}H_{41}O(NH_2)$ , crystallises in colourless needles, melts at 84°, and is readily soluble in ether and benzene, sparingly soluble in alcohol, insoluble in water. The *anilide* is crystalline, melts at 55°, and is readily soluble in ether and benzene, sparingly soluble in alcohol.

*Dierucin*,  $C_3H_5OH(C_{22}H_{41}O_2)_2$ .—When rape oil is allowed to stand for a long time, a yellowish, tallow-like deposit is frequently found in the casks; this by repeated solution in ether and subsequent addition of alcohol can be obtained in silky needles. Dierucin melts at 47°, and is readily soluble in ether and light petroleum, insoluble in cold but soluble in hot alcohol. A trierucin could not be separated from rape oil.

Brassic acid is best prepared by warming erucic acid with dilute nitric acid to the melting point and then adding sodium nitrite; the product is quite pure after two crystallisations from alcohol. The *ethyl salt* is obtained directly from the acid, or by the action of nitrous acid on ethyl erucate; it crystallises in laminæ showing a vitreous lustre, melts at 29—30°, and boils above 360° without decomposition; the vapour-density could not, however, be determined. The *anhydride*,  $C_{44}H_{82}O_3$ , formed by heating the acid with phosphorus trichloride, crystallises in lustrous tables, melts at 28—29°, and is insoluble in water and alcohol, readily soluble in ether and benzene. The *amide* melts at 90°, and resembles in its properties the amide of erucic acid; both anides can be obtained by heating the corresponding ethyl salts to 230° with ammonia.

*Tribrassidin* is formed when rape oil (100 parts) is treated with nitric acid of sp. gr. = 1.2 (5 parts) and sodium nitrite (1 part); after some time, the resulting crystalline mass is washed, dissolved in ether, and from the solution cooled to 0° a lustreless, crystalline powder is obtained. Tribrassidin melts at 47°, but when heated above its melting point and allowed to cool, the melting point is subsequently found to be 36°; it is insoluble in alcohol, readily soluble in ether and chloroform. *Dibrassidin*,  $C_3H_5OH(C_{22}H_{41}O_2)_2$ , is formed when dierucin is treated with nitrous acid; it forms feebly lustrous crystals, melts at 65°, and is less soluble in ether than tribrassidin.

By distilling the calcium salts of erucic and brassic acids, two ketones are obtained which seem to be different; they are both very sparingly soluble in alcohol.

W. P. W.

**Dry Distillation of Calcium Tetramethylenecarboxylate with Lime.** By H. G. COLMAN and W. H. PERKIN, Jun. (*Ber.*, 19, 3110—3115).—The products of this reaction are much ethylene (together with hydrogen and small quantities of carbonic anhydride and methane), ditetramethylene ketone, and an oil boiling at 136—137°, and uniting with hydrogen sodium sulphite, phenylhydrazine, and hydroxylamine; this is either tetramethylenealdehyde or acetyltetramethylene, but there is not sufficient evidence to say which.

*Ditetramethylene ketone*,  $\text{CO}(\text{C}_4\text{H}_7)_2$ , is a colourless oil, of peppermint-like odour; it boils at 204—205°, gives a colourless, crystalline compound with hydrogen sodium sulphite, and is acted on by bromine with evolution of hydrogen bromide. The phenylhydrazine compound is obtained as a yellow oily precipitate. The *oxime*,  $\text{C}_{19}\text{H}_{15}\text{NO}$ , forms a colourless syrup. A. J. G.

**Oxalimide.** By H. OST and A. MENTE (*Ber.*, 19, 3228—3230).—Oxamic acid is best prepared by heating hydrogen ammonium oxalate at 140°, stirring all the time, extracting with aqueous ammonia, and converting into the sparingly soluble barium salt. This is converted into the ammonium salt, and precipitated with hydrochloric acid. The yield is 16 per cent.

*Oxalimide*,  $\text{<}\overset{\text{CO}}{\text{CO}}\text{>NH}$ , is obtained by treating 20 grams of oxamic acid with 50 grams of phosphorus pentachloride and 20 grams of phosphorus oxychloride, and heating at 80—90°. The product is put into ice-water, warmed at 40°, filtered, and extracted with water at 60°. It is purified by dissolving in very dilute, warm aqueous ammonia, precipitating with hydrochloric acid, and recrystallising from water. It forms very lustrous prisms, which seem to be monoclinic. It is sparingly soluble in water, more soluble in warm aqueous ammonia. Boiling water decomposes it into oxamide and oxalic acid. Concentrated aqueous ammonia converts it into oxamide. When a cold saturated solution of oxalimide is treated with mercurous chloride, a crystalline mercury salt,  $\text{C}_2\text{O}_2\text{N}\cdot\text{HgCl}$ , separates.

Oxalimide is also formed by the action of nitrous acid on comenamic acid (dihydroxypyridinecarboxylic acid). This reaction, together with the results of experiments made by v. Pechman and others, is in favour of the view that meconic and cumalinic acids are derivatives of pyridone,  $\text{C}_5\text{H}_4\text{O}\cdot\text{NH}$ . N. H. M.

**Ethyl Oxalacetate.** By W. WISLICENUS (*Ber.*, 19, 3225—3228).—*Ethyl oxalacetate*,  $\text{COOEt}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{COOEt}$ , is prepared by dissolving 20 grams of ethyl oxalate in 100 grams of absolute ether, adding 3 grams of sodium wire, and then gradually adding 12 grams of pure ethyl acetate. After 12 hours, the product is solid, and is then washed with absolute ether, and dried over sulphuric acid. The *sodium-derivative*,  $\text{C}_8\text{H}_{11}\text{O}_5\text{Na}$ , crystallises from absolute alcohol in microscopic, matted needles; it is decomposed by dilute sulphuric acid. The ethyl salt is a rather viscous oil, almost without colour and odour; it decomposes when heated. The dilute alcoholic solution

gives with ferric chloride an intense dark red coloration. When boiled with dilute alkali or baryta-water, it yields oxalic and acetic acids. Warm 10 per cent. sulphuric acid decomposes it with evolution of carbonic anhydride and formation of pyruvic acid. When saponified by Ceresole's method for the preparation of acetoacetic acid, *monethyl oxalacetate*,  $C_6H_8O_5$ , is obtained. The latter crystallises from benzene in stellate groups of needles, melting at about  $90^\circ$ . It is readily soluble in alcohol, ether, and water, and has a strongly acid reaction.

*Phenylhydrazine ethyl oxalacetate* crystallises in plates; when boiled with water, it yields an acid,  $C_{10}H_8N_2O_3$  (analogous to that obtained by Knorr from phenylhydrazine ethyl acetoacetate (Abstr., 1884, 1377). This dissolves readily in alcohol, sparingly in water, and also its decomposes at about  $250^\circ$  without melting.

N. H. M.

**Glycuronic Acid.** By H. THIERFELDER (*Ber.*, 19, 3148).—Bromine converts glycuronic acid into saccharic acid, thus showing the presence in the former acid of an aldehydic group, and also its close relation to dextrose.

L. T. T.

**Fermentation of Citric Acid.** By F. WATTS (*J. Soc. Chem. Ind.*, 5, 215—218).—Warington (this Journal, 1875, 936) has made an attempt to ascertain the amount and nature of the volatile acids in concentrated Sicilian lemon-juice, with a view to determine the acids other than citric which occur in concentrated juice. When perfectly fresh juice is distilled, the distillate is neutral, and consists only of water, with a small amount of essential oil derived from the peel. It is thus clear that volatile acids are not normal constituents of the juice. When lemon-juice is allowed to remain for some days in an open vessel, a film of mould gradually forms on the surface, consisting of a large number of minute cells of *saccharomyces mycoderma*. If this juice is now distilled, the distillate is found to be acid. From an examination of the distillate purified by redistillation, the author infers the presence of acetic acid, traces of formic acid, and possibly some propionic acid, and indirectly the existence of ethyl alcohol, with possibly some propyl alcohol, and minute quantities of methyl alcohol in the original juice after fermentation. It is also shown by experiment, that under the influence of *saccharomyces mycoderma* citric acid is split up directly into carbonic anhydride and water, oxygen being absorbed. It was found that the growth of this fungus ceased shortly after air was excluded.

D. B.

**Decomposition of Amides by Water and Dilute Acids.** By BERTHELOT and ANDRÉ (*Compt. rend.*, 103, 1051—1057).—Urea is decomposed by hydrochloric acid at the ordinary temperature. 100 c.c. of solution containing 1.0293 gram of urea was mixed with 10 c.c. of hydrochloric acid containing 3.78 grams of HCl, allowed to remain 24 hours, diluted with water, neutralised with magnesia, and the ammonia estimated by Schloesing's method. After boiling for one and a half hours about one-ninth of the total nitrogen in the urea was obtained in the form of ammonia (0.0523 gram). A similar

quantity of urea solution was boiled for an hour and a half with 2 grams of magnesia, and 0.0353 gram of ammonia was obtained, the amount evolved being practically the same in each half hour. The difference between the two quantities represents the ammonia formed by the action of hydrochloric acid in the cold, and is equivalent to the conversion of about 4 per cent. of the total nitrogen into ammonia in 24 hours. The action of the acid increases with the concentration, and also with the temperature.

It is well known that urea is partially decomposed when boiled with water. At the ordinary temperature, however, there is no appreciable decomposition, even after five days. Dilute sodium hydroxide solution decomposes urea slowly in the cold, but the action is much less marked than that of hydrochloric acid.

Asparagine is also decomposed by hydrochloric acid in the cold to a somewhat less extent than urea, and the decomposition increases with the concentration of the acid. It is decomposed by magnesia, as Boussingault observed, and also by boiling water, although only to a very slight extent. The action of soda is much more marked than with urea. 0.5 gram of asparagine mixed with 50 c.c. of water and 6 grams of sodium hydroxide, loses one-third of the total nitrogen in 24 hours, and about half of the total nitrogen in five days, or almost the whole of the nitrogen which is evolved as ammonia in the ordinary reaction.

Oxamide, when triturated with hydrochloric acid of 10 per cent., loses 0.7 per cent. of the total nitrogen in the form of ammonia in two hours. When boiled with magnesia, 6.3 per cent. of the total nitrogen is evolved as ammonia in the first half hour, and 3.4 per cent. in the second half hour. The first loss is due to the decomposition of the oxamide, and the second to decomposition of magnesium oxamate.

In all these cases the action of acids varies with the nature of the amide, is proportional to the time of action, and increases with the concentration of the acid and with the temperature.

The action of acids or alkalis on the amides derived from the alcoholic amines and from the hydroxy-acids will be different, since these amines are reconverted into ammonia with great difficulty. Hydrochloric acid tends to regenerate the amines from their derivatives, in consequence of the alkalinity of the amines. In the case of substances of complex function, like glycollamine and the leucines, both acids and alkalis will tend to produce the same azotised and oxygenised derivative, because each can combine with it.

Aspartic acid is not sensibly affected either by boiling water or by magnesia. Uric acid yields no ammonia when boiled with magnesia for an hour, but if triturated for two hours with hydrochloric acid of 10 per cent., it loses about 1 per cent. of the nitrogen in the form of ammonia.

C. H. B.

**Derivatives of Acetothiënone.** By H. BRUNSWIG (*Ber.*, 19, 2890—2896).—*Bromacetothiënone*,  $C_4SH_3 \cdot CO \cdot CH_2Br$ , prepared by the bromination of acetothiënone dissolved in carbon bisulphide, is a pale yellow oil, the vapour of which affects the mucous membrane. It cannot be distilled under ordinary pressures without decomposition;

at a low temperature it forms small, yellow crystals. The *anilide*,  $C_4SH_3 \cdot CO \cdot CH_2 \cdot NPh$ , crystallises in leaflets melting at  $80^\circ$ ; its acetyl derivative,  $C_4SH_3 \cdot CO \cdot CH_2 \cdot NPhAc$ , forms hard, brown crystals melting at  $141.5^\circ$ , and its nitroso-derivative, rhombic crystals melting at  $81^\circ$ , soluble in ether and alcohol, sparingly soluble in water. The *thiocyanate*,  $C_4H_3S \cdot CO \cdot CH_2 \cdot SCN$ , crystallises in colourless leaflets melting at  $88^\circ$ ; sparingly soluble in water and light petroleum, readily soluble in chloroform. *Dibromacetothiënone*,  $C_4SH_3 \cdot CO \cdot CHBr_2$ , is a heavy, colourless oil, solidifying in a freezing mixture, and completely decomposed when heated under ordinary pressure.

*Cinnamyl thiënyl ketone*,  $C_4SH_3 \cdot CO \cdot CH : CHPh$ , prepared by saturating with hydrogen chloride a mixture of acetothiënone and benzaldehyde in equimolecular proportions, crystallises in grouped needles or prisms, very soluble in ether and chloroform, sparingly soluble in water. The dibromo-compound crystallises in colourless leaflets melting at  $157^\circ$ , and is soluble in alcohol. V. H. V.

**Isomerism of the Thiophenic Acids. Derivatives of  $\beta$ -Thiophenic Acid.** By A. DAMSKY (*Ber.*, 19, 3282—3286; compare this vol., p. 129).—The ordinary method of preparing  $\beta$ -thiophenic acid by the oxidation of  $\beta$ -thiotolen affording only a poor yield, the author prepared  $\beta$ -ethylthiophen and oxidised it with potassium permanganate; no advantage, however, was derived thereby, since the amount of  $\beta$ -acid obtained was not greater than that formed by the oxidation of  $\beta$ -thiotolen. The best yield, 8 per cent. of the theoretical quantity, was obtained by oxidising  $\beta$ -thiotolen in quantities of 1 gram with a mixture of 6.7 grams of sodium hydroxide, and 3.3 grams of potassium permanganate in 333 grams of water. When dissolved in water at  $15^\circ$  or  $18^\circ$ , 100 c.c. of the solution contain 0.44 gram of  $\beta$ -thiophenic acid; the solubility of the barium salt is 11.54 at  $17^\circ$ , and that of the calcium salt is 7.92 at  $14.5^\circ$ . The *amide* crystallises in slender, colourless needles, melts at  $177.5$ — $178^\circ$ , and is very sparingly soluble in ether; the *phenylcarbamide* crystallises in concentrically-grouped needles, melts at  $206^\circ$ , and is sparingly soluble in alcohol.

*$\beta$ -Ethylthiophen*,  $C_4SH_3Et$ .—When ethyl ethenyltricarboxylate (*Abstr.*, 1883, 45) is treated with the calculated quantities of sodium ethoxide and ethyl bromide, a vigorous action takes place, accompanied by considerable development of heat, and ethyl butenyltricarboxylate is obtained as an oil. This is saponified, and from the acid, by heating it at  $120$ — $170^\circ$  until evolution of carbonic anhydride ceases,  $\beta$ -ethylsuccinic acid is obtained, which by distillation with phosphorus trisulphide yields  $\beta$ -ethylthiophen. This is an oil resembling  $\alpha$ -ethylthiophen in properties. W. P. W.

**Reduction of  $\alpha\alpha$ -Thiophendicarboxylic Acid.** By F. ERNST (*Ber.*, 19, 3274—3278).—*Tetrahydrothiophendicarboxylic acid*,

is prepared by adding 15 parts of sodium amalgam (4 per cent. Na) to 1 part of  $\alpha\alpha$ -thiophendicarboxylic acid and 0.5 part of sodium hydroxide dissolved in water, and heating at  $100^\circ$  for two hours; the

product is converted into the silver salt, and from this by treatment with hydrogen sulphide the hydro-acid is obtained. It crystallises in yellowish-white probably monoclinic tables, melts at  $162^{\circ}$  (corr.), is readily soluble in water, less so in ether, and shows all the properties of a hydro-acid. Thus it reduces an ammoniacal silver solution, and when heated with sulphuric acid decomposes into thiophenic acid and carbonic oxide. The *barium* salt,  $C_4SH_6(COO)_2Ba$ , crystallises in small lustrous scales; and the *silver* salt,  $C_4SH_6(COOAg)_2$ , is a white powder. When an alcoholic solution of the hydro-acid is saturated with hydrogen chloride, *methylyltetrahydrothiophendicarboxylate*,

is obtained as an oil which cannot be distilled and does not solidify.

$\alpha$ -Thiophencarboxylic acid, on reduction, yields an acid which crystallises in colourless needles, melts at about  $48^{\circ}$ , is readily soluble in water, and reduces ammoniacal silver solution. W. P. W.

**Synthetical Investigations in the Thiophen Series.** By F. ERNST (*Ber.*, 19, 3278—3282).—The author has endeavoured to effect the synthesis of an anthracene of the thiophen series, but without success. The following compounds prepared in the course of the work are described:—

*Orthotoluyyl thiënyl ketone*,  $C_6H_4Me \cdot CO \cdot C_4SH_3$ , obtained by the action of orthotoluic chloride on thiophen in the presence of aluminium chloride, is a colourless oil; when boiled for some time it loses water, and is completely resinified. The *acetoxime* is a non-volatile oil.

*Phenyl thiotolyl ketone*,  $C_6H_5 \cdot CO \cdot C_4SH_2Me$ , is formed by treating coal-tar thiotolen with benzoic chloride in the presence of aluminium chloride. The ketone is a syrup, and on long boiling loses water and is resinified. The *acetoxime* was prepared, but is not described. When thiënylglyoxylic acid is reduced with sodium amalgam in the cold, *thiënylglycollic acid*,  $C_4SH_3 \cdot CH(OH) \cdot COOH$ , is obtained. It crystallises in white needles, melts at  $115^{\circ}$ , is readily soluble in water, alcohol, ether and benzene, and decomposes on distillation. Oxidation with manganese dioxide converts it into thiophenaldehyde; the yield, however, is small. The *barium* and *calcium* salts are readily soluble in water; the *silver* salt is obtained as a white precipitate.

*Thiënylacetic acid*,  $C_4SH_3 \cdot CH_2 \cdot COOH$ , is obtained by boiling thiënylglycollic acid with hydriodic acid and amorphous phosphorus. It forms colourless crystals, melts at  $76^{\circ}$ , and is soluble in hot water, alcohol and ether. The *barium* salt forms white crystals readily soluble in water; the *silver* salt is obtained as a white precipitate.

W. P. W.

**Synthesis of  $\alpha$ -Phenylthiophen.** By W. KUES and C. PAAL (*Ber.*, 19, 3141—3144).—Following out their previous work (*Abstr.*, 1886, 536), the authors find that if  $\beta$ -benzopropionic or  $\beta$ -benzoisuccinic acid is substituted for levulinic acid, similar reactions occur. In these cases, however, the intermediate hydroxy-product appears to be less stable than thiotolen, and traces only were obtained. The main product was  $\alpha$ -phenylthiophen,  $C_4SH_3Ph$  [ $Ph = 1$ ]. With the

isosuccinic acid, evolution of carbonic anhydride and formation of the ketonic acid takes place before the reaction occurs.  $\alpha$ -Phenylthiophen crystallises in plates melting at  $40-41^\circ$ , and is soluble in carbon bisulphide and the usual organic solvents, insoluble in water. It is volatile in steam, and has the characteristic odour of diphenyl. It dissolves in cold concentrated sulphuric acid, and is reprecipitated unchanged on the addition of water. It shows the indophenin reaction, but does not give any characteristic coloration with Laubenheimer's reaction. When added to cold bromine, it forms *parabromophenyltribromothiophen*, which crystallises in white needles melting at  $145-146^\circ$ , sparingly soluble in alcohol and acetic acid, easily in carbon bisulphide and benzene. It is a very stable compound, may be heated with dilute nitric acid at  $180^\circ$  without change, and is only oxidised by continued boiling with chromic acid in acetic solution, and then forms parabromobenzoic acid. Attempts made to form a phenyltribromothiophen were unsuccessful. A mixture of a compound crystallising in white needles melting at  $55-56^\circ$  (probably a phenyldibromothiophen) with a very soluble bromo-derivative, melting at  $33-36^\circ$ , was produced.

L. T. T.

**Pentathiophen-group.** By K. KREKELER (*Ber.*, 19, 3266—3274).—The lactone of  $\alpha$ -methylhydroxyglutaric acid (Block and Tollens, *Abstr.*, 1886, 533) is prepared by slowly adding 100 grams of levulic acid to 100 grams of potassium cyanide, finely rubbed with 10 grams of water, the whole being well cooled. It is then kept for 24 hours in a loosely-closed vessel, treated with the necessary amount of fuming hydrochloric acid, and left for three or four days. It is extracted with ether, saponified by heating for one hour on a water-bath with fuming hydrochloric acid, and again extracted with ether. It is purified by means of the barium salt. The hydroxy-acid is converted into methylglutaric acid by boiling with twice its volume of hydriodic acid and amorphous phosphorus.

$\beta$ -Methylpentathiophen,  $\text{CH}_2 < \begin{smallmatrix} \text{CMe}:\text{CH} \\ \text{CH}=\text{CH} \end{smallmatrix} > \text{S}$ , is obtained by distilling 5 grams of sodium methylglutarate (dried at  $160^\circ$ ) with 10 grams of phosphorus trisulphide at  $180-250^\circ$ . From 550 grams of sodium salt, 20 grams of crude oil were obtained; this is boiled for some hours with strong potash solution, distilled, the oily distillate treated with a little dilute permanganate solution, and then re-distilled over sodium. It is a colourless, very refractive oil, boiling at  $134^\circ$ , and has the odour of pure xylene. Sp. gr. = 0.9938 at  $19^\circ$  (water at  $19^\circ = 1$ ). When the solution of the substance in glacial acetic acid is treated with a solution of isatin in the same solvent, and then with sulphuric acid (keeping it cold), an intense dark-green coloration is produced. When poured into water, a green flaky precipitate is formed, soluble in ether. Laubenheimer's reaction yields a dark violet coloration in sulphuric acid.

$\beta$ -Methylacetopentathiënone,  $\text{C}_5\text{SH}_4\text{MeAc}$ , is prepared by treating a solution of 1 part of  $\beta$ -methylpentathiënone in 10 parts of light petroleum with the calculated amount of acetic chloride, and adding aluminium chloride until the evolution of hydrogen chloride ceases.

It is purified by steam distillation. It is a clear heavy oil, having an odour resembling that of acetophenone; it boils at 233—235° (uncorr.). The *ketoxime*,  $C_6SH_4Me \cdot CMe : N \cdot OH$ , was prepared by Peter's method (Abstr., 1885, 141). It crystallises from ether in long, branched needles melting at 68°; it dissolves readily in alcohol and ether.

When  $\beta$ -methylpentathiophen is treated with 0.3 per cent. alkaline potassium permanganate solution, the oxidation takes place very quickly with formation of acetic and oxalic acids.

When air saturated with methylpentathiophen is passed through fuming nitric acid a nitro-compound is formed. The alcoholic solution of the latter, treated with a drop of potash solution, acquires an intense violet-red colour which disappears in a few minutes.

N. H. M.

#### Action of Light on Nitrobenzene in Alcoholic Solution.

By G. CIAMICIAN and P. SILBER (*Ber.*, 19, 2899—2900).—In continuation of experiments on the transformation of quinone to quinol on exposing its alcoholic solution to sunlight (Abstr., 1886, 695), the authors have studied the chemical change induced in nitrobenzene under similar conditions. Among the products obtained, were aldehyde, aniline, and a quinoline base, probably quinaldine.

V. H. V.

**Orthoethyltoluene: Oxidation of Orthodialkyl-derivatives of Benzene with Potassium Permanganate.** By A. CLAUS and E. PIESZCEK (*Ber.*, 19, 3083—3092).—The common statement that ortho-xylene, on oxidation with potassium permanganate, yields first orthotoluic acid and then phthalic acid is incorrect, nothing but phthalic acid being formed; not even a trace of orthotoluic acid is detectable. By the oxidation of orthoethyltoluene with potassium permanganate, orthotoluic, phthalic, and terephthalic acids were obtained according to the temperature and concentration of the solutions. At 100°, in alkaline solution, total combustion took place. The results obtained with cymene completely corresponded with those obtained with orthoethyltoluene.

*Bromorthoethyltoluene* is a colourless oil boiling at 220—221° (uncorr.); when heated with nitric acid, sp. gr. 1.2, in sealed tubes at 190—200°, it is oxidised to a *bromorthotoluic acid*,  $[Me : COOH : Br = 1 : 2 : 4]$ . This forms snow-like flocks composed of slender needles, melts at 118° (uncorr.), is sparingly soluble in cold water, readily soluble in alcohol, ether, and hot water, and yields readily soluble crystalline salts with the alkali metals, and with barium and calcium. It is not identical with the acid described by Jacobsen (Abstr., 1885, 143), to which he assigned the same constitution; the authors consider it more probable that his acid has the constitution  $[1 : 3 : 4]$ .

By the action of nitric acid on orthoethyltoluene in the cold, a *mono-* and *dinitro-*derivative are formed; the latter is a pale-yellow oil, and does not solidify at 0°.

*Orthoethyltoluene- $\beta$ -sulphonic acid*,  $C_6H_3MeEt \cdot SO_3H [1 : 2 : 4]$ , is obtained, together with the  $\alpha$ -acid which has not yet been investigated, by the action of pyrosulphuric acid on orthoethyltoluene; it forms a deliquescent, colourless, crystalline mass. The potassium, sodium,

barium, calcium, lead, copper, and silver salts are described. The *chloride* is a yellow oil, the *amide* forms a yellow, buttery mass.

A. J. G.

**Oxidation of the Homologues of Phenol.** By B. HEYMANN and W. KÖNIGS (*Ber.*, 19, 3304—3315).—Continuing their experiments (Abstr., 1886, 542), the authors find that the oxidation of the homologues of phenol can readily be effected if the phenols are converted into the corresponding dipotassium phosphates; these double salts are prepared by heating the phenols (1 mol.) with phosphoric oxychloride (1 mol.), carefully adding water to the cooled product, extracting the resulting chlorinated phosphorus compounds with ether, and decomposing them with potassium carbonate. The double phosphates are then oxidised with alkaline potassium permanganate, acidified with hydrochloric acid, and boiled for a short time. The double phosphates of the phenols are found to be more stable than the corresponding double sulphates, and a better yield is obtained when the former are oxidised. By this method, orthocresol is readily oxidised to salicylic acid.

Thymol treated with potassium pyrosulphate yields a double sulphate,  $C_6H_3MePr^{\alpha} \cdot SO_4K$  [ $Me : SO_4K : Pr = 1 : 3 : 4$ ], crystallising in fine silky fibres, which decomposes readily on keeping or when heated on a water-bath, although it is stable in alkaline solution; it is sparingly soluble in 50 per cent. alcohol, readily soluble in absolute alcohol and in water. When the double sulphate or double phosphate is oxidised, thymohydroxycumic acid,  $COOH \cdot C_6H_3Pr^{\beta} \cdot OH$  [ $COOH : OH : Pr = 1 : 3 : 4$ ] (Abstr., 1879, 158), is obtained.

*Carvacryl potassium sulphate*,  $C_6H_3MePr \cdot SO_4K$ , crystallises in silvery scales, decomposes very readily on keeping or on gently heating, is stable in alkaline solution, and is soluble in water and absolute alcohol. *Carvacryl dipotassium phosphate*,  $C_6H_3MePr \cdot PO_4K_2 + 5H_2O$ , crystallises in large, silvery laminae decomposing at  $100^\circ$ , readily soluble in water and in absolute alcohol. Some tricarcacryl phosphate was formed in the preparation of the double salt. When oxidised with permanganate, both the double sulphate and double phosphate yield *parahydroxyisopropylsalicylic acid*,  $COOH \cdot C_6H_3(OH) \cdot CMe_2 \cdot OH$  [ $COOH : OH : CMe_2 \cdot OH = 1 : 2 : 4$ ], which crystallises from water in large, flat needles, and in slender, concentrically grouped needles from chloroform. The acid melts at  $130$ — $135^\circ$ ; a more exact determination was not possible owing to the tendency to dehydrate and form parapropenylsalicylic acid. Hydroxyisopropylsalicylic acid is sparingly soluble in cold water, readily soluble in chloroform, alcohol and ether, insoluble in carbon bisulphide, and gives with ferric chloride an intense reddish-violet coloration. The *silver* salt,  $C_{10}H_{11}O_4Ag$ , crystallises in colourless needles; the *copper* salt,  $(C_{10}H_{11}O_4)_2Cu + H_2O$ , crystallises in green prisms which do not lose their colour on drying; it is sparingly soluble in water. When heated with concentrated hydriodic acid and amorphous phosphorus, the acid is reduced to isohydroxycumic acid,  $OH \cdot C_6H_3Pr^{\beta} \cdot COOH$  (Abstr., 1878, 731).

*Parapropenylsalicylic acid*,

$COOH \cdot C_6H_3(OH) \cdot CMe : CH_2$  [ $COOH : OH : (CMe : CH_2) = 1 : 2 : 4$ ],

is readily obtained from hydroxyisopropylsalicylic acid by gently warming it on a water-bath with dilute hydrochloric acid. It crystallises in slender needles, melts at 145—146°, is sparingly soluble in cold water, readily soluble in alcohol, ether and boiling carbon bisulphide, and gives an intense reddish-violet coloration with ferric chloride. It is volatile with steam, and when heated at 150° sublimes with slight decomposition. The *silver* salt,  $C_{10}H_9O_3Ag$ , forms a crystalline powder, very sparingly soluble in water; the *copper* salt,  $(C_{10}H_9O_3)_2Cu + 2H_2O$ , forms small, green crystals insoluble in water, the anhydrous salt is not hygroscopic. By reduction with sodium amalgam in the cold, an acid agreeing in its properties with Jacobsen's isohydroxycumic acid (*loc. cit.*) was obtained; the melting point, however, was 96—97° instead of 93—94°.

When a boiling aqueous solution of hydroxyisopropylsalicylic acid is treated with an equal volume of concentrated hydrochloric acid, a polymeride, *propenylsalicylic acid*,  $(C_{10}H_{10}O_3)_x$ , is obtained in small, white crystals which melt at 230° with evolution of carbonic anhydride. It is insoluble in water and carbon bisulphide, soluble in hot acetic acid, alcohol and ether, and the alcoholic solution is coloured an intense reddish-violet with ferric chloride. The acid is not volatile with steam nor is it reduced by sodium amalgam.

Attempts to oxidise the ethyl, isopropyl, isobutyl, and amyl potassium sulphates led to no result.

W. P. W.

**Action of Sodium Methoxide on Bromobenzene.** By F. BLAU (*Monatsh. Chem.*, **7**, 621—636).—When bromobenzene is heated with sodium methoxide in sealed tubes, anisoil is formed together with phenol; the sodium methoxide thus acting like a mixture of the alcohol and alkali: a considerable proportion of the bromobenzene is unaltered. The reactions with di- and symmetrical tri-bromobenzenes are precisely analogous; thus from the former are obtained brom-anisoil, dimethylquinol, and bromophenol; from the latter a dibromophenol and dibromanisoil. The dibromophenol forms white crystals melting at 76·5°, readily soluble in alcohol and ether, sparingly in water and petroleum; on fusion with alkali, it yields phloroglucol; it is, therefore, a symmetrical compound.

V. H. V.

**Bisulphides with Mixed Organic Radicles.** By R. OTTO and A. RÖSSING (*Ber.*, **19**, 3132—3138).—Hitherto no organic bisulphides with mixed radicles have been obtained. The authors find that such compounds are formed when a mixture of two mercaptans are treated with bromine, and that the reactions take place the more readily the more closely allied are the radicles of the reacting mercaptans. The reaction is  $R\cdot SH + R'\cdot SH + Br_2 = 2HBr + R\cdot S_2\cdot R'$ .

*Phenyl paratolyl bisulphide*,  $C_7H_7\cdot S_2\cdot Ph$ , is obtained by dissolving molecular proportions of phenyl and paratolyl hydrosulphides in ten times their volume of ether, and slowly adding a molecular proportion of bromine. This substance is a thick, pale-yellow oil. It is insoluble in water, miscible in all proportions with alcohol and ether, has an odour somewhat resembling that of tolyl hydrosulphide, is heavier than water, and scarcely volatile in steam. When heated with alcohol and zinc-dust, it is decomposed into the corresponding zinc mercaptides.

*Ethyl amyl bisulphide*, prepared in a similar way, is a thin, colourless liquid of very strong and unpleasant garlic-like odour. It is insoluble in water, soluble in ether and alcohol, lighter than water, and volatile in steam.

*Ethyl phenyl bisulphide*.—The authors attempted to obtain this compound by the above method, but it was only formed in very small quantity, the principal products being diethyl and diphenyl bisulphides. But by modifying Schiller and Otto's method for the preparation of organic bisulphides (this Journal, 1877, i, 306), the authors were successful. 10 grams of phenylsulphinic acid (1 mol.) and 15 grams of ethyl mercaptan (3 mols.) in alcoholic solution were heated in sealed tubes at 100°. The action took place according to the equation  $\text{PhSO}_2\text{H} + 3\text{EtSH} = \text{PhS}_2\text{Et} + \text{Et}_2\text{S}_2 + 2\text{H}_2\text{O}$ . Ethyl phenyl bisulphide is a thick, oily, strongly refractive liquid, heavier than water, and only very slightly volatile in steam. It is insoluble in water, soluble in ether and alcohol. Phenyl paratolyl bisulphide was also prepared by the action of phenyl hydrosulphide on paratolylsulphinic acid.

When the ethyl salts of the thiosulphonic acids are heated with mercaptans reactions similar to the above occur; these are not, however, of so simple a kind, but take place simultaneously according to the two equations:—

Phenyl disulphoxide ( $\text{Ph}\cdot\text{S}_2\text{O}_2\cdot\text{Ph}$ ) and ethyl mercaptan thus yield ethyl bisulphide, phenyl bisulphide, and ethyl phenyl bisulphide.

L. T. T.

**Action of Silicon Fluoride on Organic Bases.** By C. L. JACKSON and A. M. COMEY (*Ber.*, 19, 3194—3195).—The authors intend studying these reactions. When silicon fluoride is passed over aniline, a compound of the formula  $3\text{NH}_2\text{Ph}\cdot 2\text{SiF}_4$  is formed. This compound was obtained by Laurent and Delbos (*Ann. Chim. Phys.*, 22, 101), but its composition was not established. It forms white, microscopic needles, and sublimes without fusion. It is insoluble in ether, benzene, and light petroleum. With water or alcohol, it forms aniline hydrosilicofluoride.

Ortho- and para-toluidine, diphenylamine, and dibenzylamine form similar compounds.

L. T. T.

**Aniline and Diphenylamine from Phenol.** By V. MERZ and P. MÜLLER (*Ber.*, 19, 2901—2917).—In this paper, the various methods used, and the conditions required for the conversion of phenol into aniline and diphenylamine are fully described. Thus when phenol and ammonium zinc chloride or simply ammonium chloride are heated at 330°, 70 to 80 per cent. of the phenol is converted into the amine, the yield of which is dependent on an excess of the ammonium salt, the temperature, and the time of heating. The same change may also be effected with zinc oxide or magnesia and ammonium chloride, the presence of an excess of the latter preventing the formation of diphenylamine. Experiments in an autoclave were not so satisfactory;

the pressure when the mixture was heated at  $320^{\circ}$ , was 20 to 25 atmospheres. V. H. V.

### Action of Alcoholic Hydrogen Chloride on Nitrosamines.

By O. FISCHER and E. HEPP (*Ber.*, 19, 2991—2995).—The authors find that certain nitrosamines undergo intramolecular change by the action of alcoholic hydrogen chloride thus; for example, methylphenylnitrosamine is converted into 1 : 4 nitrosomethylaniline.

1 : 4 *Nitrosmethylaniline* is prepared by adding alcoholic hydrogen chloride to an ethereal solution of methylphenylnitrosamine; a vigorous action takes place after some time, and small yellow needles of the 1 : 4 nitrosomethylaniline hydrochloride separate in an almost pure state. The base is obtained by precipitation with sodium carbonate or ammonia, either in yellowish-green laminae, or from very dilute solutions in large, steel-blue prisms; it is readily soluble in alcohol, ether, and chloroform, sparingly soluble in benzene, and only slightly soluble in light petroleum and in water. It melts at  $118^{\circ}$  and suffers decomposition when more strongly heated. When heated with solution of sodium hydroxide, it is decomposed into 1 : 4 nitrosophenol and methylamine; whilst by reduction methylparaphenylenediamine is obtained. Paranitrosomethylaniline is a secondary base, and by the action of nitrous acid yields 1 : 4 *nitrosomethylphenylnitrosamine*,  $\text{NO}\cdot\text{C}_6\text{H}_4\cdot\text{NMe}\cdot\text{NO}$ ; this compound crystallises from alcohol in nodules, and melts at  $101^{\circ}$ . Careful oxidation with nitric acid of sp. gr. = 1.13 converts it into 1 : 4 *nitromethylphenylnitrosamine*; this forms yellow needles melting at  $104^{\circ}$ .

When methylaniline, dissolved in alcoholic hydrogen chloride, is treated in the cold with one molecular proportion of sodium nitrite, there separate after long standing two compounds, 1 : 4 nitrosomethylaniline hydrochloride and 1 : 4 nitrosomethylphenylnitrosamine, the latter being formed in the greater quantity, and a corresponding proportion of the methylaniline remaining unacted on.

1 : 4 *Nitrosoethylaniline*, obtained in a manner similar to the methyl-derivative, crystallises in green laminae, melts at  $78^{\circ}$ , and is readily soluble in alcohol, ether and benzene, sparingly soluble in water. Its *hydrochloride* crystallises in stellate groups of needles. By reduction, *ethylparaphenylenediamine* is obtained; this base is a thick oil and distils at  $270^{\circ}$ . Its *hydrochloride* forms colourless, narrow scales readily soluble in water, less soluble in alcohol. From 1 : 4 nitrosoethylaniline, 70 per cent. of the nitrosophenol and 80 per cent. of the ethylamine hydrochloride required by theory were obtained by heating it with sodium hydroxide solution.

1 : 4 *Nitrosoethylorthotoluidine* melts at  $140^{\circ}$  and crystallises in green scales, frequently exhibiting a bluish shimmer.

1 : 4 *Nitrosodiphenylamine*, obtained from Witt's diphenylnitrosamine, crystallises in green tables showing a bluish shimmer, melts at  $143^{\circ}$ , and dissolves readily in alcohol, ether, and chloroform, giving brown solutions, and in sulphuric acid with a red colour, which at once changes to violet on warming. The *hydrochloride* crystallises in brown tables having a bronze lustre, or in dark reddish-brown needles, and is decomposed by water with liberation of the base. W. P. W.

**Preparation of Benzylamine and Phenethylamine.** By S. HOOGWERFF and W. A. VAN DORP (*Rec. Trav. Chim.*, **5**, 252—254).—Hofmann has suggested the action of bromine on phenylacetamide in presence of dilute alkali as a convenient method for the preparation of benzylamine (*Abstr.*, 1886, 45). It is here shown that the yield is considerably increased by preparing the alkaline hypobromite first and then adding it subsequently to the amide.

The preparation of benzylamine and phenethylamine by this method is described. V. H. V.

**Isodinitrodimethylaniline.** By P. v. ROMBURGH (*Rec. Trav. Chim.*, **5**, 240—245).—According to Mertens, when dinitrophenyl-nitramine is heated with phenol, tetranitrodimethylazobenzene, a red compound is produced, reconvertible into the nitramine by treatment with nitric acid (*Abstr.*, 1885, 1022). As, however, trinitrophenyl-methylnitramine yields a similar red substance, reconvertible into the nitramine, which has been shown to be trinitrophenylmethylaniline, it is probable that the red substance obtained by Mertens is a dinitro-methylaniline. The analytical results support this view quite as well as that of Mertens. As a confirmation, the author by acting on tetramethylbenzidine with nitric acid, obtained a product resembling the isodinitrodimethylaniline of Mertens, which when boiled with nitric acid yielded the corresponding nitramine; from this, the red substance was obtained, the analysis of which showed that it was a tetranitrodimethylbenzidine. When treated with nitric acid, this yielded the theoretical quantity of the nitramine. V. H. V.

**New Synthesis of Thiodiphenylamine.** By A. BERNTHSEN (*Ber.*, **19**, 3255—3256).—Thiodiphenylamine is obtained by heating ortho-amidophenyl mercaptan and catechol at 220—240° for about 30 hours. The product is extracted with alkali and acid, and crystallised from ether and light petroleum. This synthesis forms an important support in favour of thiodiphenylamine being a di-ortho-compound (compare Bernthsen, *Abstr.*, 1886, 53, and Möhlau, *Ber.*, **19**, 2013).

N. H. M.

**Ethereal Carbonates.** By G. BENDER (*Ber.*, **19**, 2950—2952).—Oxycarbimidophenol, described by Kalckhoff (*Abstr.*, 1883, 1169) and previously by Groenvik (*Bull. Soc. Chim.*, **25**, 177), and hydroxymethenylamidophenol, prepared by Sandmeyer (this vol., p. 135), are identical with the author's anhydro-orthamidophenyl carbonate (*Abstr.*, 1887, 37) which melts at 137—138°. Kalckhoff's compound on further purification becomes white, and its acetyl-derivative is soluble in water like the corresponding substance obtained by the author. The ethyl salt prepared by Sandmeyer has the formula  $C_6H_4 \begin{smallmatrix} N \\ \diagup \diagdown \\ O \end{smallmatrix} > C \cdot OEt$ , that of the salt obtained by the author is  $C_6H_4 \begin{smallmatrix} N \\ \diagup \diagdown \\ O \end{smallmatrix} Et > CO$ . In the existence of these two isomerides, the parent substance exhibits a remarkable analogy to carbostyryl and isatin; it also has a pseudo-form in addition to its ordinary

one, although whether the latter is a lactim or lactam cannot yet be decided.

The author's ethyl salt melts at  $29^{\circ}$  and has a bitter taste. Concentrated hydrochloric acid is without action on it at  $100^{\circ}$ , but dissolves it in the cold forming a highly unstable hydrochloride.

W. P. W.

**Benzyl-derivatives of Hydroxylamine.** By F. WALDER (*Ber.*, 19, 3287--3294).—Further investigation has shown that the conclusions respecting the composition of these compounds arrived at in the author's previous paper (*Abstr.*, 1886, 796) are erroneous. A complete analysis of the compound obtained by the action of methyl iodide and sodium on dibenzylhydroxylamine and described as tri-benzylbenzoxammonium iodide, shows that it has the formula  $N_2(C_7H_7)_4O, HI$ . The hydriodide can be decomposed by alkalis, but, since the base is soluble in water and only sparingly soluble in ether, a separation is better effected by employing moist silver oxide. The base crystallises over sulphuric acid, distils with decomposition at high temperatures, and is very deliquescent; when heated with water, it yields dibenzylhydroxylamine, whilst by the action of acetic anhydride acetyldibenzylhydroxylamine is obtained. The *platinochloride*,  $N_2(C_7H_7)_4O, H_2PtCl_6$ , crystallises in slender, yellow needles, melts at  $153^{\circ}$ , and is insoluble in cold water and ether. The *sulphate*,  $N_2(C_7H_7)_4O, H_2SO_4$ , forms transparent prisms, melts at  $152^{\circ}$ , and is insoluble in alcohol and ether, readily soluble in water containing acid. The *nitrate*,  $N_2(C_7H_7)_4O, 2HNO_3$ , crystallises in white, feathery, flat needles, melts at  $159^{\circ}$ , and is sparingly soluble in water. The *hydrochloride*,  $N_2(C_7H_7)_4O, 2HCl$ , forms thick prisms showing a nacreous lustre, is insoluble in ether, and only sparingly soluble in water after it has once separated from solution. A second *hydriodide*,  $N_2(C_7H_7)_4O, 2HI$ , crystallises in bright yellow aggregates, melts at  $27^{\circ}$ , and is soluble in alcohol.

From a black, resinous mass formed in the preparation of the hydriodide,  $N_2(C_7H_7)_4O, HI$ , a black, crystalline compound may be obtained; it appears to be a periodide of the formula  $N_2(C_7H_7)_4O, MeI, I_2$ .

The base previously described as benzylbenzenylamine proves to be *dibenzylamine*,  $NH(C_7H_7)_2$ . It is found that when dibenzylhydroxylamine is heated with phosphorus trichloride and the product extracted with dry ether, an unstable, bright-yellow viscid oil containing phosphorus and chlorine is obtained, which on addition of water yields dibenzylamine. The *nitrosamine*,  $(C_7H_7)_2N \cdot NO$ , forms brittle, curved, white crystals, melts at  $61^{\circ}$ , and is readily soluble in alcohol, ether and light petroleum, insoluble in water. The *platinochloride*,  $N(C_7H_7)_2H, H_2PtCl_6$ , crystallises in golden-yellow needles; the *nitrate*,  $N(C_7H_7)_2H, HNO_3$ , crystallises in slender glistening needles, melts at  $186^{\circ}$ , and is sparingly soluble in water. When heated with benzyl chloride at  $100^{\circ}$ , the base is converted into tri-benzylamine.

When dibenzylhydroxylamine hydrochloride is treated with potassium nitrite in the cold, *nitrosodibenzylhydroxylamine*,  $N(C_7H_7)_2O \cdot NO$ , is obtained; this crystallises in flat, white needles, melts at  $82-84^{\circ}$ ,

and is soluble in alcohol and ether, sparingly soluble in light petroleum, insoluble in water. If, however, cooling be omitted, and the nitrate be added rapidly to the hydrochloride, *nitrosodibenzylamine* is obtained,  $N(C_6H_5)_2OH + 2HNO_2 = HNO_3 + H_2O + N(C_6H_5)_2 \cdot NO$ .

The author finds that mono-, di-, and tri-benzylamine are also formed when dibenzylhydroxylamine is prepared by Schramm's method (Abstr., 1884, 51). W. P. W.

**Correction.** By L. KNORR (*Ber.*, 19, 3303).—In a previous paper (Abstr., 1884, 1198), a compound,  $C_{14}H_{16}N_2O_4$ , was stated to have been obtained by the action of ethyl acetoacetate on orthophenylenediamine, instead of on paraphenylenediamine. Sulphuric acid is without action on the compound in the cold, but at  $100^\circ$  paraphenylenediamine is eliminated. W. P. W.

**Action of Ethyl Acetoacetate on Aromatic Diamines.** By O. N. WITT (*Ber.*, 19, 2977—2978 and 3299).—By the action of ethyl acetoacetate on orthotoluylenediamine, ethenyltoluylenediamidine is formed. This confirms the results obtained by Ladenburg and Rügheimer (Abstr., 1879, 915), the priority of whose work is acknowledged by the author in the second communication.

**Condensation Products from Carbo-imides and Orthodiamines.** By C. DAHM and K. GASIOROWSKI (*Ber.*, 19, 3057—3060).

—*Carborthotoluylenediphenyltetramine*,  $C_7H_6 < \begin{smallmatrix} NH \\ NH \end{smallmatrix} > C(NHPh)_2$ , is prepared by heating carbodiphenylimide and orthotoluylenediamine (molecular weights) for four hours at  $130$ — $140^\circ$ . It crystallises from benzene in needles melting at  $161^\circ$ , and is readily soluble in alcohol and ether. It does not react with an excess of imide. The *hydrochloride*,  $2C_{20}H_{20}N_4 \cdot 3HCl$ , crystallises in white needles melting at  $173$ — $174^\circ$ ; it is very soluble in alcohol and ether, rather sparingly in water. The *sulphate* was also prepared.

*Carborthotoluylenediparatolyltetramine*,  $C_{22}H_{24}N_4$ , is prepared in a manner similarly to the above-mentioned compound. The product is extracted with boiling benzene, and the white powder dissolved in alcohol, from which it separates in needles melting at  $196^\circ$ . The *hydrochloride*,  $2C_{22}H_{24}N_4 \cdot 3HCl$ , crystallises from the strong acid solution in needles melting at  $143^\circ$ . N. H. M.

**Derivatives of Parachlorazobenzene.** By E. MENTHA and K. HEUMANN (*Ber.*, 19, 2970—2974; comp. Abstr., 1886, 874).—*Chlorodiamidodiphenyl*,  $NH_2 \cdot C_6H_4 \cdot C_6H_3Cl \cdot NH_2$ .—When parachlorazobenzene in alcoholic solution is treated with zinc chloride and sulphuric acid, and the solution, after precipitating the zinc with hydrogen sulphide, is made alkaline with caustic soda, chlorodiamidodiphenyl is obtained and can be extracted with ether. It is a bright yellow powder, which very readily becomes oxidised. The *hydrochloride*,  $C_{12}H_{11}N_2Cl \cdot 2HCl$ , crystallises in tufts of white needles.

*Paranitrochlorazobenzene*,  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$  [4:1:4], is prepared by treating parachlorazobenzene with fuming nitric acid. It forms slender, pale-yellow needles, melts at  $132.5^\circ$ , and is insoluble in water, sparingly soluble in cold alcohol and ether, readily soluble in acetic acid.

*Parachlorazobenzenesulphonic acid*,  $\text{SO}_3\text{H} \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4\text{Cl}$ , [4:1:4], is obtained by heating parachlorazobenzene with 10 per cent. fuming sulphuric acid at  $60-70^\circ$  for some time. It crystallises in brown needles, melts at  $148^\circ$ , and is very soluble in water and alcohol. The *sodium* and *barium* salts are described. The *chloride*,  $\text{C}_{12}\text{H}_8\text{N}_2\text{Cl} \cdot \text{SO}_2\text{Cl}$ , melts at  $130^\circ$ , and crystallises in glistening, red prisms, soluble in alcohol and ether; boiling with water converts it into the acid. The *amide* forms brownish-yellow prisms, melts at  $211^\circ$ , and is insoluble in water, sparingly soluble in ether and cold alcohol. W. P. W.

**Cyanazobenzene and Parazobenzenecarboxylic Acid.** By E. MENTHA and K. HEUMANN (*Ber.*, 19, 3022—3025).—*Paracyanazobenzene*,  $\text{C}_{13}\text{H}_9\text{N}_3$ , is prepared by slowly adding a solution of diazobenzene chloride (from 40 grams of amido-azobenzene hydrochloride) to a solution of copper sulphate (100 grams) and potassium cyanide (90 per cent., 112 grams) in 600 c.c. of water at  $90^\circ$ . When cold, it is filtered, well washed, and dried; it is then sublimed and recrystallised from benzene, from which it separates in short brown needles. It melts at  $100-101^\circ$ , is insoluble in water, readily soluble in warm alcohol, ether, and benzene.

*Parazobenzenecarboxylic acid*,  $\text{NPh} : \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{COOH}$ , is obtained by boiling the above nitrile in the pure state for three hours with concentrated aqueous potash. It crystallises from alcohol in long, lustrous, brown prisms, soluble in ether and warm benzene. When heated above  $210^\circ$ , it becomes dark, and decomposes at a higher temperature. When heated with lime, a sublimate is obtained which melts at  $170-171^\circ$ , and is probably azophenylene. The *potassium salt* crystallises in brownish-yellow needles soluble in water and in alcohol; the *barium salt* forms needles sparingly soluble in water, rather readily soluble in alcohol. Several other salts were prepared. N. H. M.

**Chloroparazotoluene.** By E. MENTHA (*Ber.*, 19, 3026).—*Chloroparazotoluene*,  $\text{C}_{11}\text{H}_{13}\text{N}_2\text{Cl}$ , is prepared by treating 4.5 grams of amido-parazotoluene (obtained by Nöling and Witt's method, *Abstr.*, 1884, 742) with 200 c.c. of water and 150 c.c. of strong hydrochloric acid, and adding a solution of 5 grams of cuprous chloride in 45 c.c. of hydrochloric acid. It is then heated to  $90^\circ$ , and a solution of 2.5 grams of sodium nitrite in 25 c.c. of water gradually added. The product is filtered, treated with hydrochloric acid and with soda solution, and ultimately crystallised from alcohol. It forms brown plates which melt at  $97^\circ$ , dissolves readily in ether, alcohol, and benzene, and closely resembles parachlorazobenzene (compare *Abstr.*, 1886, 874). N. H. M.

**Reduction of Aldoximes and Acetoximes.** By H. GOLDSCHMIDT (*Ber.*, 19, 3232—3234).—*Carvylamine*,  $C_{10}H_{17}N$ , is obtained by reducing carvoxime in alcoholic solution with sodium amalgam in presence of acetic acid.

Benzylamine can be conveniently prepared by gradually adding 160 grams of  $2\frac{1}{2}$  per cent. sodium amalgam to a solution of 5 grams of benzaldoxime in 20 c.c. of alcohol at  $50-60^\circ$ ; the solution must be kept acid by addition of acetic acid. It is poured into water, saturated with ether, made alkaline, and again extracted with ether. The ethereal extract is dried, and treated with hydrogen chloride; benzylamine hydrochloride then separates as a white precipitate. Benzhydramine and isobutylamine were prepared in a similar manner from benzophenoxime and isobutylaldoxime respectively.

N. H. M.

**Pyrogenic Formation of Phenazine.** By A. BERNTHSEN (*Ber.*, 19, 3256—3258).—The author succeeded in isolating phenazine from the product obtained by passing aniline through a red-hot tube (*Abstr.*, 1886, 471). The product was repeatedly exhausted with moderately dilute hot hydrochloric acid, the brown solution precipitated with ammonia, extracted with ether, and the ethereal solution shaken several times with dilute hydrochloric acid. In this way, the stronger bases were dissolved, but not the phenazine. The ether was distilled off, the residue extracted with hot dilute hydrochloric acid, filtered when cold, and precipitated with ammonia. It was then sublimed, and the lustrous, yellow needles identified as phenazine. This pyrogenic formation of phenazine corresponds with that of anthracene from toluene.

N. H. M.

**Safranine Dyes.** By R. NIETZKI (*Ber.*, 19, 3017—3022).—Previous experiments (*Abstr.*, 1883, 731) made it probable that safranine contains two amido-groups, and that the third nitrogen-atom is tertiary or quaternary.

When phenosafranine,  $C_{18}H_{14}N_4$ , is boiled with alcohol, sulphuric acid, and sodium nitrite, the compound  $C_{18}H_{13}N_3$  is formed. This is a dye of a bluer shade than safranine, from which it is also distinguished by the absence of fluorescence of its alcoholic solution and in its behaviour towards strong sulphuric acid:—safranine dissolves with a green colour, which changes to blue and red on addition of water; the new compound dissolves, yielding a yellowish-brown solution, which when diluted becomes first green and then red. The *monacetyl-derivative* is violet, and yields crystalline, yellow salts.

The second amido-group in safranine can be removed only with difficulty, and in strongly acid solution. A reddish-violet base was obtained, which yields brownish-yellow salts. It shows the same reactions as the acetyl-derivatives of safranine.

The two constitutional formulæ for safranine lately proposed by Bernthsen (this vol., p. 139) are shown by the author to be incorrect. With the one, the existence of the two isomeric diethylsafranines obtained by the author (*loc. cit.*) cannot be accounted for; the other formula permits the existence of the two isomerides, but only one of

the latter could be diazotised. It has been shown that both the diethylsafranines very readily yield diazo-compounds. N. H. M.

**Constitution of the Safranines.** By O. N. WITT (*Ber.*, 19, 3121—3124).—The author criticises the constitution assigned to the phenosafranines by Andresen (*Abstr.*, 1885, 1026) and by Bernthsen (*this vol.*, p. 139), and suggests the following:—

Leucosafranine.

Phenosafranine hydrochloride.

A. J. G.

**Constitution of Safranine.** By R. NIETZKI (*Ber.*, 19, 3163—3166).—The author supports the correctness of the formulæ suggested by Witt (see preceding Abstract). O. Lehmann has examined crystallographically the nitrates of the two dimethylsafranines previously described by the author, and the non-identity of which has been lately called in question by Bernthsen (*this vol.*, p. 139). Lehmann declares the two compounds to be undoubtedly different.

The author has carried out the idea mentioned in his last paper on this subject, and tested the safranine-forming power of the six isomeric xylidines,  $C_6H_3Me_2 \cdot NH_2$ , and of the three isomeric compounds ( $C_6H_2Me_3 \cdot NH_2$ ) cumidine, mesidine, and isocumidine when heated with paradiamidodiphenylamine. The results—taking  $NH_2$  as always occupying the position 1—may be expressed as follows:—The xylidines 1 : 3 : 4 and 1 : 2 : 4 gave safranine; 1 : 2 : 5, 1 : 2 : 6, and 1 : 3 : 5 gave no safranine; and 1 : 2 : 3 gave only traces, which were probably due to traces of the 1 : 3 : 4 compound present as impurity in the xylidine used. Ordinary cumidine, [1 : 2 : 4 : 5], gave a safranine, whilst mesidine, [1 : 2 : 4 : 6], and isocumidine, [1 : 3 : 4 : 5], gave none. It is therefore clear that the position of the methyl-groups in the monamine plays a determining part in the formation or non-formation of safranines.

The author considers that Witt's formula is much more in harmony with the above and other facts known about safranine than is either Andresen's or Bernthsen's formula.

L. T. T.

**Paranitroformanilide.** By T. B. OSBORN and W. G. MIXTER (*Amer. Chem. J.*, 8, 346—347).—This substance,  $NO_2 \cdot C_6H_4 \cdot NH \cdot COH$ , was prepared by adding formanilide to fuming nitric acid, sp. gr. 1.53, in a freezing mixture, and pouring the product into cold water; it was washed with water and ether, then crystallised from alcohol. It

melts at 187° or 194°, according as it has been crystallised from alcohol or from hot water. When boiled with caustic potash, it yields paranitraniline. Attempts to obtain azo-compounds by its reduction were unsuccessful. H. B.

**Orthazoparabromacetanilide.** By C. H. MATTHIESSEN and W. G. MIXTER (*Amer. Chem. J.*, **8**, 347—349).—Parabromacetanilide was converted into orthonitroparabromacetanilide and then treated in warm alcoholic solution with zinc and strong aqueous ammonia for half an hour. The red precipitate was washed with water, dilute acid, and alcohol. During the reduction, a portion of the bromine is displaced with formation of azoacetanilide, which is only removed by heating with concentrated hydrochloric acid at 100°. The product thus purified is *orthazoparabromacetanilide*,  $N_2(C_6H_3Br \cdot NHAc)_2$ . It is a pale red substance melting at 280—282°, and is acted on by potash with great difficulty. H. B.

**Halogen-derivatives of Oxanilide.** By J. O. DYER and W. G. MIXTER (*Amer. Chem. J.*, **8**, 349—357).—*Tetrachloroxanilide*,

is obtained by passing chlorine into an acetic acid solution of oxanilide. It separates in slender, white fibres melting at about 255°, and is difficult to obtain quite pure. On decomposition, it yields metadichloraniline, melting at 63°.

*Paradibromoxanilide*,  $C_2O_2(NH \cdot C_6H_4Br)_2$ , is obtained by adding bromine in excess to a boiling acetic acid solution of oxanilide. It melts above 300°. Treated with alcoholic potash, it yields parabromaniline.

*Paradiiodoxanilide* is prepared by the action of iodine and strong nitric acid; crystallised from aniline it is quite white. It decomposes before melting. Treated with potash it yields paraiodaniline.

Boiling alcoholic potash converts oxanilide into oxanilic acid, and then into oxalic acid and aniline. The substituted oxanilides behave similarly. *Metadichloroxanilic acid*,  $C_6H_3Cl_2 \cdot NH \cdot CO \cdot COOH$ , is formed along with metadichloraniline by the hydrolysis of the tetrachloroxanilide. It dissolves in 808 parts of water at 25° and melts at 122°; the potassium salt crystallises from hot water in fine fibres.

*Parabromoxanilic acid*,  $C_6H_4Br \cdot NH \cdot CO \cdot COOH$ , is readily soluble in hot water, and in 515 parts of water at 25°; it melts at 198°. The potassium salt is anhydrous, and forms tabular, monoclinic crystals; the calcium, barium, and silver salts are also anhydrous, and sparingly soluble in water. *Paraiodoxanilic acid*,  $C_6H_4I \cdot NH \cdot CO \cdot COOH$ , melts with decomposition at 197—200°, and dissolves in 1385 parts of water at 25°; the potassium salt is anhydrous. H. B.

**Action of Concentrated Sulphuric Acid on Aromatic Ketones.** By A. CLAUS (*Ber.*, **19**, 2879—2881).—In this paper, preliminary experiments are described on the decomposition of aromatic ketones by fuming sulphuric acid. The reaction consists in the decomposition of the ketone and formation of a carboxylic acid and a sulphonic acid: thus mesityl phenyl ketone yields mesitylsulphonic and benzoic acids. It is proposed to carry on a series of investiga-

tions to determine in the case of mixed ketones containing a simple and a replaced phenyl-group, whether in all cases the former remains combined with the carbonyl grouping and the latter yields the sulphonic acid, as also to investigate the changes produced in the case of a ketone containing the substituted phenyl groupings of differing degrees of complexity. At a low temperature, a sulphonic acid of the ketone is formed; thus barium salts of mesitylphenylketone mono-sulphonic and para-xylylphenylketone disulphonic acids are described.

V. H. V.

**Aromatic Ketones.** By O. PAMPEL and G. SCHMIDT (*Ber.*, **19**, 2896—2899).—*Phenyl ethyl ketone* (propiophenone),  $\text{COEtPh}$ , is conveniently prepared by Friedel and Crafts' aluminium chloride reaction. Its acetoxime- and phenylhydrazine-compounds are colourless oils; with bromine, it yields a monobromo-derivative as a dark oil, which gives an anilide,  $\text{COPh}\cdot\text{C}_2\text{H}_4\cdot\text{NHPh}$ , separating in yellow, glistening crystals melting at  $38^\circ$ ; its acetyl-derivative crystallises in colourless needles melting at  $103^\circ$ .

*Naphthyl methyl ketone*,  $\text{C}_{10}\text{H}_7\cdot\text{COMe}$ , prepared by aid of the aluminium chloride reaction, is a pale-yellow oil boiling at  $296\text{--}299^\circ$ . Its acetoxime- and phenylhydrazine-derivatives are crystalline compounds melting at  $101^\circ$  and  $146^\circ$  respectively. Its *anilide*,

separates in golden-red crystals melting at  $130^\circ$ ; its thiocyanate crystallises in micaceous crystals.

V. H. V.

**Benzene-derivatives of High Molecular Weight.** By F. KRAFFT (*Ber.*, **19**, 2982—2988).—*Pentadecyl phenyl ketone*,  $\text{C}_{15}\text{H}_{31}\cdot\text{COPh}$ , is obtained by gradually adding aluminium chloride ( $1\frac{1}{2}$  parts) to a cooled solution of palmitic chloride (1 part) in benzene (2 parts) and afterwards gently warming; the product is poured into water, excess of benzene removed by distillation, and by fractional distillation under 15 mm. pressure the ketone is approximately separated from the regenerated palmitic acid, the last traces of which are removed from an alcoholic solution of the distillate by precipitation as barium palmitate. The ketone crystallises in large, glistening laminae, melts at  $59^\circ$ , boils at  $250\cdot5\text{--}251^\circ$  under 15 mm. pressure, and is very sparingly soluble in cold alcohol, soluble in ether and hot alcohol. On oxidation with chromic acid, it yields benzoic and pentadecylic acids.

*Hexadecylbenzene*,  $\text{C}_{16}\text{H}_{33}\text{Ph}$ , is prepared by the action of sodium on a mixture of cetyl iodide and iodobenzene. It crystallises in glistening tables, which subsequently become opaque, melts at  $27^\circ$ , and boils at  $230^\circ$  under 15 mm. pressure. When dissolved in fuming sulphuric acid, hexadecylbenzene yields a *monosulphonic acid*, and by fusing its sparingly soluble sodium salt with potassium hydroxide at  $250^\circ$ , *hexadecylphenol*,  $\text{C}_{16}\text{H}_{33}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$ , is obtained. This is a colourless, odourless and tasteless compound, melting at  $77\cdot5^\circ$ , and boiling at  $260\text{--}261^\circ$  under 16 mm. pressure. *Hexadecylnitrobenzene* is a crystalline powder, melts at  $35\text{--}36^\circ$ , and when reduced yields *hexadecylamidobenzene*, which melts at  $53^\circ$ , and distils without decomposition at  $254\text{--}255^\circ$  under 14 mm. pressure;

its *platinochloride*,  $(C_{16}H_{33} \cdot C_6H_4 \cdot NH_2)_2, H_2PtCl_6$ , is soluble in ether and alcohol.

*Octadecylbenzene*,  $C_{18}H_{37}Ph$ , is obtained by the action of sodium on a solution of octadecyl iodide and iodobenzene in benzene. It forms either an oil which soon solidifies, or crystallises in colourless, odourless and tasteless, silvery scales, melts at  $36^\circ$ , and boils at  $249^\circ$  under 15 mm. pressure. *Octadecylbenzenesulphonic acid* is prepared by treating octadecylbenzene with fuming sulphuric acid and gently warming; the sodium salt when heated with eight times its weight of potassium hydroxide at  $250-270^\circ$  for 10 to 12 hours, yields *octadecylphenol*,  $C_{18}H_{37} \cdot C_6H_4 \cdot OH$ , almost quantitatively. This crystallises in glistening laminae, melts at  $84^\circ$ , and boils without decomposition at  $277^\circ$  under 15 mm. pressure. Octadecylbenzene is converted by fuming nitric acid into an almost colourless *mononitro-compound* melting at about  $48^\circ$ ; by reduction, this yields *octadecylamidobenzene*, which melts at about  $61^\circ$ , and boils at  $274^\circ$  under 15 mm. pressure.

*Hexyldiphenylmethane*,  $C_6H_{13} \cdot CHPh_2$ , is formed when 0.2 part of aluminium chloride is slowly added to 1 part of *œnanthylidene chloride* dissolved in 4 parts of benzene; after standing for two days, the whole is heated at  $30^\circ$  for a short time. It melts at  $14^\circ$ , and boils at  $186^\circ$  under 10 mm., or  $193^\circ$  under 15 mm. pressure. By the action of nitric acid, *hexyldinitrodiphenylmethane*,  $C_6H_{13} \cdot CH(C_6H_4 \cdot NO_2)_2$ , is obtained, and this on reduction yields *hexyldiamidodiphenylmethane*. *Hexyltetramethyldiamidodiphenylmethane* can be prepared either from the latter, or by the condensation of *œnanthaldehyde* and dimethylaniline with zinc chloride. It melts at  $59.5^\circ$ , boils at  $272-278^\circ$ , and yields a *platinochloride*,  $C_{23}H_{31}N_2, H_2PtCl_6$ , sparingly soluble in water and ether-alcohol.

When a larger proportion of aluminium chloride is added to *œnanthylidene chloride* in benzene, *heptylbenzene*,  $C_7H_{15}Ph$ , is obtained. It boils at  $108-110^\circ$  under 10 mm. pressure. The corresponding *hexyl phenyl ketone*,  $C_6H_{13} \cdot COPh$ , is prepared by the action of 0.5 part of aluminium chloride on 1 part of *heptoic chloride* in 2-3 parts of benzene. It melts at  $17^\circ$ , boils at  $155^\circ$  under 15 mm. pressure, and yields an *acetoxime*, which melts at  $55^\circ$ , and crystallises from alcohol in stellate groups of needles. By the action of zinc chloride on *heptoic chloride* and dimethylaniline, a base, melting at  $72.5^\circ$  and boiling at  $278^\circ$  under 15 mm. pressure, is obtained together with *hexyl dimethamidophenyl ketone*,  $C_6H_{13} \cdot CO \cdot C_6H_4 \cdot NMe_2$ . The ketone melts at  $48.5^\circ$ , boils at  $190^\circ$  under 20 mm. pressure, and yields an *acetoxime*, which crystallises in silvery glistening scales.

**Paraxylyl Ethyl Ketone and its Oxidation to Orthometadimethylbenzoylacetic Acid.** By A. CLAUS and E. FICKERT (*Ber.*, 19, 3182-3184).—*Paraxylyl ethyl ketone*,  $C_6H_3Me_2 \cdot COEt$ , obtained from paraxylene and propionyl chloride, is a colourless, mobile, highly refractive liquid having an aromatic odour and strong bitter taste. It is lighter than water, and boils at  $237-238^\circ$  (uncorr.). When oxidised with dilute solution of potassium permanganate, it yields a mixture of xyllylcarboxylic acid and *paraxylyl-β-ketonic* (*orthometadimethylbenzoylacetic*) acid,  $C_6H_3Me_2 \cdot CO \cdot CH_2 \cdot COOH$ . The acids are best separated

by means of their barium salts, the ketonate being very sparingly soluble. The ketonic acid is sparingly soluble in water and light petroleum, easily in alcohol, ether, benzene, &c. It crystallises in needles melting at  $132^{\circ}$  (uncorr.). The *sodium* salt (with  $1\text{H}_2\text{O}$ ) is easily, the *calcium* ( $+ 2\frac{1}{2}\text{H}_2\text{O}$ ), *barium* ( $+ 4\text{H}_2\text{O}$ ), and *silver* salts very sparingly soluble.

Similar reactions have been obtained with aromatic ketones containing the ethyl and propyl, &c., groups, and are now being investigated.

**Nitrophenyl Benzoates and Nitrobenzoates and their Products of Decomposition.** By G. NEUMANN (*Ber.*, 19, 2979—2982).—Continuing his previous work (*Abstr.*, 1886, 350, 939), the author prepared *metanitrophenyl benzoate* by heating metanitrophenol with benzoic chloride. It is readily soluble in acetic acid, alcohol and hot light petroleum, and forms pale yellow crystals, which melt at  $95^{\circ}$ . When treated with nitric acid of sp. gr. 1.48, it yields *metanitrophenyl metanitrobenzoate*. This compound forms white crystals, melts at  $129^{\circ}$ , and is readily soluble in cold chloroform and hot alcohol, ether, and light petroleum.

*Metaparanitrophenyl metanitrobenzoate* is obtained by the action of nitric acid of sp. gr. 1.53 on metanitrophenyl benzoate. It crystallises in bright yellow needles, melts at  $149^{\circ}$ , and is sparingly soluble in most ordinary solvents, especially in ether and light petroleum. Metanitrophenyl benzoate, when dissolved in a mixture of equal parts of nitric acid of sp. gr. 1.51 and sulphuric acid of sp. gr. 1.82, yields trinitroresorcinol and metanitrobenzoic acid.

W. P. W.

**Method for the Introduction of Carboxyl into Aromatic Hydrocarbons.** By E. LELLMANN and O. BONHÖFFER (*Ber.*, 19, 3231).—Benzoic acid can readily be prepared by acting with diphenylcarbamide chloride on benzene in presence of aluminium chloride, and heating the benzoyldiphenylamine so obtained with hydrochloric acid. Paratoluic and xylic acids,  $[\text{COOH} : \text{Me}_2 = 1 : 2 : 4]$ , were obtained in a similar manner from toluene and metaxylene respectively. Paraxylene does not react with the chloride; hence it would seem that the group  $\text{CO}\cdot\text{NPh}_2$  can only take up the para-position with respect to methyl.

N. H. M.

**Phenylglycidic Acid.** By J. PLÜCHL (*Ber.*, 19, 3167—3172).—In answer to the communications of Lipp (this vol., p. 142) and E. Erlenmeyer, jun. (*ibid.*), the author upholds the correctness of his view (*Abstr.*, 1884, 604) that his acid  $\text{C}_9\text{H}_5\text{O}_3$  is the true phenylglycidic

acid,  $\text{CHPh}\cdot\text{CH}\cdot\text{COOH}$ , and that Glaser's acid is  $\beta$ -hydroxycinnamic acid.

The author finds that paranitrobenzaldehyde forms with hippuric acid a condensation-derivative corresponding with benzoylimidocinnamic anhydride. This substance when heated with fuming nitric acid first forms paranitrobenzoylimidocinnamic acid, but at  $120$ — $130^{\circ}$  it is

decomposed, yielding a brownish-red compound (a polymeric nitrophenylethylene oxide), whilst carbonic anhydride is at the same time evolved. Lipp's paranitrophenylglycidic acid gives the same decomposition-products. The author points out that in many other cases also the introduction of a nitro-group into the benzene nucleus causes a variation in the behaviour of the side-chain in reactions.

E. Erlenmeyer, jun., objects to the author's formula, because the latter's phenylglycidic acid yields a phenylhydrazine and a hydroxylamine compound and shows the thiophen reaction. The author states that with ammonia his acid gives a compound  $C_9H_7NO$ . He believes

this compound to have the constitution  $CHPh \begin{array}{c} \text{CH} \\ | \\ \text{N} \end{array} \text{CO}$ , and thinks

that Erlenmeyer's compounds have probably analogous structures.

As further strongly supporting the correctness of his formula, the author cites—(1) the gradual decomposition of the acid, when exposed to moist air, into benzaldehyde and a new acid; (2) the formation of a polymeric phenylethylene oxide (and not Erlenmeyer and Lipp's polymeric phenylethylaldehyde) by the action of hydrochloric acid; and (3) the easy convertibility of the acid into *phenylpyruvic acid*; the latter is easily soluble in boiling water, crystallises in tables, and melts at  $160-161^\circ$ . It is still under investigation.

**Benzoquinonecarboxylic Acids.** By J. U. NEF (*Annalen*, **237**, 1—39).—This paper contains a description of the derivatives of durene, durylic acid, and quinonetetracarboxylic acid, which has already been published by the author (*Abstr.*, 1886, 64, 241, 550). The following substances have not been previously mentioned:—The acetic derivative of diamidodurylic acid, prepared by the action of acetic anhydride on the amido-acid at  $140^\circ$ , crystallises in quadratic plates, and melts at  $275^\circ$ .

*Dihydroxydurylic acid*,  $C_6Me_3(OH)_2 \cdot COOH$  (*Abstr.*, 1886, 241), is soluble in alcohol, ether, and in hot water. The acid forms an amorphous lead salt, and reduces ammoniacal silver nitrate solution. The ethyl salt,  $C_6Me_3(OH)_2 \cdot COOEt$ , forms colourless needles. It melts at  $109^\circ$ , and is soluble in hot water, alcohol and the usual solvents, with the exception of light petroleum. The alcoholic solution is oxidised by ferric chloride, *ethyl duroquinonecarboxylate*,  $C_6 \cdot O_2Me \cdot COOEt$ , being formed. This substance is best prepared by the action of an ethereal solution of ethyl iodide on silver duroquinonecarboxylate. It crystallises in golden needles, melts at  $51^\circ$ , and sublimes easily. It is insoluble in cold water, but dissolves freely in alcohol, ether and in (warm) light petroleum. On reduction with sulphurous acid, it yields ethyl dihydroxydurylate. Duroquinonecarboxylic acid is completely converted into *nitropseudocumenequinone*,  $C_6O_2Me_3 \cdot NO_2$ , by the action of warm strong nitric acid. The nitroquinone crystallises in golden scales, soluble in ether, chloroform, benzene, light petroleum, alcohol, and nitric acid. It melts at  $113^\circ$ , and sublimes readily. The corresponding *quinol*,  $C_6Me_3(OH)_2 \cdot NO_2$ , is obtained by the action of sulphurous acid on the alcoholic solution of the nitroquinone at  $100^\circ$ .

|  | Properties.                                      | Solutions.                               | Colour with $\text{Fe}_2\text{Cl}_6$ . | NaOEt.                           | Zn + HCl in alcoholic solution.               | Oxidation with Br in $\text{CS}_2$ .                                |
|--|--|--|--|----------------------------------|---|---|
| Ethyl succinosuccinate .....                   | colourless needles, m. p. $126-127^\circ$        | pale blue fluorescence                   | cherry                                 | colourless, afterwards pale pink | —   | ethyl paradihydroxyterephthalate                                    |

| Ethyl quinoltetracarboxylate .....             | yellow needles, m. p. $126-129^\circ$            | strong blue fluorescence                 | blue-green                             | red                              | ethyl paradiketohexamethylenetetracarboxylate | ethyl quinonetetracarboxylate                                       |
| Paradihydroxyterephthalic acid ....            | yellow scales                                    | yellowish-green, with green fluorescence | intense blue                           | —                                | —   | $\text{CO}_2$ evolved: nitranilic acid                              |
| Quinoltetracarboxylic acid .....               | pale yellow, broad needles                       | yellow, with green fluorescence          | intense blue                           | —                                | —   | $\text{CO}_2$ evolved: total decomposition<br><br><i>no</i> quinone |
| Ethyl paradiamidoterephthalate....             | golden needles, m. p. $168^\circ$ , strong base  | brown, with golden yellow fluorescence   | —                                      | —                                | ethyl succinosuccinate                        |   |
| Ethyl diamidopyromellitate. ....               | red prisms, m. p. $134^\circ$ , feeble base      | red, yellowish-red fluorescence          | —                                      | —                                | ethyl paradiketohexamethylenetetracarboxylate | ethyl quinonepyromellitate  |

It crystallises in golden needles, melts at  $106^{\circ}$ , and is soluble in ether, alcohol, chloroform, acetic acid and in hot water.

The compound obtained by the reduction of ethyl dinitropyromellitate, and described by the author as ethyl azopyromellitate (Abstr., 1886, 64), is now found to be *ethyl diamidopyromellitate*,

By reducing the alcoholic solution with zinc-dust and sulphuric acid, ethyl paradiketo-hexamethylenetetracarboxylate is produced. Ethyl diamidopyromellitate yields a diacetic derivative,

which crystallises in colourless plates and melts at  $149^{\circ}$ . It is freely soluble in acetone, chloroform, acetic acid, and hot alcohol. It is not decomposed by boiling with alkalis or with hydrochloric acid.

*Ethyl quinoltetracarboxylate*,  $\text{C}_6(\text{OH})_2(\text{COOEt})_4$  (Abstr., 1886, 550), bears a striking resemblance in its properties to Herrmann's ethyl quinonedihydrodicarboxylate, which Baeyer has shown (Abstr., 1886, 445) to be ethyl paradihydroxyterephthalate. *Quinoltetracarboxylic acid* crystallises with  $1\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ , which it retains at  $100^{\circ}$ . It dissolves freely in hot water, forming a fluorescent solution, from which it is precipitated by mineral acids. Ferric chloride gives a blue coloration. The soluble salts of this acid form yellow solutions which exhibit a green fluorescence. Attempts to oxidise quinoltetracarboxylic acid to quinonetetracarboxylic acid were unsuccessful.

Ethyl quinoltetracarboxylate is converted into *ethyl paradiketo-hexamethylenetetracarboxylate* by shaking the alcoholic solution with zinc-dust and hydrochloric acid (Abstr., 1886, 551). This substance yields ethyl quinoltetracarboxylate on treatment with bromine and carbon bisulphide, and it readily enters into reaction with ammonium acetate and with phenylhydrazine.

The resemblance between the derivatives of ethyl diamidopyromellitate and ethyl succinosuccinate is shown in the table (p. 256).

W. C. W.

**Constitution of Azo-opianic Acid.** By C. LIEBERMANN (*Ber.*, 19, 2920—2922).—Although the so-called azo-opianic acid has been recognised as the anhydride of orthamido-hemipinic acid, yet hitherto it has not been found possible to convert the latter into the former by the abstraction of the elements of water. In this paper, however, it is shown that both orthamido-hemipinic and azo-opianic acids yield an identical acetylazo-opianic acid. The last acid, when warmed with alkali and subsequently acidified, yields acetylorthamido-hemipinic acid,  $\text{C}_6\text{H}(\text{OMe})_2(\text{COOH})_2\cdot\text{NHAc} + \text{H}_2\text{O}$ , which crystallises in colourless needles, melting at  $160$ — $170^{\circ}$  with complete decomposition. The acetyl-group is still retained when the acid is heated with concentrated sulphuric acid; a result to be explained by the former researches of the author and Kleemann, which have proved that the acetyl-group in acetylazo-opianic acid is attached to the nitrogen and not to the oxygen-atom.

V. H. V.

**An Isomeride of Hemipinimide.** By C. LIEBERMANN (*Ber.*, 19, 2923—2927).—The author has recently shown that hemipinimide is produced by boiling a mixture of opianic acid with hydroxylamine hydrochloride in equimolecular proportions. If, however, the change be effected at ordinary temperatures, a substance isomeric with hemipinimide is produced, which it is proposed to call *opianoximic anhydride*. It crystallises in long, colourless needles, melting at 114—115°; its alcoholic solution, unlike that of hemipinimide, is not fluorescent. When melted, the substance is converted with considerable development of heat into hemipinimide. This anhydride only displays feeble acidic properties, but on protracted heating with water it is converted into hemipinic acid.

Similarly when ethyl opianate and hydroxylamine hydrochloride are heated, the above anhydride is also formed; all attempts to prepare opianoximic acid have hitherto failed. V. H. V.

**Isomeric Aldehydophenoxyacetic Acids.** By T. ELKAN (*Ber.*, 19, 3041—3054).—*Paraldehydophenoxyacetic acid*,

is obtained by heating equivalent amounts of parahydroxybenzaldehyde and monochloroacetic acid in a silver dish on a water-bath, and adding sufficient caustic soda to give an alkaline reaction. When it begins to solidify, a slight excess of chloroacetic acid is added, the solution being always kept alkaline; it is then treated several times with water and evaporated to dryness. The product is dissolved in hot water, precipitated when cold with hydrochloric acid, and the yellowish acid so obtained purified by boiling with calcium carbonate. It crystallises from water in small plates, melting at 198°, is very sparingly soluble in cold water, more soluble in alcohol, ether, benzene, and chloroform, and shows aldehydic properties. It yields a sparingly soluble double compound with hydrogen sodium sulphite, and reduces ammoniacal silver solution, but not Fehling's solution. The *silver salt*,  $\text{C}_9\text{H}_7\text{O}_4\text{Ag}$ , crystallises in needles. Bromine-water acts on the acid with formation of a *bromine-derivative*,  $\text{C}_9\text{H}_7\text{O}_4\text{Br}$ ; this crystallises from hot water in slender branched needles, melting at 185°. *Ethyl paraldehydophenoxyacetate* is a crystalline substance which begins to decompose at 100°, and melts at 155°. The *hydroxylamine-derivative*,  $\text{C}_9\text{H}_9\text{O}_4\text{N}$ , forms large spear heads, melting at 145°.

*Metaldehydophenoxyacetic acid*,  $\text{C}_9\text{H}_8\text{O}_4$ , is prepared in a manner similar to the para-compound. It crystallises from warm water in slender needles, which melt at 148°, and shows the same aldehydic reaction as the isomeride; it is rather more soluble than the latter. The *silver* and *ethyl salts* were prepared. The *monobromo-derivative* forms lustrous plates, melting at 154°. The *hydroxylamine-compound* crystallises in slender needles, melting at 168°. When oxidised with potassium permanganate, both isomerides yield the corresponding dicarboxylic acids.

*Phenoxyacetic-paracarboxylic acid*,  $\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{OCH}_2 \cdot \text{COOH}$  [ $= 1 : 4$ ], crystallises in white needles, melting at 278°; it dissolves

readily in alcohol, ether and glacial acetic acid, less in benzene and chloroform, and only very sparingly in water. The *silver salt* was analysed. The *phenylhydrazine-derivative*,  $C_{15}H_{14}N_2O_3$ , forms slender, yellowish-white needles, which melt at  $159^\circ$ , and dissolve sparingly in water, readily in alcohol and ether.

*Phenoxyacetic-metacarboxylic acid* melts at  $206^\circ$ , and is analogous in its solubility, &c., to the para-acid. The *phenylhydrazine-compound* forms slender needles which melt at about  $140^\circ$ .

*Phenoxyacetic-paracrylic acid*,  $COOH:CH:CH \cdot C_6H_4 \cdot OCH_2 \cdot COOH$ , is prepared by gently boiling equal parts of paraldehydophenoxyacetic acid and dry sodium acetate with acetic anhydride (3 parts). It melts at  $225^\circ$ , dissolves readily in alcohol, ether, and glacial acetic acid; it is also soluble in benzene and light petroleum.

*Phenoxyacetic-metacrylic acid*,  $C_{11}H_{10}O_5$ , is obtained in like manner to the para-compound, and crystallises in needles melting at  $219^\circ$ .

*Orthacrylaldehydophenoxyacetic acid*,

is prepared by exactly neutralising a dilute solution of orthaldehydophenoxyacetic acid, heating it at  $50^\circ$  to  $60^\circ$ , and gradually adding simultaneously an aqueous solution of acetaldehyde, and 5 per cent. soda solution so as to keep the solution always slightly alkaline. It is then warmed on a water-bath, cooled down, and acidified with dilute sulphuric acid. The acid crystallises from hot water in transparent plates which melt at  $153^\circ$ .

The *meta-acid* crystallises (with 1 mol.  $H_2O$ ) in long, yellowish needles which melt at  $100^\circ$ .

The *para-acid* forms a crystalline, yellowish precipitate melting at  $182^\circ$ . All three isomerides show aldehydic properties; they combine with hydrogen sodium sulphite, reduce ammoniacal silver solutions, and condense with phenylhydrazine.

*Phenoxyacetic-orthacrylic acid methyl ketone*,

is obtained by adding pure acetone (from the hydrogen sodium sulphite compound) to the warm slightly alkaline solution of sodium orthaldehydophenoxyacetate. It melts at  $108^\circ$ . The *meta-compound*,  $C_{12}H_{12}O_4$ , crystallises in well-formed, anhydrous prisms which become opaque when kept. It melts at  $122^\circ$ . The *para-compound* melts at  $177-178^\circ$ .

The *hydroxylamine-derivative* of orthaldehydophenoxyacetic acid (Rüssing, Abstr., 1885, 388) crystallises in plates, very readily soluble in hot water, alcohol, and ether, more sparingly in benzene, chloroform, &c. It melts at  $138^\circ$ .

N. H. M.

**Vanillinoxyacetic Acid.** By T. ELKAN (*Ber.*, 19, 3054—3056). — *Vanillinoxyacetic acid*,  $CHO \cdot C_6H_3(OMe) \cdot O \cdot CH_2 \cdot COOH$  [ $= 4 : 2 : 1$ ], is prepared by fusing monochloroacetic acid with vanillin in a silver dish, and adding an excess of caustic potash until the solution is distinctly alkaline. After four hours (during which the water lost by

evaporation must be from time to time replaced) the reaction is completed. It crystallises from hot water in slender, yellowish-white needles, melts at  $188^{\circ}$ , and dissolves readily in ether, alcohol, chloroform, &c. It combines with phenylhydrazine and with hydrogen sodium sulphite, and reduces ammoniacal silver solution. The *copper* and *silver* salts were prepared.

*Vanillic-oxyacetic acid*,  $\text{COOH} \cdot \text{C}_6\text{H}_3(\text{OMe}) \cdot \text{O} \cdot \text{CH}_2 \cdot \text{COOH}$  [=4:2:1], is formed in the preparation of vanillinxyacetic acid, when the treatment with potash and chloracetic acid is too prolonged. It crystallises from water in slender, branched needles which melt at  $256^{\circ}$ ; it dissolves in ether, benzene, chloroform, &c. The *copper salt* has a fine green colour; it is insoluble.

N. H. M.

**Derivatives of Pyruvic Acid.** By G. GERSON (*Ber.*, 19, 2963—2969).—When ethyl  $\alpha$ -cyano- $\alpha$ -hydroxypropionate is treated with phenylhydrazine, a compound melting at  $116^{\circ}$  and identical with Fischer's ethyl phenylhydrazinepyruvate (*Abstr.*, 1884, 52) is obtained.

*Ethyl  $\alpha$ -anilido- $\alpha$ -cyanopropionate*,  $\text{NHPh} \cdot \text{CMe}(\text{CN}) \cdot \text{COOEt}$ , is prepared by treating ethyl  $\alpha$ -cyano- $\alpha$ -hydroxypropionate with aniline in alcoholic solution. It crystallises in large, transparent cubes belonging to the rhombic system, with the axial ratio  $a:b:c = 0.79023:1:1.56366$ ; the following faces were observed:  $\infty\text{P}$  predominating,  $\infty\bar{\text{P}}\infty$ ,  $\infty\bar{\text{P}}\infty$  narrow,  $\bar{\text{P}}\infty$  fairly large,  $\bar{\text{P}}\infty$  smaller than  $\bar{\text{P}}\infty$ . It melts at  $101.5^{\circ}$ , and is insoluble in water but readily soluble in alcohol and ether.

*Ethyl anilidoisosuccinamate*,  $\text{NHPh} \cdot \text{CMe}(\text{CONH}_2) \cdot \text{COOEt}$ , is formed when ethyl  $\alpha$ -anilido- $\alpha$ -cyanopropionate is dissolved in concentrated sulphuric acid, poured into water, and neutralised with ammonia. It crystallises from benzene in slender, white needles, melts at  $86^{\circ}$ , is sparingly soluble in cold water, readily soluble in hydrochloric acid, alcohol and benzene, but insoluble in light petroleum. The crystalline *hydrochloride* is very soluble in water. On boiling ethyl anilidoisosuccinamate with a solution of soda as long as ammonia is evolved, acidifying with acetic acid, converting into lead salt, and decomposing it with hydrogen sulphide,  *$\alpha$ -anilidopropionic acid*,  $\text{NHPh} \cdot \text{CMeH} \cdot \text{COOH}$  (Tiemann and Stephan, *Abstr.*, 1883, 199), is obtained in white crystals melting at  $160^{\circ}$ .

*Ethyl  $\alpha$ -orthotoluido- $\alpha$ -cyanopropionate*,  $\text{C}_7\text{H}_7 \cdot \text{NH} \cdot \text{CMe}(\text{CN}) \cdot \text{COOEt}$ , prepared in a similar manner to the anilido-compound, crystallises in rosettes of small, white needles, melts at  $93^{\circ}$ , and is insoluble in water, sparingly soluble in cold alcohol, readily soluble in hot alcohol and benzene. On treating it with concentrated sulphuric acid, and neutralising with ammonia, it yields *ethyl orthotoluidoisosuccinamate*,

which crystallises in long, transparent needles, and resembles the anilido-compound in all its properties. By boiling the isosuccinamate with potash solution, &c., *orthotoluidopropionic acid*,

is obtained in slender, white needles which melt at  $116^{\circ}$ , and dissolve readily in water, alcohol, and benzene.

*Ethyl  $\alpha$ -paratoluido- $\alpha$ -cyanopropionate* crystallises in light brown, glistening spangles, melts at  $80.5^{\circ}$ , and is insoluble in alcohol and benzene, sparingly soluble in water.

*Ethyl  $\alpha\alpha$ -naphthylamido- $\alpha$ -cyanopropionate* forms slender, white scales which melt at  $134^{\circ}$ , and are readily soluble in alcohol and benzene, sparingly soluble in cold water. By treatment with sulphuric acid, &c., *ethyl  $\alpha$ -naphthylamidoisossuccinamate* is obtained in long white needles melting at  $159^{\circ}$ . It dissolves readily in alcohol and benzene, sparingly in cold water.

*Ethyl  $\alpha\beta$ -naphthylamido- $\alpha$ -cyanopropionate* crystallises in small rosettes, is almost insoluble in water and cold alcohol, soluble in hot alcohol and benzene, and decomposes at  $200^{\circ}$  without melting.

W. P. W.

**Two New Diketonic Acids.** By W. KUES and C. PAAL (*Ber.*, 19, 3144—3148).—The authors have examined the insoluble crystalline substance obtained by them during the hydrolysis of ethyl benzoylisosuccinate (*Abstr.*, 1886, 354), and find it to be *ethyl diphenacylmalonate*,  $C(CH_2Bz)_2(COOEt)_2$ . Its formation must be due to the formation of some ethyl disodiummalonate and the action of the bromacetophenone thereon. This substance forms large, colourless prisms, melts at  $118$ — $119^{\circ}$ , and distils almost without decomposition. It is easily soluble in water, benzene, acetic acid, and carbon bisulphide, more sparingly in alcohol, and is insoluble in light petroleum. It reacts strongly with phenylhydrazine, but no homogeneous substance could be isolated from the product. Hydroxylamine is without action on it, as are also aqueous solutions of the alkalis. When digested with strong alcoholic potash, it is saponified, and yields *diphenacylmalonic acid*, crystallising in colourless prisms, melting with evolution of carbonic anhydride at  $134^{\circ}$ . It is sparingly soluble in water, easily so in ether, alcohol and acetic acid, insoluble in benzene. It forms a compound with phenylhydrazine. When carefully melted, carbonic anhydride is evolved and *diphenacylacetic acid*,  $CH(CH_2Bz)_2 \cdot COOH$ , is formed. This crystallises in silky needles, easily soluble in ether, alcohol, and benzene, and melts at  $132$ — $133^{\circ}$ . When heated with an acetic solution of phenylhydrazine, it yields a compound of the formula  $C_{30}H_{26}N_4O$ , crystallising in white needles which melt at  $164$ — $166^{\circ}$ , and are soluble in alcohol and acetic acid, insoluble in alkalis. The hydrazine-compound is not decomposed by dilute acids. Adopting the views of the composition of such compounds advocated by E. Fischer and W. Roser, the authors consider the following as the most probable formula for this substance:—

L. T. T.

**Action of Zinc Alkyl Compounds on Ethyl Malonate.** By E. LANG (*Ber.*, 19, 2937—2939).—Zinc methyl or zinc ethyl acts at ordinary temperatures on ethyl malonate with evolution of methane and ethane, and formation of a crystalline magma of ethyl phloro-

glucinoltricarboxylate,  $C_6(OH)_3(COOEt)_3$ . The reaction thus consists of the abstraction of the elements of alcohol and subsequent condensation.  
V. H. V.

**Furfurane-derivatives from Resorcinol.** By A. HANTZSCH (*Ber.*, 19, 2927—2934).—It has been shown that the sodium compounds of the monohydric phenols, when treated with ethyl chloracetate, yield at first ethyl phenoxyacetoacetate, and finally ethyl furfurocarboxylate. The dihydric phenols undergo a similar but more complicated reaction, according as the mono- or di-sodium compound reacts with one or two molecules of the ethereal salt. In the former case, hydroxycumarones are obtained, in the latter, benzodifurfuro-derivatives, the nature of the isomerism of which is dependent on the relative position of the carbon-atom to which the furfuryl-ring is attached. Thus in the case of resorcinol two such isomeric hydroxy- and difurfuro-derivatives are possible, precisely as two quinolines, the meta- and the ana-series, are synthetically formed from amines of the meta-series.

*Ethyl metahydroxycumarilate*,  $OH \cdot C_6OH_3 \cdot COOEt$  [ $OH : COOEt : Me = 2 : 2' : 3'$ ], formed from mono-sodium resorcinol and ethyl chloracetate, crystallises in white needles melting at  $178^\circ$ , readily soluble in ether. The corresponding acid crystallises with  $\frac{1}{2}$  mol.  $H_2O$  in needles which melt at  $226^\circ$ , with evolution of carbonic anhydride and formation of *hydroxymethylcumarone*,  $C_6OH_4Me \cdot OH$ . This compound crystallises in needles melting at  $96$ — $97^\circ$ , soluble in water, alcohol, and ether.

From disodium resorcinol and ethyl chloracetate, two isomeric ethyl benzodimethylfurfurodicarboxylates are formed, the nature of the isomerism of which is analogous to that of anthracene and phenanthrene. These are provisionally designated the  $\alpha$ - and  $\beta$ -series, as the experimental results are insufficient to fix the formula of each compound.

*Ethyl metabenzodimethyl- $\alpha$ -difurfurocarboxylate*,  $C_{10}O_2H_2Me_2(COOEt)_2$ , crystallises in needles melting at  $186^\circ$ , and its isomeride in more soluble aggregates, melting at  $140$ — $141^\circ$ . Both isomeric ethereal salts are readily saponified; the corresponding acids melt above  $310^\circ$  with decomposition, and are sparingly soluble in water, but more soluble in alcohol. Both the acids and their salts are difficult to distinguish one from the other. Only one of the isomeric difurfuranes,  $CH \begin{smallmatrix} CMe \\ \diagup \\ O \end{smallmatrix} - C_6H_2 - \begin{smallmatrix} CMe \\ \diagdown \\ O \end{smallmatrix} CH$ , is described, corresponding with the ethereal salt which melts at  $186^\circ$ ; it is a clear brown oil, boiling at  $270^\circ$ , solidifying in a freezing mixture, and melting at  $17^\circ$ ; with concentrated sulphuric acid, it gives a light blue coloration resembling that obtained with cœruglucnone.  
V. H. V.

**Furfurane-derivatives from Phloroglucinol.** By E. LANG (*Ber.*, 19, 2934—2937).—The reactions between the butyric alcohol, phloroglucinol, and ethyl chloracetate in presence of sodium ethylate, are analogous to those of resorcinol described in the preceding Abstract. The three series of compounds are formed in a similar way, yet the presence of alcohol is necessary for the production of

the dihydroxy-product, and its absence for that of the trifurfuraldehyde-derivatives.

*Ethyl meta- $\alpha$ -dihydroxymethylcumarilate*,  $C_8OH_2Me(OH)_2 \cdot COOEt$ , forms small white needles melting at  $242^\circ$ , readily saponified and converted into the corresponding acid, which crystallises with  $\frac{1}{2}$  mol.  $H_2O$ , and melts at  $281^\circ$  with evolution of carbonic anhydride.

*Ethyl benzotrimethyltrifurfurocarboxylate*,  $C_6(\langle \overset{CMe}{\underset{O}{\text{---}}} \rangle C \cdot COOEt)_3$ , obtained by treating trisodium phloroglucinol with 3 mols. of ethyl chloracetate, crystallises in satiny needles, melting at  $296-298^\circ$ , sparingly soluble in all menstrua. The corresponding acid separates with 1 mol.  $H_2O$  in a gelatinous form. On distillation with alkali, the benzotrimethyltrifurfurane,  $C_6(\langle \overset{CMe}{\underset{O}{\text{---}}} \rangle CH)_3$ , is obtained; it crystallises in needles melting at  $115-120^\circ$ , and is very soluble in most menstrua.

V. H. V.

**Sulphobenzidedisulphonic Acid.** By R. OTTO and A. RÖSSING (*Ber.*, 19, 3124—3129).—*Sulphobenzidedisulphonic acid*,

is prepared as already described (Abstr., 1879, 649), by the action of sulphuric hydroxychloride (2 mols.) on sulphobenzide. It is very probably the dimetasulphonic acid. It forms a yellowish, fibro-crystalline, deliquescent mass, readily soluble in alcohol and water, but insoluble in ether and benzene. It forms only normal salts. The potassium salt crystallises with 1 mol.  $H_2O$ ; the sodium with 3 mols.  $H_2O$ , calcium with  $6\frac{1}{2}$  mols.  $H_2O$ , barium 5 mols.  $H_2O$ , copper with  $3\frac{1}{2}$  mols.  $H_2O$ , and the lead salt with 3 mols.  $H_2O$ . The *chloride* crystallises in small, fatty plates, and melts at  $175-176^\circ$ . The *amide* forms white needles, melts at  $240^\circ$ , is nearly insoluble in ether and benzene, sparingly soluble in boiling water, more soluble in alcohol. The *anilide* forms lustrous, white plates, and melts at  $212^\circ$ . The *ethyl* salt melts at  $81-82^\circ$ . The *diphenylsulphone*,  $SO_2(C_6H_5 \cdot SO_2Ph)_2$ , is obtained in small quantity by heating the disulphonic acid with benzene and phosphoric anhydride; it melts at  $192-193^\circ$ .

Experiments to obtain a trisulphonic acid from sulphobenzide were unsuccessful.

A. J. G.

**Non-existence of Claesson's Phenylsulphineacetic Acid.** By R. OTTO and E. ENGELHARDT (*Ber.*, 19, 3138—3141).—Claesson states (this Journal, 1876, i, 567) that he obtained the above acid (aceto-phenylsulphinic acid),  $Ph \cdot SO \cdot CH_2 \cdot COOH$ , by the partial oxidation of phenylthioglycollic (phenylthiacetic) acid. The authors have carefully repeated these experiments, and find that the substance described by Claesson was not a homogeneous compound, but a mixture of phenylsulphonacetic acid,  $Ph \cdot SO_2 \cdot CH_2 \cdot COOH$ , with unoxidised phenylthioglycollic acid.

L. T. T.

**Metatoluenesulphonic Acid and its Salts.** By K. VALLIN (*Ber.*, 19, 2952—2953).—The metatoluenesulphonic acid employed in the previous research (Abstr., 1880, 256) contained para-acid as an

impurity; the author has, therefore, repeated the work with pure meta-acid obtained from toluidinesulphonic acid [ $\text{CH}_3 : \text{SO}_3\text{H} : \text{NH}_2 = 1 : 3 : 4$ ] by diazotising and boiling with alcohol. The acid crystallises in slender needles or thin scales. The potassium, sodium, silver, calcium, barium, lead, magnesium, zinc, cadmium, and copper salts are described. The *chloride*,  $\text{C}_7\text{H}_7\cdot\text{SO}_2\text{Cl}$ , has not been solidified; the *amide* crystallises from water in laminæ melting at  $107^\circ$ , from alcohol in monoclinic crystals melting at  $108^\circ$ . At  $14^\circ$ , 1 part of the amide dissolves in 376.7 parts of water and 5.74 parts of alcohol. The *hydrosulphide*,  $\text{C}_7\text{H}_7\cdot\text{SH}$ , boils at  $195\text{--}205^\circ$ , and does not solidify at  $-20^\circ$ .

*Sodium paratoluenesulphonate* does not crystallise with 3 mols. of  $\text{H}_2\text{O}$ , but either with 2 mols. in laminated masses, or at low temperatures in rectangular tables with probably 4 mols.  $\text{H}_2\text{O}$ . The hydrosulphide of the para-acid melts at  $43\text{--}44^\circ$  and boils at  $194^\circ$ , that of the ortho-acid melts at  $15^\circ$  and boils at  $193^\circ$ . W. P. W.

**Toluenedisulphonic Acids.** By P. KLASON (*Ber.* **19**, 2887—2890).—Toluenemetasulphonic acid is convertible into a mixture of two disulphonic acids, separable by the difference in solubility of their barium salts, the less soluble separating with 1 mol.  $\text{H}_2\text{O}$  as a crystalline powder. Its potassium salt crystallises with 1 mol.  $\text{H}_2\text{O}$  in pointed prisms, the acid chloride in rhombic tables melting at  $96^\circ$ , and the amide in minute prisms melting at  $224^\circ$ . This acid is identical with one obtained by Håkaussön from the mother-liquors of potassium  $\alpha$ -toluenedisulphonate. The more soluble barium salt crystallises in prisms containing  $3\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ , the chloride in truncated prisms melting at  $95^\circ$ ; the amide melts at  $214^\circ$ . This acid is identical with one obtained by Limpricht from toluidinedisulphonic acid. V. H. V.

**Cumene-orthosulphonic Acid and Orthocumic Acid.** By A. CLAUS and J. A. SCHULTE IM HOF (*Ber.*, **19**, 3012—3017).—When cumene- $\beta$ -sulphonic acid (*Abstr.*, 1885, 903) is oxidised with chromic mixture, it is destroyed without formation of intermediate products; it is therefore concluded that the acid has the constitution [ $\text{C}_9\text{H}_7 : \text{SO}_3\text{H} = 1 : 2$ ].

*Orthocumic acid*,  $\text{CHMe}_2\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ , is obtained by fusing the potassium or barium salt of the above sulphonic acid with sodium formate; it is insoluble in cold water, readily soluble in alcohol, ether, glacial acetic acid, &c. When heated at  $200^\circ$ , it becomes brown and partly sublimes and does not melt at  $300^\circ$ . It distils with steam. The *barium* and *calcium* salts (each with 2 mols.  $\text{H}_2\text{O}$ ) and the *magnesium* salt (with 6 mols.  $\text{H}_2\text{O}$ ) crystallise in needles readily soluble in water. The alkali salts are crystalline but very hygroscopic. The *chloride* forms a yellow oil readily soluble in ether, chloroform, &c.; when treated with dry ammonia, it is converted into the *amide*. The latter crystallises from alcohol in small needles melting at  $124^\circ$  (uncorr.).

Orthocumic acid is not acted on by chromic mixture of ordinary strength. When oxidised with potassium permanganate, it is con-

verted into phthalic acid; no hydroxycumic acid is formed. The reaction is of interest, as showing that the reaction by which isopropyl in paracumic acid is oxidised to hydroxyisopropyl does not hold good when the isopropyl-group is in the ortho-position to carboxyl (R. Meyer, *Abstr.*, 1878, 878). N. H. M.

**Action of Aldehydes, Anhydrides, and Diazo-compounds on the three Methylindoles.** By E. FISCHER (*Ber.*, 19, 2988—2991).—When benzaldehyde (1 part) is heated with methylketole (2 parts) at 100°, an almost quantitative yield of *benzylidenemethylketole*,  $\text{Ph}\cdot\text{CH} : (\text{C}_6\text{H}_5\text{N})_2$ , is obtained. This substance crystallises well from acetone, and most probably has the constitution

With paraldehyde and zinc chloride, methylketole yields a crystalline compound soluble in hot alcohol and in acetone. 1' Methylindole combines slowly with benzaldehyde at 100°, the reaction, however, is hastened by the addition of a small quantity of zinc chloride; the product crystallised from acetone melts at 197°, and is isomeric with that obtained from methylketole. Skatole and benzaldehyde on the contrary combine only slowly in the presence of zinc chloride at 100°, and the resulting compound, which forms colourless crystals, differs from the preceding derivatives in its much greater solubility and lower melting point.

Equal parts of phthalic anhydride and methylketole heated at 100° with zinc chloride yield a compound,  $\text{C}_9\text{H}_9\text{N}\cdot\text{C}_8\text{H}_4\text{O}_3$ , which when heated to about 200° is converted into an acid,  $\text{C}_9\text{H}_8\text{N}\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ , with loss of carbonic anhydride. From 1' methylindole at 100° a compound having different properties is obtained. The action of acetic anhydride on methylketole in the presence of sodium acetate has already been studied (*Abstr.*, 1881, 734); since, however, the acetyl derivative reacts with phenylhydrazine to form a compound,  $\text{C}_{17}\text{H}_{17}\text{N}_3$ , and is therefore a ketone, Jackson's formula,  $\text{C}_6\text{H}_4 < \begin{smallmatrix} \text{CH} \\ \text{NAc} \end{smallmatrix} > \text{CMe}$ ,

must be regarded as incorrect; the substitution of acetyl occurring probably in the position 3'. When 1' methylindole is heated at 100° with acetic anhydride and zinc chloride, a ketone is obtained which is probably identical with Baeyer's acetylindole (*Abstr.*, 1879, 938). Methylketole readily reacts with diazobenzene chloride in the presence of acetates dissolved in weak alcohol, and forms an azo-compound of the composition  $\text{C}_6\text{H}_5\text{N} : \text{N}\cdot\text{C}_9\text{H}_8\text{N}$ . It crystallises in yellow needles, melts at 115—116°, and by reduction with zinc and hydrochloric acid yields aniline and amidomethylketole. W. P. W.

**Hydrocarrotene and Carrotene.** By F. REINITZER (*Monatsh. Chem.*, 7, 597—608).—Two crystalline substances have been extracted from carrots, the one, colourless, hydrocarrotene, the other, dark red, carrotene; these have been more recently examined by Huseman and Arnaud, the latter of whom has found carrotene associated with chlorophyll in the leaves of various plants, and assigns to it the formula

of an unsaturated hydrocarbon,  $C_{26}H_{38}$ , whilst hydrocarrotene is considered to be allied to cholesterin.

The method used for the extraction of these substances is fully described, as also their separation from one another by frequent recrystallisation from boiling acetone and methyl alcohol. Hydrocarrotene is insoluble in water, sparingly soluble in cold, more readily in boiling alcohol, very soluble in acetone, from which it crystallises out in long needles, but from methyl alcohol in micaceous leaflets. It contains 5 per cent. of water, melts at  $137.4^\circ$ ;  $[\alpha]_D = -37.4^\circ$ ,  $t = 21^\circ$ ,  $C = 4.131$  in chloroform. In these physical properties, as also in various chemical reactions, it resembles cholesterin, a view further confirmed by the formation of its acetate and benzoate, the melting points and specific rotatory powers of which are compared with those of other cholesterins. Hydrocarrotene appears to be more nearly identical with phytosterin, although it is thought advisable for the present to retain its particular name. From cholesterin itself, hydrocarrotene differs in its behaviour with bromine, which is at first absorbed, and subsequently the change is accompanied with evolution of hydrobromic acid. The bromide formed crystallises in long, colourless, transparent needles, moderately soluble in alcohol, readily soluble in ether and carbon bisulphide. Husemann's observation that hydrocarrotene is converted into carotene by bromine is apparently erroneous. The improbability that carotene, a coloured substance, is a hydrocarbon, is pointed out, although no experiments are described, but allusion is made to the similarity of carotene to a colouring matter present in the paradise apple, *Lycopersicum esculentum*.

V. H. V.

**Diphenylmetaxylylmethane and Diphenylorthoxylylmethane.** By W. HEMILIAN (*Ber.*, 19, 3061—3075).—*Diphenylmetaxylylmethane*,  $CHPh_2 \cdot C_6H_3Me_2$  [Me : Me :  $CHPh_2 = 1 : 3 : 6$ ], is prepared in a manner similar to diphenylparaxylylmethane (Hemilian, *Abstr.*, 1884, 321) by heating benzhydrol, dissolved in pure metaxylene, with phosphoric anhydride for four hours at its boiling point. The product is treated with water and with aqueous soda, and the oil distilled. It solidifies when kept for a few days, and is purified by treating a warm, saturated solution in glacial acetic acid with twice the amount of ether, and allowing it to evaporate slowly. It forms large six-sided prisms which melt at  $61.5^\circ$  and distil above  $360^\circ$ . It dissolves readily in alcohol, ether, benzene, &c. When boiled for a long time with chromic mixture, and the product extracted with boiling soda solution, an insoluble residue is obtained, consisting of *diphenylmethylphthalide*,  $CPh_2 < \begin{smallmatrix} C_6H_3Me \\ O \cdot CO \end{smallmatrix} >$ ; this crystallises from alcohol in lustrous prisms, which melt at  $147^\circ$  and distil at above  $360^\circ$  without change; it is soluble in ether, benzene, &c., insoluble in aqueous alkalis.

*Methyltriphenylmethanecarboxylic acid*,  $CHPh_2 \cdot C_6H_3Me \cdot COOH$ , is obtained by boiling diphenylmethylphthalide with alcoholic soda solution, and reducing the sodium salt of the hydroxy-acid so formed by boiling with zinc in alkaline solution. It forms large, lustrous tabular crystals, which melt at  $203^\circ$  and distil without change. It is

rather readily soluble in hot alcohol, ether and acetic acid. The *barium salt* (with 3 mols.  $\text{H}_2\text{O}$ ) crystallises in slender needles, almost insoluble in water, rather readily soluble in boiling 70 per cent. alcohol. Other salts were prepared. When carefully oxidised, it is reconverted into diphenylmethylphthalide. When the solution of the acid in strong sulphuric acid is poured into water, a precipitate is obtained consisting of *methylphenylanthranol*,  $\text{C}_{21}\text{H}_{16}\text{O}$ . It crystallises from alcohol in small yellow plates which soften at  $150^\circ$  and melt at  $170^\circ$ ; when oxidised, it is converted into *methylphenylhydroxanthranol*,  $\text{C}_6\text{H}_3\text{Me} < \begin{smallmatrix} \text{CPh}(\text{OH}) \\ -\text{CO} \cdot \text{C}_6\text{H}_4- \end{smallmatrix} >$ . The latter forms large colourless prisms melting at  $213^\circ$ ; it is insoluble in aqueous alkali; the solution in sulphuric acid has an intense purple-red colour. When distilled with an excess of alkali, paramethyltriphenylmethane is obtained identical with that prepared by E. and O. Fischer from phenylparatolylcarbinol and benzene (Abstr., 1879, 384).

*Diphenylphthalidecarboxylic acid*,  $\text{O} < \begin{smallmatrix} \text{CPh}_2 \\ -\text{CO} \end{smallmatrix} > \text{C}_6\text{H}_3 \cdot \text{COOH}$ , is contained, as sodium salt, in the alkaline extract from the oxidation experiment with diphenylmetaxylylmethane. It crystallises from warm alcohol in large, tabular crystals (with 1 mol.  $\text{EtOH}$ ); it is insoluble in water, readily soluble in alcohol, ether, benzene, &c.; it melts at  $228^\circ$  and distils unchanged. The *calcium salt* (with 3 mols.  $\text{H}_2\text{O}$ ) crystallises from 70 per cent. alcohol in slender, lustrous needles; the *silver salt* crystallises from the same solvent in hair-like needles, insoluble in water. When the acid is distilled with excess of baryta, benzophenone and barium isophthalate are formed.

*Triphenylmethanedicarboxylic acid*,  $\text{CHPh}_2 \cdot \text{C}_6\text{H}_3(\text{COOH})_2 [=1:2:4]$  is prepared by the action of zinc-dust on the alcoholic solution of the anhydro-acid. It forms slender, lustrous needles, readily soluble in alcohol and acetic acid. It melts at  $278^\circ$ , and partly sublimes at a higher temperature. The *calcium salt* (with 2 mols.  $\text{H}_2\text{O}$ ) forms matted, microscopic needles; the *barium* and *silver salts* are also described. When distilled with excess of baryta, it is converted into triphenylmethane.

*Diphenylortho-xylylmethane*,  $\text{C}_6\text{H}_3\text{Me}_2 \cdot \text{CHPh}_2 [1:2:5]$ , was prepared from ortho-xylene (from orthobromotoluene). It crystallises in long, lustrous needles, melts at  $68.5^\circ$  and distils at above  $360^\circ$ . It is readily soluble in alcohol, ether, benzene, &c. When oxidised with chromic mixture, a mixture of acids is obtained, but no indifferent phthalide-derivative. When the mixed acids are treated with potassium permanganate, *triphenylcarbinol-dicarboxylic acid*,

is formed. The latter forms silky, matted, slender needles, very readily soluble in alcohol, ether, and glacial acetic acid, rather soluble in boiling water, and sparingly soluble in benzene. The *salts*, with the exception of the alkali salts, are very sparingly soluble. The acid melts at  $180^\circ$  with effervescence, and is converted into the *anhydride*,  $\text{C}_{21}\text{H}_{14}\text{O}_4$ . This is a transparent, amorphous substance, readily soluble in alcohol, ether, and benzene. Boiling water has no action on it. When the acid is distilled with an excess of baryta, it is converted into triphenylcarbinol.

N. H. M.

**Diamidostilbene and Diamidostilbenesulphonic Acid.** By F. BENDER and G. SCHULTZ (*Ber.*, 19, 3234—3239).—By reducing ortho-nitrotolueneparasulphonic acid, Neale obtained an azosulphonic acid, which, when treated with stannous chloride, yielded a compound which he described as hydrazotoluenesulphonic acid (*Abstr.*, 1880, 806). The authors show that this compound is toluidinedisulphonic acid, as it yields toluidine when distilled with lime.

*Diamidostilbenesulphonic acid,*

is obtained by dissolving 50 grams of sodium paranitrotolueneortho-sulphonate in boiling water, gradually adding 100 c.c. of 33 per cent. soda solution. The solution is diluted, 50 grams of zinc-dust are then gradually added, and the whole boiled until the colourless solution no longer becomes coloured on exposure to air. It is filtered, precipitated with hydrochloric acid, again filtered, and dried. It is almost insoluble in water. The salts are readily soluble. When distilled with soda-lime, it yields stilbene. The base obtained by Klinger by the action of zinc chloride on the condensation product from paranitrotoluene and sodium methoxide (*Ber.*, 16, 943), and described by him as diamidobenzyltoluene, is shown by the authors to be diparamidostilbene; the same base was also prepared by the reduction of dinitrostilbene from paranitrobenzyl chloride. The properties of the base are as described by Klinger (*loc. cit.*), except that the acetyl-derivative melts at 312° (not 212°).

By combining tetrazostilbene chloride with 2 mols. of  $\alpha$ -naphthol-sulphonic acid, a blue-violet dye is formed. With  $\beta$ -naphthol-disulphonic acid (R),  $\alpha$ -naphthylaminesulphonic acid and salicylic acid (each 2 mols.), blue, red, and yellow azo-dyes are formed respectively.

N. H. M.

**Brominated Derivatives of Diphenic Acid.** By A. CLAUS and M. ERLER (*Ber.*, 19, 3149—3156).—Bromine, even in the nascent state, acts exceedingly slowly at ordinary atmospheric temperature on diphenic acid, but at 60° and upwards reaction takes place readily. If less than 2 mols. of bromine are employed to 1 mol. acid, a part of the acid remains unacted on. At temperatures from 60—120°, the product consists of a mixture of bromodiphenic acid and bromodiphenic acid dibromide; at temperatures ranging from 120—200°, part of the latter derivative is converted into dibromodiphenic acid, and above 200° only mono- and di-bromodiphenic acids are found in the product of bromination.

*Bromodiphenic acid*,  $\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOH}$ , crystallises in acicular prisms melting at 235—236° (uncorr.). It is not volatile in steam, and sublimes only with considerable decomposition, the small sublimate (melting slightly lower than the acid) appearing to be the *anhydride*. The acid is very sparingly soluble in boiling water, easily in alcohol, ether, and benzene. The neutral and acid sodium salts are very soluble, the barium (with 3H<sub>2</sub>O), silver, and copper neutral salts are very sparingly soluble in water. The ethyl salt forms crystals melting at 65° (uncorr.). *Bromodiphenic acid dibromide* is

always formed (sometimes to the extent of 15 per cent.) in the bromination below  $200^{\circ}$  of diphenic acid, but its production from the bromo-acid already formed appears only to take place to a very slight extent. It is sparingly soluble in alcohol and cold chloroform, and crystallises in colourless glistening needles having a very bitter taste. It turns brown at  $200^{\circ}$ , and melts at about  $256^{\circ}$  (uncorr.) with decomposition. Heated in closed tubes at  $200^{\circ}$ , it undergoes decomposition, dibromodiphenic acid being formed. The dibromide is very sparingly soluble in the usual solvents, but dissolves readily in alkalis and alkaline carbonates, to form solutions of unstable salts, which, especially when warmed, rapidly decompose into salts of dibromodiphenic acid. It is soluble in concentrated sulphuric acid and in fuming nitric acid, and is reprecipitated unchanged on the addition of water. The neutral *sodium* salt forms glistening scales, but its solution is rapidly decomposed if boiled.

*Dibromodiphenic acid*,  $C_{12}H_6Br_2(COOH)_2$ , is easily soluble in alcohol, ether, and glacial acetic acid. It crystallises in needles, melts at  $245^{\circ}$  (uncorr.), and is not volatile in steam. It sublimes with difficulty, yielding the *anhydride*. Its *alkali* salts are easily soluble, the *calcium* (with  $3H_2O$ ), *silver*, and *lead* salts sparingly soluble. The *ethyl* salt is crystalline, and melts at  $105\text{--}106^{\circ}$ . This dibromodiphenic acid is evidently isomeric, but not identical, with that (melting at  $295^{\circ}$  obtained by Ostermayer, *Ber.*, 7, 1091) from dibromophen-anthraquinone.

When the bromo-acids are subjected to dry distillation with lime, brominated diphenylene ketones are formed. *Bromodiphenylene ketone*,  $C_{12}H_7Br:CO$ , forms yellow scales melting at  $122^{\circ}$  (uncorr.), and is easily soluble in alcohol, ether, benzene, &c., very sparingly in water. When heated with zinc-dust, it yields fluorene. No hydrogen sodium sulphite compound could be obtained. *Dibromodiphenylene ketone* forms yellow scales melting at  $133^{\circ}$  (uncorr.).

L. T. T.

**$\beta$ -Naphthol- $\beta$ -Disulphonic Acid.** By A. CLAUS and O. SCHMIDT (*Ber.*, 19, 3172—3179).—The authors have endeavoured to determine the constitution of this acid by the action of phosphoric chloride on it. The material used was the commercial sodium salt (the so-called G-salt). Reaction takes place readily, but if only the temperature of the water-bath is used,  *$\beta$ -naphtholdisulphonic chloride* is produced. This is a thick, reddish-brown liquid, and neither it nor the corresponding amide could be obtained in a crystalline form.

If the sodium salt is heated at  $100\text{--}200^{\circ}$  with more than two molecular proportions of the pentachloride, the principal products are ethereal phosphates corresponding with those obtained by Claus and Zimmermann from  *$\beta$ -naphtholsulphonic acid* (*Abstr.*, 1881, 914).

If the reaction is carried out above  $200^{\circ}$  (under pressure), and with a large excess (5 mols.) of the pentachloride, dichloronaphthol and trichloronaphthalene are formed. The yield is, however, small, 100 grams of salt only yielding about 6 to 8 grams of chloro-derivatives. Dichloronaphthalene (probably from impurity of monosulphonate in the salt) and tetrachloronaphthalene are also always present in small

quantity. The *dichloronaphthol* is easily isolated, as it alone of the products is soluble in alkalis. It crystallises in colourless needles, which melt at  $125^{\circ}$  (uncorr.), and sublime with partial decomposition. It is moderately soluble in boiling water, easily in alcohol, ether, &c. The *trichloronaphthalene* is readily soluble in ether, benzene, chloroform, glacial acetic acid and boiling alcohol. It crystallises in white needles, melts at  $90^{\circ}$  (uncorr.), and may be sublimed. It is not identical with the trichloronaphthalene of the same melting point obtained by Claus and Knyrim (Abstr., 1886, 156). When heated with dilute nitric acid at  $210^{\circ}$ , it yields a *dichlorophthalic acid*, a yellow syrup, which could not be obtained in a crystalline form. The *potassium*, *sodium*, and *barium* salts are easily soluble, the *silver* salt sparingly soluble, the *lead* salt insoluble. This acid is being further investigated. When heated with chromic acid in acetic solution, the trichloronaphthalene yields a *trichloronaphthaquinone*, which, however, is very readily further oxidised to a chlorinated phthalic acid. Attempts to separate the quinone from the unchanged trichloronaphthalene were unsuccessful, but alkalis removed it in form of a salt of a chlorinated hydroxyquinone. The best result was, however, obtained by treating the mixture with aniline, when *dichloronaphthaquinone anilide*,  $C_{10}H_5Cl_2O_2 \cdot NPh$ , was obtained. This is almost insoluble in water, sparingly soluble in ether. It crystallises in dark reddish-violet scales, melts at  $228^{\circ}$ , and may be sublimed. The formation of this anilide by the displacement of a chlorine-atom (the corresponding quantity of hydrochloric acid being formed) leaves no doubt that the original quinone is a trichlorinated compound. But as experience teaches that if in a chlorinated naphthalene a chlorine-atom is present in the  $\alpha$ -position, that chlorine-atom is expelled in the formation of an  $\alpha$ -naphthaquinone, the above trichloronaphthalene must have the constitution  $[Cl_3 = 2 : 3 : 2']$ . Which of the chlorine-atoms represents the hydroxyl, and which the sulphonic groups in the original acid cannot yet be decided.

L. T. T.

**Action of Aldehydes on Phenols.** By L. CLAISEN (*Ber.*, 19, 3316—3320).—When  $\alpha$ -naphthol is treated with benzaldehyde, a white pulverulent compound, *benzaldi- $\alpha$ -naphthol*,  $CHPh(C_{10}H_6 \cdot OH)_2$ , is obtained, which turns brown on exposure to the air and dissolves readily in alkalis, the alkaline solution assuming a dark reddish-violet but unstable colour when oxidised.

The reaction, however, proceeds differently when  $\beta$ -naphthol is treated with benzaldehyde. When an acetic acid solution of the two, to which a few drops of hydrochloric acid has been added, is maintained at a low temperature, *benzalglycoldinaphthylacetal*,

separates as a crystalline compound melting at  $203$ — $205^{\circ}$ , and sparingly soluble in ordinary solvents, almost insoluble in aqueous alkalis. Heated with acetic acid and a few drops of hydrochloric acid at  $100^{\circ}$ , it is converted into *benzaldi-naphthyl oxide*,

this melts at 189—190°, crystallises well, and is insoluble in alkalis. Benzal-di-naphthyl oxide is also obtained when the acetic acid solution of benzaldehyde and  $\beta$ -naphthol with a little hydrochloric acid or sulphuric acid, is heated at 100°, or in the absence of the acids at 200°.

The author has also obtained results which are not in complete accordance with those published by Claus and Trainer (this vol., p. 231), and points out that the ethylenediphenol described by them has already been prepared by Fabinyi (*Ber.*, **11**, 283). With acetaldehyde,  $\beta$ -naphthol yields compounds similar to those formed when it is treated with benzaldehyde; thus either *ethylenediphenylacetal*,  $C_2H_4(OC_{10}H_7)_2$ , melting at 200—201°, or *ethylene- $\beta$ -dinaphthyl oxide*,  $C_2H_4 : (C_{10}H_7)_2 : O$ , melting at 173°, is obtained; both crystallise well and are insoluble in alkalis. The compound described as dinaphthylacetal by Claus and Trainer, but melting at 162–163°, was not obtained in the author's experiments.

The remainder of the paper is devoted to a theoretical discussion, in which the author states his views as to the cause of the difference in behaviour of  $\alpha$ - and  $\beta$ -naphthol under these conditions, and arrives at conclusions at variance with those put forward by Claus and Trainer (*loc. cit.*).

W. P. W.

**$\alpha$ -Naphthyl Methyl Ketone.** By A. CLAUS and P. FEIST (*Ber.*, **19**, 3180—3182).—The authors have also independently obtained this ketone lately described by Pampel and Schmidt (this vol., p. 252), but some of their results differ from those of the latter authors. They find that the ketone solidifies if cooled below 0°, and the crystals then melt at 34°. They find the melting point of the acetoxime to be 145° (uncorr.), that of the hydrazine 173° (uncorr.).

When this ketone is treated in the cold with a dilute aqueous solution of the theoretical quantity of potassium permanganate,  *$\alpha$ -naphthylglyoxylic* ( *$\alpha$ -naphthoylformic*) acid,  $C_{10}H_7\alpha\text{-CO}\cdot\text{COOH}$ , is formed. This acid is a thick oil which only solidifies slowly and with difficulty. It is very unstable, and is easily oxidised by dilute nitric acid or warm permanganate to  $\alpha$ -naphthoic acid and carbonic anhydride. The *calcium* and *barium* salts (each with  $4\frac{1}{2}H_2O$ ) are easily, the *silver* salt very sparingly, soluble. The formation of  $\alpha$ -naphthoic acid proves this acid to be an  $\alpha$ -naphthyl-derivative. It is probably identical with Bössneck's acid melting at 113.5° (*Abstr.*, 1883, 808); the difficulty experienced in crystallising it being in all probability due to traces of oily impurity.

L. T. T.

**Pyrene.** By E. BAMBERGER and M. PHILIP (*Ber.*, **19**, 3036—3040).—*Naphthalenetetracarboxylic dianhydride*,  $C_{14}H_4O_6$ , is obtained by slowly heating naphthalenetetracarboxylic acid (*Abstr.*, 1886, 948) to 150—170°, or by recrystallising the acid from glacial acetic acid. It does not change when heated at 300°, at a higher temperature it sublimes in lustrous needles an inch long. When naphthalenetetracarboxylic acid is suddenly heated to 200—250°, it is converted partly into the anhydride and partly into naphthalenetetracarboxylic acid.

*Naphthalenetetracarboxylic diimide*,  $C_{14}H_6O_4N_2$ , is formed when the anhydride is treated with aqueous ammonia, and separates in groups of branched needles. It is very sparingly soluble, does not alter in appearance at  $270^\circ$ , and sublimes at a higher temperature in yellow, lustrous needles. The formation of the above dianhydride and diimide shows that the two pairs of carboxyl-groups in naphthalene-tetracarboxylic acid have the ortho-position.

Pyrene ketone,  $C_{13}H_8O$ , crystallises from alcohol in gold-coloured lustrous plates melting at  $142^\circ$ ; when oxidised with potassium permanganate, it is converted into Behr and Van Dorp's naphthalic acid (*Annalen*, **172**, 266).  
N. H. M.

**Terebenthene - derivatives.** By PESCI and BETTELLI (*Arch. Pharm.* [3], **24**, 1037).—The preparation of the hydrocarbon phellandrene, of nitrophellandrene, phellandrendiamine and amidophellandrene, from *Oleum phellandrii*, was recently described (Abstr., 1886, 1038). Subsequently by similar treatment with nitrous acid, lævorotatory terebenthene has yielded a dextrorotatory nitroterebenthene,  $C_{10}H_{15}\cdot NO_2$ , from which nascent hydrogen produces the primary base amidoterebenthene,  $C_{10}H_{15}\cdot NH_2$ , which again is lævorotatory.  
J. T.

**Formation of Euxanthic Acid from Euxanthone by the Animal Organism.** By S. v. KOSTANECKI (*Ber.*, **19**, 2918—2920).—Spiegel has proved that euxanthic acid is decomposed by concentrated sulphuric acid into euxanthone and glycuronic acid. From the phenolic character of euxanthone, and the fact that the magnesium salt of euxanthic acid, known as Indian-yellow, is prepared from urine, the author has endeavoured with success to form euxanthic acid from euxanthone, the glycuronic acid being supplied by the animal system. If euxanthone be administered to a dog, the presence of euxanthic acid can be detected in the urine by means of its magnesium salt. This result is analogous to the conversion of phenol or naphthol into their corresponding glycuronic acids by the animal organism.  
V. H. V.

**Kamala.** By A. G. PERKIN and W. H. PERKIN, jun. (*Ber.*, **19**, 3109—3110).—Kamala, a yellow dyestuff, is used in considerable quantity by the natives of India. It is contained in the seed capsules of *Mallotus philippensis*, and occurs in commerce as a yellowish-brown powder, which, under the microscope, is seen to consist of transparent brown, resinous globules mixed with woody fibres and seeds; no crystals were observed.

*Mallotoxin*,  $C_{11}H_{10}O_3$  or  $C_{18}H_{16}O_5$ , was obtained by shaking finely-divided kamala with carbon bisulphide, concentrating the yellowish solution on the water-bath, treating the yellowish-brown precipitate obtained with small quantities of carbon bisulphide to remove resinous impurities, and finally crystallising from benzene or toluene. It forms small, flesh-coloured needles, soluble in alkalis to a yellowish-red solution, from which acids reprecipitate the original substance; it is nearly insoluble in water, readily soluble in alcohol and acetic acid. A yellow

acetyl-derivative,  $C_{11}H_8O_3Ac_2$  or  $C_{18}H_{13}O_5Ac_3$ , was obtained. Further experiments are in progress to determine the correct formula.

A. J. G.

**Synthesis of Pyrroline.** By G. CIAMICIAN and P. SILBER (*Ber.*, 19, 3027).—The authors showed previously (Abstr., 1884, 1115) that succinimide may be readily converted into tetrachloropyrroline, but were unable to completely reduce the latter to pyrroline. This can be readily effected by Hepp's method, which consists in boiling the chloride with the corresponding amount of potassium iodide in a reflux apparatus. The iodide so obtained is very readily reduced to pyrroline by warming with potash solution in presence of zinc-dust.

N. H. M.

**Behaviour of Methylketole: Constitution of Pyrroline.** By G. CIAMICIAN (*Ber.*, 19, 3028—3029).—Ciamician and Dennstedt obtained (Abstr., 1882, 1214) pyridine-derivatives by the action of chloroform or bromoform on the potassium compound of pyrroline, and suggested that quinoline-derivatives could probably be obtained in a similar manner from indole. Experiments made by the author show that quinoline-derivatives can be obtained from methylketole by means of the chloroform reaction, and also by heating with hydrochloric acid at  $200^\circ$  (compare *Ber.*, 14, 1341).

Both methylketole, and in a less degree indole, show all the colour reactions of pyrroline. The author considers the relation between indole and pyrroline to be established by these results. N. H. M.

**Synthesis of Pyrroline-derivatives.** By C. PAAL and C. W. T. SCHNEIDER (*Ber.*, 19, 3156—3163).—This is a continuation of the author's previous work (Abstr., 1886, 559).

*Ethylene- $\alpha$ -tetramethyldipyrroline*,  $C_2H_4(C_4NH_2Me_2)_2$  [ $C_2H_4 : Me_2 = 1 : 2 : 5$ ], was obtained by the action of acetylacetone on ethylenediamine. It crystallises with 4 mols.  $H_2O$  in glistening, white scales, melts at  $125$ — $126^\circ$ , sublimes unchanged, and is volatile in steam. It is insoluble in water, soluble in alcohol, ether, &c. It is soluble in mineral acids with red coloration, colours pine shavings carmine, and gives a purple-red with Laubenheimer's reagent. It forms a yellow *platinochloride*.

*Trimethylene- $\alpha$ -tetramethyldipyrroline*,  $C_3H_6(C_4NH_2Me_2)_2$ , is formed when trimethylenediamine is substituted for ethylenediamine in the above reaction. It forms a pale yellow, crystalline substance melting at  $76$ — $77^\circ$ , insoluble in water, soluble in alcohol and ether. It resembles the ethylene compound in properties.

*Paradiphenylene- $\alpha$ -tetramethyldipyrroline*,  $C_{12}H_8(C_4NH_2Me_2)_2$ , from benzidine and acetylacetone, crystallises in colourless tables soluble in alcohol, ether, &c. It is very unstable, especially when in solution. It melts at  $130^\circ$ , and is decomposed at a slightly higher temperature.

When ethyl acetophenoneacetate is used in place of acetylacetone, the ethers of a series of dipyrrolinedicarboxylic acids are obtained.

*Ethyl ethylene- $\alpha$ -dimethyldiphenyldipyrroline- $\beta$ -dicarboxylate*,

crystallises with  $4\text{H}_2\text{O}$  in glistening scales melting at  $197^\circ$ . It distils unchanged, but is sensitive to light. It is insoluble in water and light petroleum, soluble in alcohol, benzene, chloroform and glacial acetic acid. It is insoluble in hydrochloric acid, but dissolves in concentrated nitric or sulphuric acid, and is reprecipitated unchanged on the addition of water. It shows Laubenheimer's reaction. On hydrolysis, it yields the free crystalline *acid*, which melts at  $181^\circ$ , and at a slightly higher temperature evolves carbonic anhydride, forming the pyrroline-derivative  $\text{C}_2\text{H}_4(\text{C}_4\text{NH}_2\text{MePh})_2$ . The acid is insoluble in most solvents, very sparingly soluble in alcohol and in glacial acetic and concentrated hydrochloric acids.

*$\beta$ -Ethocarboxyl- $\alpha$ -methylphenylpyrroline-acetic acid,*

formed on substituting amido-acetic acid for the diamine in the last reaction, crystallises in needles melting at  $131^\circ$ . It is almost insoluble in water, soluble in alcohol, ether, and benzene. It dissolves in alkalis and alkaline carbonates, and forms well-characterised salts. When heated with alcoholic potash, it yields the free bibasic *acid*,

This forms small white needles which melt at  $152^\circ$  with evolution of carbonic anhydride.

*Ethyl metaphenylene- $\alpha$ -dimethyldiphenyldipyrroline- $\beta$ -dicarboxylate,*

crystallises in white needles which melt at  $185^\circ$ . It is insoluble in water, soluble in most other solvents, and in concentrated sulphuric acid.

*Ethyl paradiphenylene- $\alpha$ -dimethyldiphenyldipyrroline- $\beta$ -dicarboxylate,*  $\text{C}_{12}\text{H}_8(\text{NC}_4\text{HMePh}\cdot\text{COOEt})_2$ , from benzidine and ethyl acetophenone-acetoacetate, crystallises in thin needles melting at  $178$ – $179^\circ$ . When saponified, it yields the corresponding potassium salt, which, however, resinifies easily. The free acid could not be obtained.

*$\beta$ -Ethocarboxyl- $\alpha$ -methylphenylpyrrolinemetabenzic acid,*

crystallises in small, yellow needles melting at  $160^\circ$ , and soluble in alcohol, ether, &c. It forms characteristic salts. When heated with alcoholic potash, it yields the corresponding bibasic *acid*, which forms colourless, hairy needles melting at  $210^\circ$ . When strongly heated, carbonic anhydride is evolved.

*Ethyl azobenzene- $\alpha$ -methylphenylpyrroline- $\beta$ -carboxylate,*

from amido-azobenzene, forms deep red crystals melting at  $123^\circ$ . It is easily soluble in alcohol, ether, &c. When saponified, it yields the corresponding *acid*, which forms large, red crystals soluble in ether, alcohol, &c. It melts at  $195^\circ$ , and evolves carbonic anhydride at a slightly higher temperature.

All these substances show Laubenheimer's reaction. L. T. T.

**Synthesis by Means of Ethyl Acetoacetate.** By L. KNORR (*Annalen*, 236, 290—332).—The author has already shown (Abstr., 1885, 554) that ethylic diacetosuccinate reacts with ammonia and with primary amines, yielding substituted pyrroline-derivatives. A similar action takes place with hydroxylamine. By heating an aqueous solution of hydroxylamine hydrochloride (12 parts) and sodium acetate (24 parts) with ethyl diacetosuccinate (30 parts), dissolved in glacial acetic acid, the *ethyl hydroxydimethylpyrroline-dicarboxylate*,  $\text{OH}\cdot\text{C}_4\text{H}_7\text{NMe}_2(\text{COOEt})_2$ , is obtained as a crystalline compound, soluble in alcohol and ether, and in dilute alkalis, but insoluble in acids. This substance melts between  $98^\circ$  and  $100^\circ$ . A precipitate of the composition  $\text{C}_{12}\text{H}_{16}\text{KNO}_5$  is obtained on adding ether to an alcoholic solution of the ethyl salt and potassium ethoxide.

A mixture of hydroxydimethylpyrrolinecarboxylic acid and *monethyl hydroxydimethylpyrrolinedicarboxylate* is formed when the ethylic salt is saponified by alcoholic potash. The latter compound,  $\text{C}_{10}\text{H}_{13}\text{NO}_5$ , crystallises in needles, soluble in alcohol. It melts at  $185^\circ$ , with decomposition, yielding ethylic hydroxydimethylpyrrolinecarboxylate.

*Hydroxydimethylpyrrolinecarboxylic acid*,

decomposes at  $138^\circ$ , yielding hydroxydimethylpyrroline,  $[\text{OH} : \text{Me}_2 = 1 : 2 : 5]$ . The acid crystallises in needles, and dissolves freely in alcohol. It is decomposed by prolonged boiling with water. The metallic salts are not characteristic. The formation of the ethyl salt has just been mentioned. Hydroxydimethylpyrroline exhibits the pinewood reaction. It is soluble in alcohol, ether, chloroform, benzene and alkalis. It reduces ammoniacal silver solutions at the ordinary temperature, and Fehling's solution on boiling.

The derivatives of trimethylpyrrolinedicarboxylic acid,

phenyldimethylpyrrolinedicarboxylic, and  $\beta$ -naphthyldicarboxylic acid have been previously described by the author (Abstr., 1885, 555). These acids are decomposed when heated, yielding pyrrolines. *Trimethylpyrroline*  $[1 : 2 : 5]$  boils at  $173^\circ$  (corr.); *phenyldimethylpyrroline*  $[\text{Ph} : \text{Me}_2 = 1 : 2 : 5]$ , melts at  $51^\circ$ , and boils at  $252^\circ$  (corr.), and  $\beta$ -*naphthyldimethylpyrroline*,  $[\text{C}_{10}\text{H}_7 : \text{Me}_2 = 1 : 2 : 5]$ , melts at  $71^\circ$ , and boils at  $341^\circ$  (corr.). These compounds are freely soluble in alcohol, ether, chloroform, and benzene.

$\alpha$ -*Naphthyldimethylpyrrolinedicarboxylic acid*,  $[\text{C}_{10}\text{H}_7 : \text{Me}_2 : (\text{COOH})_2 = 1 : 2 : 5 : 3 : 4]$ , crystallises in needles, and decomposes at  $244^\circ$ , yielding  $\alpha$ -*naphthyldimethylpyrroline*. This substance melts at  $123^\circ$ , boils at  $310$ — $315^\circ$  (corr.), and dissolves freely in ether, alcohol, and chloroform.

*Ethyl  $\alpha$ -naphthyldimethylpyrrolinedicarboxylate* melts at  $91$ — $92^\circ$ . The potassium salt,  $\text{C}_{18}\text{H}_{13}\text{K}_2\text{NO}_4$ , is insoluble in alcohol. The barium,  $\text{C}_{18}\text{H}_{13}\text{BaNO}_4$ , and silver,  $\text{C}_{18}\text{H}_{13}\text{AgNO}_4$ , salts, are crystalline.

*Ethyl methylphenylamidodimethylpyrrolinedicarboxylate* is obtained

as an uncrystallisable oil by the action of ethyl diacetosuccinate on methylphenylhydrazine. The free acid,  $C_{15}H_{16}N_2O_4$ , crystallises in prisms, and decomposes at  $231^\circ$  into carbonic anhydride and *methylphenylamidodimethylpyrroline*,  $C_{13}H_{16}N_2$ , a crystalline substance, which melts at  $41^\circ$  and boils at  $310^\circ$  (corr.).

*Ethyl metamidotolyldimethylpyrrolinedicarboxylate*, is formed by boiling equivalent quantities of metatoluylenediamine and ethyl diacetosuccinate in acetic acid solution. The ethyl salt crystallises in prisms and melts at  $134^\circ$ . The free acid,  $C_{15}H_{16}N_2O_4 + 2H_2O$ , crystallises in plates of a yellow colour. It is soluble in alcohol, ether, acids, and alkalis. It decomposes at  $203^\circ$ , yielding *metamidotolyldimethylpyrroline*. This compound melts at  $73^\circ$ , and boils at  $322^\circ$  (corr.) It is soluble in alcohol, ether, and acids, and volatilises in a current of steam.

*Ethyl toluylenedidimethylpyrrolinedicarboxylate*,

is obtained as a heavy oil by the action of metatoluylenediamine (m. p.  $99^\circ$ ) on excess of an acetic acid solution of ethyl diacetosuccinate. The free acid,  $C_{23}H_{22}N_2O_8$ , is sparingly soluble in alcohol and ether, and insoluble in water and dilute acids. It melts at  $248^\circ$  with decomposition.

*Dimethylpyrrolinedicarboxylacetic acid*,

splits up at  $214^\circ$ , yielding carbonic anhydride and an oily liquid, probably *dimethylpyrroline-acetic acid*,  $C_4NH_2Me_2 \cdot CH_2 \cdot COOH$ . The acid forms crystalline potassium and silver salts,  $C_{10}H_8K_3NO_6$  and  $C_{10}H_8Ag_2O_6$ . The ethyl salt is prepared by boiling an acetic acid solution containing equivalent quantities of glycocine and ethyl diacetosuccinate.

*Ethyl dimethylpyrrolinedicarboxylate*,  $C_4NHMe_2(COOEt)_2 [2 : 4 : 3 : 5]$ , is most conveniently prepared by adding a strong solution of sodium nitrite (2 parts) to 7 parts by weight of ethyl acetoacetate, dissolved in strong acetic acid. 25 parts of zinc-dust is added to the well-cooled product. On adding water to the mixture, the ethyl salt is deposited in needle-shaped crystals. This substance melts at  $134-135^\circ$ , and is distinguished from its symmetrical isomeride by the absence of basic properties. Many of the properties of this compound and of its derivatives have been already described by the author (Abstr., 1884, 1368). Monethyldimethylpyrrolinedicarboxylate melts with decomposition at  $202^\circ$  (not  $200^\circ$  as previously stated), forming ethyl dimethylpyrrolinecarboxylate.

Dimethylpyrrolinedicarboxylic acid decomposes at  $260^\circ$  into carbonic anhydride and dimethylpyrroline [Me : Me = 2 : 4] (*loc. cit.*).

*Ethyl dimethylpyrrolineamylidocarboxylate*,

is formed by the action of zinc-dust on equivalent quantities of acetoacetic anilide and ethylic nitrosoacetoacetate dissolved in acetic acid. It melts at  $216^{\circ}$ , and dissolves in hot alcohol and acetic acid. On treatment with strong sulphuric acid, it yields 2 : 4 dimethylpyrroline, and on boiling with alcoholic potash it is converted into the *monanilide* of *dimethylpyrrolinedicarboxylic acid*,  $\text{COOH}\cdot\text{C}_4\text{NH}\cdot\text{Me}_2\cdot\text{CONHPh}$ . This substance softens at  $180^{\circ}$ , and decomposes at  $198^{\circ}$ . It also splits up when boiled with dilute sulphuric acid, yielding carbonic anhydride and *dimethylpyrrolinecarboxylanilide*,  $\text{C}_4\text{NH}_2\cdot\text{Me}_2\cdot\text{CONHPh}$ .

*Ethyl dimethylpyrrolineanilidocarboxylate* [ $\text{Me}_2 : \text{COOEt} : \text{CONHPh} = 2 : 4 : 3 : 5$ ], is prepared by reducing with zinc-dust an acetic acid solution of ethylic acetoacetate and nitrosoacetoacetic anilide. It crystallises in needles, melts at  $180^{\circ}$ , and yields 2 : 4 dimethylpyrroline on treatment with sulphuric acid.

*Dimethylpyrrolinedicarboxylanilide*,

is formed by reducing a mixture of the anilides of acetoacetic and nitrosoacetic acids. It melts about  $255^{\circ}$ , and crystallises in needles. It also yields 2 : 4 dimethyl pyrroline when warmed with sulphuric acid.

W. C. W.

**Action of Chlorine on Pyridine.** By E. H. KEISER (*Amer. Chem. J.*, 8, 308—315).—Anderson has worked on this subject (*Annalen*, 105, 340). When anhydrous pyridine is treated with dry chlorine, it finally solidifies, and by distillation a white crystalline solid boiling at  $130^{\circ}$ , and a yellow solid boiling at  $218^{\circ}$ , are obtained. The first is purified by crystallisation from alcohol; it melts at  $72^{\circ}$ , is very stable, and with platinum chloride gives a precipitate having the composition  $(\text{C}_5\text{H}_3\text{Cl}_2\text{N})_2\cdot\text{H}_2\text{PtCl}_6$ . The second substance cannot be distilled without partial decomposition; it is very deliquescent, and is soluble in water; with platinum chloride, the solution gives a precipitate of pyridine platinochloride; the yellow compound itself has the composition  $\text{C}_5\text{H}_5\text{NCl}$ , and is evidently an unstable additive product.

When chlorine is passed into pyridine diluted with its own bulk of water, nitrogen and carbonic anhydride are evolved, and on further dilution a white precipitate is thrown down, which when dry smells like bleaching powder, and with platinum chloride gives a precipitate of pyridine platinochloride; it is therefore an additive product of pyridine, probably the hypochlorite, and the carbonic anhydride and nitrogen are derived from the decomposition of this substance. When chlorine is passed into a pyridine solution containing free alkali, nitrogen is evolved with explosive violence, but if the contents of the flask be kept cool the action is more gentle, and chloroform and dichloroacetic acid are to be found in the distillate. This decomposition of pyridine by chlorine is far more readily explained by Riedel's formula (Abstr., 1883, 1152) than by Körner's.

H. B.

**Tetrahydropicoline.** By A. LIPP (*Ber.*, 19, 2843—2844).—The base obtained by the action of alcoholic ammonia on *ω*-bromobutyl methyl ketone (Abstr., 1886, 219) proves to be a *tetrahydropicoline*,

probably,  $\text{CH}_2 < \begin{smallmatrix} \text{CH}_2 - \text{CH}_2 \\ \text{NH} - \text{CMe} \end{smallmatrix} > \text{CH}$ . Under similar conditions, a pyrroline-derivative is obtained from *o*-bromopropyl methyl ketone.

W. P. W.

**Quinolinesulphonic Acids.** By A. CLAUS and P. KÜTTNER (*Ber.*, 19, 2882—2886).—Quinolineorthosulphonic acid in cooled aqueous solution forms a yellow, crystalline precipitate with bromine, an unstable, probably additive, compound; at the temperature of the water-bath, the acid is decomposed with formation of tribromoquinoline, which separates in glistening, silky needles melting at 198°, soluble in ether and alcohol, insoluble in water.

Quinolineparasulphonic acid, under similar conditions, yields a dibromoquinoline, crystallising in long needles, melting at 124—126°, and yielding, on oxidation with potassium permanganate, a bromopyridine-dicarboxylic acid identical with that described by Claus and Collischon. On adding more than two molecular proportions of bromine, a tribromoquinoline is slowly produced, isomeric with the compound described above. It crystallises in long, silky needles, melting at 170°, and is sparingly soluble in cold ether, soluble in alcohol. As regards the displacement of the sulphonic group, concentrated nitric acid resembles bromine in its action, a mononitroquinoline being produced.

V. H. V.

**Reduction of Hydroxylepidine and Methylepidone.** By L. KNORR and C. KLOTZ (*Ber.*, 19, 3299—3303).—Hydroxylepidine and methylepidone resist the action of acid reducing agents, but are readily attacked and reduced by sodium amalgam and alcohol, or by sodium and alcohol.

*Reduction of Hydroxylepidine.*—When hydroxylepidine in alcoholic solution is shaken with an excess of sodium amalgam, a compound,  $(\text{C}_{10}\text{H}_{10}\text{NO})_2$ , is obtained, insoluble in water, alkalis, and alcohol, but crystallising from acetic acid in slender needles melting at 280°. It shows feebly basic properties, and is most probably a diquinolyl-derivative.

The reduction proceeds further when metallic sodium is employed, and from the product, after removal of the alcohol, two compounds are obtained, one of which, *tetrahydrolepidine*,  $\text{C}_{11}\text{H}_{13}\text{N}$ , is separated by distillation with steam. It is a colourless, strongly refractive oil, has a pungent odour and boils at 250—253° (thermometer immersed in the vapour) at 740 mm. pressure. *Dihydrohydroxylepidine*,  $\text{C}_{10}\text{H}_{11}\text{NO}$ , separates in needles from the residual liquor left after steam distillation, melts at 101°, and is insoluble in alkali, sparingly soluble in water, readily soluble in alcohol, ether and chloroform. It shows feebly basic properties, and its salts are decomposed by water. Nitrous acid is without action in the cold, but on warming acts on it and forms an acid compound.

*Reduction of Methylepidone.*—Sodium amalgam reduces methylepidone, in cold alcoholic solution to the diquinolyl-derivative  $(\text{C}_{11}\text{H}_{12}\text{NO})_2$  (this vol., p. 159). It is insoluble in water, alkalis, and alcohol, soluble in acetic and hydrochloric acids, and melts at 268°. When metallic sodium is employed as the reducing agent,

*dimethyltetrahydroquinoline*,  $C_{11}H_{15}N$ , is obtained. It is a colourless oil speedily turning brown when exposed to air, boils at  $255^{\circ}$  (thermometer immersed in vapour) at 757 mm. pressure, and is identical with the base obtained by the reduction of lepidine methiodide with tin and hydrochloric acid. It yields a yellow platinumchloride, and an oily, orange-red nitroso-compound.

*Reduction of Carbostyryl*.—Tetrahydroquinoline is obtained when carbostyryl in alcoholic solution is reduced with metallic sodium.

W. P. W.

**$\alpha$ - and  $\gamma$ -Ethylquinoline.** By L. REHER (*Ber.*, **19**, 2995—3002).—When quinoline ethiodide is heated at  $280$ — $290^{\circ}$  for two hours, a somewhat complicated reaction takes place resulting in the formation of hydrocarbons in addition to basic products. After acidifying, the product is distilled with steam to remove the hydrocarbons, then rendered alkaline, and again steam-distilled. The mixture of bases so obtained is fractionated, and the portion boiling between  $240$  and  $280^{\circ}$ , after removing the unaltered quinoline, is repeatedly fractionated; in this way, fractions boiling at  $255$ — $260^{\circ}$  and  $270$ — $275^{\circ}$  are obtained, which consist of  $\alpha$ - and  $\gamma$ -ethylquinoline respectively, but by this method, the only feasible one, a complete separation cannot be effected.

$\alpha$ -Ethylquinoline is a very hygroscopic, colourless liquid with a quinoline-like odour, does not solidify at low temperatures, and is slightly soluble in water, readily soluble in ether, alcohol, chloroform, and carbon bisulphide, and quickly becomes coloured red on exposure to light. The *hydrochloride* and *nitrate* are readily soluble in water, and effloresce in air. The *mercuriochloride*,  $C_{11}H_{11}N, HHgCl_3$ , melts at  $118^{\circ}$ , and forms slender white needles; the *platinochloride*,  $(C_{11}H_{11}N)_2, H_2PtCl_6$ , melts at  $190^{\circ}$ , and crystallises in dense tables; the *aurochloride*,  $C_{11}H_{11}N, HAuCl_4$ , melts at  $142^{\circ}$ , and forms canary-yellow needles; the *picrate*,  $C_{11}H_{11}N, C_6H_2(NO_2)_3 \cdot OH$ , melts at  $146$ — $147^{\circ}$ , and crystallises in long, yellow needles; and in addition a crystalline *stannochloride*,  $(C_{11}H_{11}N)_2, H_2SnCl_4 + 2H_2O$ , and an oily chromate and zinc salt are described. On oxidation, an acid was obtained agreeing in its properties with quinaldinic acid.

*Tetrahydro- $\alpha$ -ethylquinoline*,  $C_{11}H_{15}N$ , is formed when  $\alpha$ -ethylquinoline is reduced with tin and hydrochloric acid. It boils at  $259$ — $263^{\circ}$ , and resembles the parent base in appearance and odour. The *hydrochloride* crystallises in white needles which remain unaltered in air.

The fraction boiling between  $270^{\circ}$  and  $275^{\circ}$  consisting chiefly of  $\gamma$ -ethylquinoline, contained a diethylquinoline which was separated by means of its mercuriochloride; this salt,  $C_9H_9NEt_2, HHgCl_3$ , melts at  $116^{\circ}$  and crystallises in needles.  $\gamma$ -Ethylquinoline resembles the  $\alpha$ -base in appearance and odour, and its salts show a great similarity to those of  $\alpha$ -ethylquinoline, but have a higher melting point. The *hydrochloride* is very soluble in water and is deliquescent; the *nitrate*,  $C_{11}H_{11}N, HNO_3$ , melts at  $115.5^{\circ}$ , and crystallises in white needles, which become brown on exposure to air, and are soluble in water and alcohol. The *mercuriochloride*,  $C_{11}H_{11}N, HHgCl_3$ , melts at  $154^{\circ}$ , crystallises in white needles, and is readily soluble in water containing

hydrochloric acid; the *platinochloride*,  $(C_{11}H_{11}N)_2H_2PtCl_6$ , melts at  $204^\circ$ , and forms brown leaf-like crystals; the *picrate* melts at  $178-186^\circ$  with decomposition, and forms long, yellow needles; and the *aurochloride*,  $C_{11}H_{11}N \cdot HCl(AuCl_3)_2$ , forms slender, yellow needles. The *methiodide* melts at  $149^\circ$  and formed yellow crystals. On oxidation, cinchonic acid is obtained.  $\gamma$ -Ethylquinoline on reduction yields a base boiling between  $271^\circ$  and  $275^\circ$ , the hydrochloride of which is not crystalline.  $\gamma$ -Ethylquinolinesulphonic acid,  $C_{11}H_{10}N \cdot SO_3H$ , is obtained by heating  $\gamma$ -ethylquinoline at  $260^\circ$  with 10 times its weight of fuming sulphuric acid. It forms slender lustrous needles, melts above  $315^\circ$ , and is insoluble in alcohol, but readily soluble in hot water.

The hydrocarbon separated from the ethyl bases by steam distillation was fractionated, and from the lowest fraction,  $210-240^\circ$ , white crystals were obtained which had a strong naphthalene-like odour, and were almost certainly naphthalene.

W. P. W.

**Colour Reaction of Guanine.** By E. v. BRÜCKE (*Monatsh. Chem.*, **7**, 617—620).—It has long been known that guanine when evaporated with nitric acid gives a yellow residue, soluble in potash with yellow coloration; the solution thus obtained, on evaporation to dryness, gives at first a purple then a violet coloration; on exposure to air the original colour returns. In this paper, it is shown that these changes are due not to the so-called metachromatism, but to the proportion of water present; thus there exist two compounds, the one, golden-red with the greater, the other, indigo-blue, with the less proportion of water. It is not improbable that an intermediate purple-red compound is also formed. Experiments, confirmatory of this view, are described, in which the coloured solutions are exposed to conditions of the presence and absence of water respectively.

**Opium Alkaloids.** By P. C. PLUGGE (*Arch. Pharm.* [3], **24**, 993—1014).—Morphine, codeine, thebaine, papaverine, narcotine, and narceine are the most important opium alkaloids. Their physiological action varies from strongly narcotic or sleep-inducing, to strongly exciting or cramp-producing, but different observers are not agreed as to the exact order of the members of the series. In the arrangement of the bases according to their poisonous nature, different observers are more nearly in accord. The author examined the reactions of salts of these alkaloids with alkaline salts of organic acids. Morphine, codeine, and thebaine, in neutral liquids, react strongly alkaline to litmus, and afford stable salts. Narcotine, papaverine and narceine, on the contrary, do not affect litmus-paper, and combine only feebly with acids. Thus narceine sulphate and chloride are slowly decomposed by cold water, more quickly by hot water. It appeared probable from this that solutions of salts of the stronger bases would give no precipitate with alkaline salts of organic acids, whilst in the case of the weak bases, the alkaloid would be precipitated as such. The following salts were employed: sodium and ammonium acetate, ammonium oxalate, sodium salicylate, sodium potassium tartrate, sodium benzoate and hydrogen sodium carbonate.

Besides the six opium bases, many other alkaloïds were examined in the course of the investigation, such as caffèine, cocaine, atropine, pilocarpine, coniine, strychnine, brucine, quinine, cinchonine, and cinchonidine, the latter, however, only with sodium acetate. None of these bases were liberated and precipitated; in the case of the cinchona bases, however, it was necessary to carefully neutralise the sodium acetate with acetic acid, or precipitation took place. With a perfectly neutral solution of sodium acetate, the only alkaloïds precipitated are the three weak opium bases, papaverine, narcotine and narceïne. These three bases are also precipitated both by slightly acid and by slightly alkaline acetate solution. Neither of the two solutions exerts any influence on the strong opium bases, consequently the ordinary non-neutralised acetate solution can be used for the separation of the bases with advantage in point of time and perhaps completeness. Narcotine, papaverine and narceïne were precipitated as pure bases by all the alkaline salts mentioned previously. Thebaine was precipitated by sodium salicylate as salicylate and by hydrogen sodium carbonate. Morphine and codeïne were not precipitated by any of the salts. Arranging the alkaloïds in series according to their molecular weights, it will be seen that the first three are strong bases and the last three feeble ones: morphine,  $C_{17}H_{10}NO_3$ ; codeïne,  $C_{18}H_{21}NO_3$ ; thebaine,  $C_{19}H_{21}NO_3$ ; papaverine,  $C_{21}H_{21}NO_4$ ; narcotine,  $C_{22}H_{23}NO_7$ ; narceïne,  $C_{22}H_{29}NO_9$ . Slightly acidified sodium acetate solution will indicate as little as 1 : 40,000 of narcotine in solution. With papaverine, the limit is 1 : 30,000. Narceïne is not nearly so sensitive, the limit being about 1 : 600. The precipitation of thebaine as salicylate gave a limit of about 1 : 2000. For quantitative estimation, narcotine is best precipitated by ammonia, where it is the only substance thrown down by this reagent; sodium acetate has, however, the advantage of precipitating it for qualitative purposes from faintly acid solutions in which all other alkaloïds, excepting papaverine and narceïne, remain in solution. Papaverine and narceïne are also best precipitated quantitatively by ammonia.

J. T.

**Cinchona Alkaloïds.** By W. J. COMSTOCK and W. KOENIGS (*Ber.*, 19, 2853—2859).—From considerations based on its chemical behaviour, the authors have adopted the formula  $C_{19}H_{22}Br_2N_2O$  for *cinchonine dibromide* instead of that given in their previous paper (*Abstr.*, 1885, 910). A crystalline *sulphate* is obtained by allowing a solution of cinchonine dibromide in 7 to 8 parts of concentrated sulphuric acid to remain for several hours. It is soluble in hot water and dilute alkalis, excess of alkali throwing out the salt, but dilute acids dissolve it with difficulty. When heated at  $130^\circ$  in a sealed tube with hydrogen bromide, it is decomposed into cinchonine dibromide and sulphuric acid.

*Dehydrocinchonine*,  $C_{19}H_{20}N_2O$ , is obtained in practically colourless needles by heating cinchonine dibromide with alcoholic potash in a reflux apparatus for 16 to 20 hours, distilling off three-fourths of the alcohol, and adding water to the residue. It is purified by precipitating its hydrochloride with ammonia, and crystallising from alcohol. The base melts at  $202\text{--}203^\circ$ , and sublimes without decom-

position if the temperature be carefully raised. It dissolves easily in alcohol, acetone, and chloroform, less easily in ether and hot benzene, and is practically insoluble in water. The *hydrobromide*,  $C_{19}H_{20}N_2O \cdot HBr$ , crystallises from water in colourless, transparent prisms, the *hydrochloride* in long, silky needles.

*Dehydrocinchonine chloride*,  $C_{19}H_{19}N_2Cl$ , is prepared by treating dehydrocinchonine hydrochloride with phosphorus pentachloride and phosphoric oxychloride, adding ammonia, and crystallising from benzene. It melts at  $148-149^\circ$ , and is readily soluble in benzene, alcohol, acetone, chloroform, and ether, but insoluble in light petroleum.

*Dehydrocinchene*,  $C_{19}H_{18}N_2$ , is obtained by boiling dehydrocinchonine chloride with alcoholic potash for 16 hours, and is purified by recrystallising its hydrogen tartrate. The free base crystallised from dilute alcohol, forms long, colourless needles which melt at about  $60^\circ$ , and contain at least 3 mols.  $H_2O$ . The *hydrobromide*,  $C_{19}H_{18}N_2 \cdot 2HBr$ , is obtained in small, broad, transparent, concentrically-grouped prisms which dissolve readily in water, but only sparingly in alcohol and ether. The *platinochloride*,  $C_{19}H_{18}N_2 \cdot H_2PtCl_6$ , a very sparingly soluble salt, is obtained in bright red tables from the solution of the base in concentrated hydrochloric acid.

*Cinchene dibromide*,  $C_{19}H_{20}Br_2N_2$ , is best prepared by gradually adding bromine to a solution of cinchene in chloroform until the yellow perbromide begins to separate, sodium hydrogen sulphite and hydrochloric acid are added, and the base precipitated from the separated aqueous layer by ammonia, is purified by conversion into the hydrobromide, &c. From its ethereal solution, it is obtained in beautiful, colourless crystals which begin to fuse at  $110^\circ$  and melt at  $113^\circ$ . The *hydrobromide* crystallises in concentrically-grouped, colourless needles; the *nitrate* and *zincchloride* also crystallise well. Boiling for 20 hours with alcoholic potash converts cinchene dibromide into dehydrocinchene.

W. P. W.

**Strychnine.** By W. F. LOEBISCH and P. SCHOOP (*Monatsh. Chem.*, **7**, 609—616).—The products obtained on distilling strychnine with zinc-dust vary according to the temperature; at a lower temperature, one atom of oxygen is removed from the molecule with formation of a compound,  $C_{21}H_{22}N_2O$ , a solid substance, soluble in alcohol with a blue fluorescence, sparingly soluble in dilute acids, insoluble in water. It does not give the strychnine reaction with potassium dichromate and sulphuric acid. At a higher temperature, the strychnine molecule is completely decomposed; hydrogen, ethylene, acetylene, and ammonia are evolved, whilst carbazole distils over. Similarly brucine and the acid,  $C_{16}H_{18}N_2O_4$ , obtained by the oxidation of strychnine with chromic acid, yield carbazole on distillation with zinc-dust. On dry distillation, strychnine yields the same gaseous products, but only comparatively small quantities of carbazole, accompanied probably by pyrroline.

V. H. V.

**Specific Rotation of Piperidine Bases.** By A. LADENBURG (*Ber.*, **19**, 2975—2977).—Completing his recent research on the

specific rotation of piperidine bases (this vol., p. 164), the author finds for  $\alpha$ -pipecoline  $[\alpha]_D = 21.74^\circ$ , and for  $\alpha$ -ethylpiperidine  $[\alpha]_D = 6.75^\circ$ .  $\alpha$ -Isopropylpiperidine and  $\beta$ -pipecoline do not yield optically active bases by conversion into dextrotartrates. From the mother-liquor of the  $\alpha$ -pipecoline hydrogen tartrate the lævorotatory base was obtained; but this, even after conversion into the hydrochloride and treatment with cadmium iodide to remove any accompanying dextrorotatory base, gave only a specific rotation of  $-19^\circ$ , and probably contained either the dextrorotatory or the inactive base as impurity which could not be separated. Experiments show that the inactive piperidine bases are compounds and not mixtures of the optically active modifications; and therefore it has been possible to effect a decomposition into two optically active salts only in those cases where the temperature employed in the crystallisation lay above or below the transition temperature of the inactive hydrogen dextro-tartrate (comp. Abstr., 1886, 968).

The unexpectedly low specific rotation of the dextrorotatory  $\alpha$ -ethylpiperidine renders it probable that the specimen employed was not pure.

W. P. W.

**Alkaloids of the Berberideæ.** By O. HESSE (*Ber.*, 19, 3190—3194).—The author has re-investigated the alkaloids in the root of *Berberis vulgaris*. He believes that there are therein at least four alkaloids besides berberine, and describes especially oxyacanthine (Wacker, *Chem. Centr.*, 1861, 321), and a new alkaloid he has obtained from the mother-liquors of oxyacanthine, and which he names *berbamine*.

He finds the true formula of oxyacanthine to be  $C_{18}H_{19}NO_3$  and not  $C_{19}H_{21}NO_3$ , as he has previously given. When crystallised from water and dried at  $100^\circ$ , this alkaloid melts at  $138-150^\circ$ , but when crystallised from alcohol or ether, it forms needles melting at  $208-214^\circ$ . It is easily soluble in chloroform, and then gives  $[\alpha]_D = +131.6^\circ$  ( $p = 4$ ,  $t = 15^\circ$ ). In light petroleum and alkalis, it is only slightly soluble, and ether extracts it completely from the alkaline solutions. The *hydrochloride*,  $C_{18}H_{19}NO_3.HCl + 2H_2O$ , forms small colourless needles which in aqueous solutions give  $[\alpha]_D = +163.6^\circ$  ( $p = 2$ ,  $t = 15^\circ$ ). The *platinchloride* is a yellow, flocculent precipitate. The *nitrate* and *sulphate* are both crystalline. When heated with potash and a little water, the base melts to a brown mass which floats on the surface of the fused potash. This brown mass is the potassium compound of  $\beta$ -oxyacanthine. This conversion into a  $\beta$ -modification also takes place very readily, even at ordinary temperatures, when the alkaloid is acted on by alkalis or barium hydroxide in the presence of alcohol. Ether now no longer extracts the alkaloid from the alkaline solution. Hydrochloric acid precipitates  $\beta$ -oxyacanthine, which is soluble both in alkalis and in excess of acid. If, however, the alkaline solution of the  $\beta$ -compound is supersaturated with hydrochloric acid,  $\alpha$ -oxyacanthine hydrochloride crystallises out. The author believes the  $\beta$ -modification is due to the alkaloid taking up an additional molecule of water. Oxyacanthine very closely resembles narcotine in properties.

*Berberamine* crystallises in small scales of the composition  $C_{18}H_{19}NO_3 + 2H_2O$ . It is easily soluble in ether. When anhydrous, it melts at  $156^\circ$ . The *hydrochloride* crystallises in scales, the *nitrate* in needles; the *platinochloride* forms a yellow crystalline precipitate.

L. T. T.

**Colchicine.** By S. ZEISEL (*Monatsh. Chem.*, **7**, 557—597).—Previous observations on the composition and properties of colchicine have, for the most part, been very discordant; in this paper, a long summary is given. The principal results obtained by the author are as follows: the composition of colchicine is expressed by the formula  $C_{22}H_{25}NO_6$ ; it combines with chloroform to form a crystalline compound,  $C_{22}H_{25}NO_6 \cdot 2CHCl_3$ , readily decomposed by water into its components. Colchicine is slightly basic, but its salts, with the exception of an aurochloride,  $C_{22}H_{25}NO_6 \cdot HAuCl_4$ , cannot be obtained from their aqueous solutions. Colchiceïne, formed from colchicine, when heated with a trace of hydrochloric or sulphuric acid, has the composition  $2C_{21}H_{23}NO_6 \cdot H_2O$ . As the difference between the two compounds is one  $CH_2$  or methylene group, and as methyl alcohol is produced in the decomposition, it follows that colchiceïne is a demethylated colchicine.

Colchiceïne possesses at once the properties of a base, as evidenced by the formation of an aurochloride,  $C_{21}H_{23}NO_6 \cdot HAuCl_4$ , and also those of a monobasic acid, or more probably of a phenol, as shown by the formation of a copper derivative  $(C_{21}H_{22}NO_6)_2Cu$ , and by the readiness with which it dissolves in alkalis. As colchicine has no acidic properties, it is probably a methoxy-derivative of a compound, of which colchiceïne is the corresponding hydroxy-derivative.

It is suggested that the molecular formula of each of the above substances is the double of that given; owing to the complex composition of the substances, the number of hydrogen-atoms is given with a certain reserve.

V. H. V.

**Ecgonine.** By C. E. MERCK (*Ber.*, **19**, 3002—3003).—The author has repeated an experiment made by Calmels and Gossin (*Abstr.*, 1885, 912), and finds that ecgonine when distilled with almost dry barium hydroxide yields methylamine and not ethylamine as one of the products; this corresponds with the behaviour of tropine under like conditions. When ecgonine hydrochloride is heated with an equal weight of phosphorus pentachloride and 10 parts of chloroform at  $100^\circ$  for 10 hours, a base is obtained which yields a well crystallised aurochloride,  $C_9H_{13}NO_2 \cdot HAuCl_4$ , corresponding with ecgonine less the elements of 1 mol.  $H_2O$ . The base has not yet been obtained in the pure state.

W. P. W.

**A New Ptomaine producing Tetanus.** By L. BRIEGER (*Ber.*, **19**, 3119—3121).—The author has already described an alkaloid, tetanine, obtained in the cultivation of Rosenbach's microbe. The beef extract in which the microbe had been cultivated for four to six weeks, was acidified with hydrochloric acid, boiled, and filtered; the filtrate evaporated and treated with lead acetate and alcohol, filtered, and the lead removed as far as possible as chloride, and finally as

sulphide. The strongly alkaline filtrate was distilled with steam, acidified with hydrochloric acid, evaporated to dryness, and treated with alcohol to remove ammonium chloride. After removing the alcohol, the new base was separated as its aurochloride.

The free base,  $C_5H_{11}N$ , is volatile, boils about  $100^\circ$ , but was not obtained free from water. The *hydrochloride* is crystalline, melts at  $205^\circ$ , and is very readily soluble in water and absolute alcohol. The *aurochloride*,  $C_5H_{11}N, HAuCl_4$ , crystallises in plates, and melts at  $130^\circ$ . The *platinochloride*,  $(C_5H_{11}N)_2, H_2PtCl_6$ , crystallises in plates, is decomposed at  $240^\circ$ , and is sparingly soluble in water. The picrate crystallises in readily soluble needles. The base gives a yellow precipitate with phosphomolybdic acid, a white precipitate with phosphotungstic acid, and a red crystalline precipitate with potassium bismuth iodide. Injected hypodermically in a comparatively large dose, it produces the symptoms of tetanus.

A. J. G.

**Albumoses.** By R. NEUMEISTER (*Zeit. Biol.*, **23**, 381–401).—The question investigated in this research was whether or not each albumose was converted into isomerides belonging to the anti- and hemi-groups of digestion products.

The method previously described by Kühne and Chittenden of separating proto- from deuterio-albumose is not a satisfactory one. Hetero-albumose is easily separated by its being precipitated when the salts are dialysed out from a mixture of the albumoses. It can also be separated from the mixture by saturating it with sodium chloride; part of the proto-albumose and the whole of the deuterio-albumose remain in solution. In the precipitate, hetero-albumose can be separated by dialysis as before. By acidifying the filtrate, which contains the deuterio-albumose and part of the proto-albumose, the proto-albumose and about half the deuterio-albumose are precipitated; this is filtered off; the deuterio-albumose remaining in solution is not mixed with any other albumose; the sodium chloride is dialysed off, the fluid is saturated with ammonium sulphate, and thus the peptone alone is left in solution; the precipitate of deuterio-albumose is redissolved and obtained free from ammonium sulphate by dialysis, and finally precipitated by alcohol. It gives no precipitate with copper sulphate; previous statements that such a precipitate occurs were due to its admixture with proto-albumose.

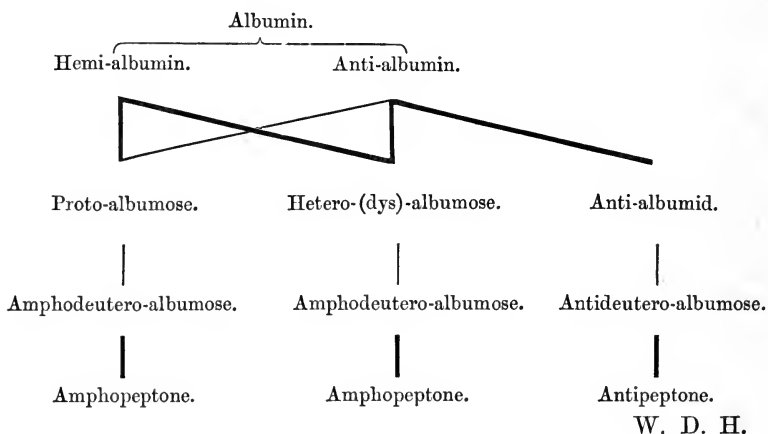

On prolonged heating of proto-albumose with 5 per cent. sulphuric acid, deuterio-albumose is formed. Hetero-albumose yields the same substance, and also anti-albumid. The same result is obtained on peptic digestion, and also on tryptic digestion, more rapidly in the latter case than the former. The formation of the so-called globulin-like substance does not occur in tryptic digestion.

No deuterio-albumose is formed directly from fibrin; but proto- and hetero-albumose are intermediate products in its formation, both by acids and by ferments.

Anti-albumid yields deuterio-albumose also, and seems to be largely a bye-product of the formation of hetero-albumose. The deuterio-albumose obtained is an anti-product yielding only anti-peptone; much insoluble anti-albumid is left after prolonged digestion, which will

yield no more albumose. This insoluble substance swells with sodium hydroxide; it is turned yellow by nitric acid, and orange on the subsequent addition of ammonia; in its solubilities it much resembles keratin.

The deutero-albumose formed from proto- and hetero-albumose is called ampho-deutero-albumose, as it is subsequently converted into amphopeptone (that is, hemi- and anti-peptone); the anti-products from proto-albumose are, however, exceedingly small in quantity, and the author suspects that his method of preparing proto-albumose does not give him that substance quite free from traces of hetero-albumose; and that perfectly pure proto-albumose will be found to be a pure hemi-albumose. The changes in the digestion of albumin are represented in the following schemes.

**Vitelloses.** By R. NEUMEISTER (*Zeit. Biol.*, **23**, 402—411).—Following on the lines of Kühne and Chittenden, the products of the digestion of vitellin have been subjected to analysis. The variety of the proteid employed was plant vitellin (phytovitellin), prepared from pumpkin seed.

Coagulated vitellin was found to be the best to employ; in peptic digestion, syntonin was formed as one product. This resembled ordinary acid albumin, except that it was insoluble in strong nitric acid, and gave the biuret reaction, not the ordinary purple colour. A substance, antivitelid, corresponding with anti-albumid, was also formed, but no coagulable substance like that obtained in the peptic digestion of globulin.

The ultimate products of digestion are peptones; vitellose is the name given to the intermediate products: proto-, hetero-, deutero- and dysvitellose, which correspond with the albumoses with similar prefixes. These may be separated from one another and from peptones as the albumoses are.

Protovitellose becomes deuterovitellose on further peptic digestion: when subjected to the action of the tryptic ferment, a trace of antivitelid

is formed; the end products are antipeptone, tyrosine, leucine, and the substance which becomes violet with bromine.

Heterovitellose and dysvitellose, derived from it, do not differ in their properties from the analogous albumoses; under tryptic digestion, much antivitellid is formed, the end product being antideutero-vitellose. Under prolonged peptic digestion, amphodeutero-vitellose is formed.

The anti- and amphi-varieties of deutero-vitellose correspond with the similarly named albumoses.

W. D. H.

## Physiological Chemistry.

**Gases of Parotid Saliva.** By R. KULZ (*Zeit. Biol.*, **23**, 321—328).—Observations on the gases of human saliva have not been previously made. The saliva was obtained by means of a gum elastic canula (which was found to be better than the metal one at first used) inserted into Stenson's duct; the saliva was collected over mercury to obviate the danger of absorption of atmospheric air.

As the mean of 11 analyses, the total quantity in volume from 100 c.c. of saliva was 7 c.c. of gas, of which 1 c.c. was oxygen, 2.5 nitrogen, and 3.5 c.c. carbonic anhydride. By the addition of phosphoric acid, a large amount (40—60 per cent.) of carbonic acid contained in the saliva as carbonates was obtained. The amount of oxygen and nitrogen in the saliva exceeds that in the blood-serum.

With regard to the carbonic anhydride present, and the alkalinity of the secretion which is due to the carbonates, it is found that food in the stomach does not alter the reaction of the saliva as it does that of the urine. After an abundant secretion of gastric juice, many observers have noted, and these experiments confirm their results, that the urine becomes less acid or even alkaline. That there is no such effect on the saliva is shown both by the estimation of the carbonic acid and by titration.

W. D. H.

**Free Hydrochloric Acid of the Gastric Juice.** By H. A. LANDWEHR (*Chem. Centr.*, 1886, 484).—The author has previously shown, in conjunction with Fick, that the action of this acid on diastase is inverted in the presence of peptones, in the sense that its activity is increased rather than suspended; the cause probably lying in its combination with amido-acid groups of the peptones. Calm has recently shown (*Deut. Arch. f. klin. Med.*, **23**) that in certain pathological conditions the gastric juice has the reactions rather of an organic acid than of dilute hydrochloric acid.

It is well known that lactic acid decomposes sodium chloride. That this taken place in cold dilute solution is readily seen by comparative observations of the acidity (methyl-violet being used as indicator) of a lactic acid solution before and after addition of sodium chloride.

The author applies these observations to a discussion of the origin and nature of the acidity of gastric juice, arriving at the following hypothesis :—Lactic acid is formed by fermentation from the mucus of the stomach, and, acting on alkaline chlorides, liberates hydrochloric acid, which is forthwith taken up in combination by the albuminoids of the food. The sodium lactate is simultaneously assimilated. With the gradual peptonising of the albuminoids, the hydrochloric acid is liberated.

C. F. C.

**Ferment Organisms of the Alimentary Canal.** By N. MILLER (*Chem. Centr.*, 1886, 580).—Of the 25 micro-organisms identified by the author in the mouth, 12 were also found in the intestines, and 8 in the stomach. Although normal gastric juice is antiseptic, the conditions in the stomach are often such as to prevent contact of the organisms therewith, which then continue active. These organisms are also carried forward into the intestines by liquids which remain only a short time in the stomach.

In most cases, these organisms exert a peptonising but only seldom a diastatic action. In some cases, they induce lactic fermentation of carbohydrate solutions; in others acetic and butyric. In some instances the fermentation was attended with the evolution of carbonic anhydride and hydrogen.

C. F. C.

**Formation of Fat in the Dog from Carbohydrates.** By J. MUNK (*Bied. Centr.*, 1886, 748—750).—A bitch was allowed to fast for 31 days, this being the period stated by Hofmann to be necessary for the removal of all fat from the system—31 per cent. of the weight was lost. The animal was then fed with 200 grams of flesh, 100 grams of gelatin, and an increasing ration of starch and sugar in equal parts (300 to 500 grams). After 25 days the animal was killed and examined, when it was found to have increased in weight at a rate of 36 grams daily, and, taking the lowest valuation, nine-tenths (960 grams) of the whole fat found in it had been put on during the 25 days. The sources from which the fat could have been formed were three: namely, fat in the flesh given, decomposed albumin, and carbohydrates. Of the fat produced by the decomposition of albumin, there would be according to Voit and Pettenkofer 12 per cent., according to Henneberg 51 per cent.—415 grams should be formed; but this quantity must be reduced to 42 to 45 per cent. if Zuntz's method of calculating Henneberg's results is to be followed; the author therefore considers that 343 to 364 grams fat must be attributed to albumin; the fat from the meat amounted to 75 grams. However, whatever may be the quantity of actual fat from albumin, there appears to be no doubt that 788 grams (max.) 470 grams or 542 to 521 grams of fat (according to the method of calculation used), had to be sought for from other sources, namely, the gelatin and starch. The author allows for argument's sake that 338 grams might come from the gelatin (this, however, according to Voit and Pettenkofer, is inadmissible), even then 162 grams of fat must have come from the carbohydrates.

E. W. P.

**Relation between the Destruction of Glucose and the Production of Animal Heat and Work.** By A. CHAUVEAU and KAUFMANN (*Compt. rend.*, 103, 974—975, 1057—1064, 1153—1159).—On comparing two organs which, under ordinary physiological conditions, have very unequal thermogenic activities, it is always found that the destruction of glucose is much greater in the organ in which combustion is most active, or, in other words, the heat developed in animal tissues, which is proportional to the amount of internal combustion, is also proportional to the quantity of glucose removed from the blood in the capillaries.

Analyses of the blood of the masseter muscle and parotid gland of the horse during a state of repose, showed that the activity of combustion in the muscle as measured by the amount of oxygen absorbed and of carbonic anhydride produced is to that in the gland as 4.57 : 1, whilst the destruction of glucose is as 5.68 : 1.

During the process of mastication and insalivation, the activity of combustion in the muscle is increased by 3.5 times, whilst the consumption of glucose in the blood traversing the muscle is increased to almost the same extent. In the gland, the ratio between the activity of combustion at rest and in action is 60 : 87, whilst the consumption of glucose is as 70 : 90. In experiments of this kind, it is important to take into account not only the composition of the blood, but also the volume which traverses the organ in unit time.

Details of the method of experiment and of the analyses are given in the original papers.

Glucose is always found in the nutritive secretions, but never in any tissues except the liver. Glycogen, on the other hand, does not occur in the blood, but only in the hepatic and muscular tissues. Analyses of muscle in repose and in action confirm the statement that glycogen accumulates while the muscle is at rest, but disappears during activity. The glucose which disappears from the capillaries leaves them in company with oxygen, and is more or less completely converted into water and carbonic anhydride in the organs and tissues. The glycogen which has accumulated in the muscles provides the materials for combustion during periods of great activity when the supply of glucose is not equal to the demand. Only a portion of the glucose which disappears from the capillaries is consumed; the remainder becomes converted into muscular glycogen by dehydration, and then forms a reserve. During excessive work, the glycogen becomes hydrated and reconverted into glucose, which is consumed.

The liver is the indirect collaborator of the muscles during activity. In fact the hepatic gland performs its functions as a glycogenic organ the more actively each time that any work is done by any part of the animal economy. This is established by the fact that the blood never becomes appreciably poorer in glucose even during activity. On the contrary, there is often an excessive production of glucose, especially if the activity is localised as in mastication.

So long as the liver furnishes glucose to the blood in sufficient quantity, so long does the animal continue to develop the quantity of heat necessary for the activity of the other organs and the maintenance of the bodily temperature. When the glycogenic function of

the liver becomes enfeebled, glucose disappears from the blood-vessels, organic combustion rapidly diminishes, and death supervenes as a result of arrested calorification. C. H. B.

**Origin of the Bile Colouring Matters.** By H. STERN (*Chem. Centr.*, 1886, 481).—The author's experiments were performed on pigeons. The bile-ducts being ligatured and provision being made for collecting the urine separately, by ligaturing the rectum above the entrance of the urethra, it was found that within  $1\frac{1}{2}$  hours the urine was highly charged with these colouring matters. After death, the tissues were found to be similarly charged. In a second series of experiments, the liver was thrown entirely out of the circulation. In this case neither in the blood, urine, nor tissues were any traces of these colouring matters found. The author concludes from his experiments that these substances originate entirely in the liver substance. C. F. C.

**Active  $\beta$ -Hydroxybutyric Acid.** By E. KULZ (*Zeit. Biol.*, 23, 329—339).—The author has previously described the occurrence of this substance in diabetic urine. It may be prepared as follows:—Diabetic urine which gives the ferric chloride reaction and is strongly laevorotatory is (after the removal of the sugar by fermentation) concentrated to a thin syrup, and neutralised with sodium hydroxide, three times as much 95 per cent. alcohol is added, which produces an abundant precipitate; from the alcoholic filtrate, the alcohol is evaporated, and more alcohol added; this is repeated until alcohol gives no further precipitate; the last traces of alcohol are removed by shaking with ether. To the residue, sulphuric acid is added, and the mixture shaken with an equal volume of ether.

The ether is driven off by heat, and the remaining brown syrup gives a precipitate with lead acetate, which is filtered off. From the filtrate, excess of lead is removed by sulphuretted hydrogen; baryta-water is added, and the barium salt of the acid is obtained in solution. Urea is then precipitated by means of mercuric nitrate, excess of mercury being removed by treatment with sulphuretted hydrogen. From the solution of the barium salt, the silver salt is obtained by adding a solution of silver sulphate; the barium sulphate is removed, and on concentration crystals of the silver salt are obtained and purified by recrystallisation. The free acid is obtained by decomposing the solution of the silver salt with sulphuretted hydrogen. The specific rotatory power of this acid is  $[\alpha]_D = -23.4$ . The ammonium salt has the specific rotation denoted by  $[\alpha]_D = -16.3$ .

Minkowski's test for this acid in urine (*Arch. exp. Path. u. Pharmak.*, 18, 41) is not regarded as trustworthy; and the obtaining of crystals of  $\alpha$ -crotonic acid, on adding sulphuric acid, is preferred. The presence of a substance which rotates polarised light to the left, which gives the ferric chloride reaction, and which is not precipitable by lead acetate, may be taken as strong presumptive evidence of the presence of  $\beta$ -hydroxybutyric acid. Benzoic acid (from the decomposition of hippuric acid), salicylic acid, and phenol, might possibly be confounded with it; methods of avoiding such a mistake are given. The

acid does not appear to be present in the urine of healthy men or animals; but it occurs in unhealthy urines not only in cases of diabetes, but also in cases of scarlet fever, measles, diphtheria, scurvy, and in certain mental affections.

W. D. H.

**Physiological Action of Convolvulin and Jalapin.** By G. DRAGENDORFF (*Chem. Centr.*, 1886, 589).—The question of the excretion of these glucosides after being taken into the human stomach has been investigated by Bernatzik (*Wiener med. Jb.*, 1862–63); traces only were found in the fæces, none in the urine. This result was confirmed by Köhler and Zincke (*W. Jb. für Pharm.*, 32, 1); who, however, succeeded in isolating these purgatives from the stomach and intestines. The author has repeated these investigations, adopting a simplified method of examination of the parts for the glucosides and products of decomposition (convolvulinic and jalapic acids), based on extraction with chloroform. 0.5 gram of the glucosides was the quantity given, cats being taken as the subject of the experiments.

The author confirmed the previous results in regard to the non-excretion of the drugs in the fæces and urine. The animals were killed after the lapse of four hours, and the organs examined; appreciable quantities of the drugs were found in the stomach and small intestines, less in the duodenum, traces only in the lungs and pancreas. No evidence was obtained that the glucosides are converted into the derived acids.

C. F. C.

## Chemistry of Vegetable Physiology and Agriculture.

**Bacterial Life in Relation to Oxygen.** By P. LIBORIUS (*Chem. Centr.*, 1886, 579).—The author classifies these organisms as follows:—

(1.) Exclusively anaerobic: amongst these there are many which multiply without attendant fermentation.

(2.) Exclusively aerobic: reduced to inactivity by deprivation of oxygen. This class includes:—*B. fluorens liquifaciens*, *B. aerophilus*, *B. cyanogenus*, *B. fuscus*, *B. aquatilis fuscus*, *B. subtilis*. With exception of the first-named, which appears to determine a special fermentation of albuminoids with formation of volatile fatty acids, the bacteria of this group have not been closely studied in relation to fermentation.

(3.) Optionally anaerobic: activity lowered, but not suspended, by deprivation of oxygen. This class includes all the pathogenic organisms: *B. anthracis*, *B. typhi abdom.* From this general view of the conditions of bacterial life, and from his own special investigations, the author concludes that an attendant fermentation is not an essential condition of anaerobic activity in the sense in which it has been so stated by Pasteur and Nägeli.

C. F. C.

**Wine and Brandy from Raspberries and Strawberries.** By A. ROMMIER (*Compt. rend.*, 103, 1266—1268).—The ferment of the raspberry, which has been described by Le Bel as *Levure wurtzii*, is not able to convert the whole of the sugar of the raspberry into alcohol. In order to ascertain if this is due to want of activity in the ferment, or to the action of some constituent of the fruit, energetic ellipsoïdal wine yeast was mixed with the liquid. Fermentation then proceeded rapidly, and not only the sugar existing in the fruit, but two or three times the quantity of added sugar, was converted into alcohol. Raspberry brandy, obtained by distilling the wine, is very aromatic, and has the odour of raspberries, then becomes slightly smoky, but finally acquires a very fine bouquet.

The ferment of strawberries is more active, but fermentation is accelerated by the addition of ellipsoïdal wine yeast. Strawberry wine from French strawberries is less acid than that from raspberries, and keeps well, provided that it contains 16 per cent. of alcohol. The brandy has a strawberry bouquet, which becomes stronger after some time, but does not alter in character.

The flavour of the brandy from English strawberries, although made with a double quantity of added sugar, is still so strong as to be unpleasant, but if diluted with water the strawberry bouquet develops in perfection, a fact which indicates that more sugar might be added with considerable advantage.

*Levure wurtzii* and others, such as *L. apiculatus*, have no inversive properties, and can therefore act only on invert sugar, and are unable to alter the saccharose which also exists in the juices of many fruits. A higher yield of alcohol can be readily obtained by adding an inversive ferment like the ellipsoïdal yeast of wine.

C. H. B.

**Zymotic Virus and Fermentation.** By S. ARLOING (*Compt. rend.*, 103, 1268—1270).—The virus of gangrenous septicæmia and of symptomatic anthrax have the power of fermenting nitrogenous substances such as peptone, albumin, and yolk of egg. The products are ammoniacal compounds, with possibly indole and skatole. Hydrogen, nitrogen and carbonic anhydride are evolved, the hydrogen being present in much greater relative proportion in the gases from albumin and yolk of egg than in those from peptone. These facts confirm the analogy between zymotic virus and ferments.

The gaseous infiltration which characterises gangrenous septicæmia and symptomatic anthrax is in all probability due to the fermentation of the carbohydrates and nitrogenous compounds in the tissues.

C. H. B.

**Loss of Nitrogen by Plants during Germination and Growth.** By W. O. ATWATER and E. W. ROCKWOOD (*Amer. Chem. J.*, 8, 327—343).—During the germination of seeds, and the early growth of plants, may there be a material loss of nitrogen? (compare Abstr., 1885, 1005). Peas were allowed to germinate and grow for a certain length of time in moist sand, and the nitrogen contained in them and also in the sand and moisture estimated. The sum of these two quantities was always less than the computed nitrogen in the original seeds, the loss varying from 6 to 16 per cent., according to the time

of the experiment and the locality. Only in cases where a quantity of the rootlets had been torn off in removing the plants from the sand did the nitrogen in the moist sand exceed 3 per cent. of the whole. Bearing in mind the work of other experimenters, the authors believe that this loss of nitrogen, which is not observed in the germination of all seeds, is not a normal process of the growth of the plant, but is caused by processes of decomposition that depend on the presence of microbes.

H. B.

**Variations in the Chemical Composition and Physical Properties of American Oats.** By C. RICHARDSON (*Amer. Chem. J.*, 8, 364—374; compare Abstr., 1885, 585).—The grains vary considerably in weight, size, weight of husk, and in the way in which the husk encloses the grain, according to the environments of the plants. The chemical composition, however, is far more constant, and the proportion of husk and kernel and the compactness of the grain prove to be the all-important factors, and the weight per bushel the best means of judging of the value of the grain. No differences can be shown to exist such as might be expected between the largest and smallest oats, those having the lowest and highest proportion of kernel, &c. The detailed results are embodied in a series of tables.

H. B.

**Loss occasioned by Improper Methods of Pickling Wheat.** By P. GRASSMAN (*Bied. Centr.*, 1886, 766—774).—It is customary to treat wheat before sowing with solution of copper sulphate, which destroys the spores of bunt (*Tilletia caries*), but generally no special attention is paid to the quantity of sulphate employed; consequently much loss ensues, owing to the destructive action of the sulphate on the germinative power of the grain. Kuhn recommends that for every 5 bushels of wheat 1 lb. of sulphate be dissolved in 50 parts of water. In this solution, the wheat is to be soaked for 12 to 16 hours, after which, the liquid being first removed from above, the grain is to be dried for 24 hours. The liquid is to be removed from above, because the diseased grains and the fungus float to the top, so that if the liquid is drawn off from below, or if the grain is lifted out through the liquid, the damaged grain and spores will be mixed again with the healthy material. Grossman has examined the effect of prolonged drying and increased strength of solution on the vitality of the seed, and finds that both of these conditions are highly detrimental to the germinative power, and that where germination is not actually destroyed, the sprout will be unhealthy and weak, and germination will be delayed. Tables are given showing in detail the results of various mixtures and times of drying on the germination.

E. W. P.

**Nitrogen Compounds in Vegetable Soils.** By BERTHELOT and ANDRÉ (*Compt. rend.*, 103, 1101—1104).—The nitrogen in vegetable soils exists mainly in the form of insoluble compounds with carbon, hydrogen, and oxygen.

Sieved and air-dried soil was suspended in water, mixed with various proportions of hydrochloric acid, kept at different temperatures for varying lengths of time, and then filtered. The filtrate was

carefully neutralised with potash, then slightly acidified, and afterwards mixed with excess of magnesia, and the ammonia estimated by Schloesing's process. The ammonia was also determined in the soil which had been in contact with water only, and the difference between the two quantities gave the amount of ammonia formed by the action of the acid on the nitrogen compounds in the soil. The quantity of ammonia thus formed increases with the concentration of the acid, the time, and the temperature. The action of the hydrochloric acid is in fact precisely similar to its action on urea, asparagine, oxamide, &c. (this vol., p. 235), and hence it follows that the nitrogen in the soil exists in part at least in the form of amides.

After estimation of the ammonia, the liquid was carefully neutralised with sulphuric acid, evaporated to dryness on the water-bath, and the nitrogen in the residue estimated by means of soda-lime. This determination gives the amount of nitrogen present in the form of soluble amido-compounds, and it was found that the proportion of these compounds increases with the time of action of the hydrochloric acid and with its concentration. The amido-compounds thus rendered soluble by the action of the acid may be divided into two groups, one of which remains in solution when the liquid is neutralised with potash, whilst the other is precipitated with the ferric, aluminium and calcium oxides. In one experiment, the ratio between the nitrogen in the two groups was 23 : 17.

Alkalis act on the nitrogenous matter in much the same way as hydrochloric acid. C. H. B.

**Manuring Rye with Thomas Slag and other Phosphates.** By M. SIEVERT (*Bied. Centr.*, 1886, 744—745).—The land had been manured in the previous year with farmyard manure, and in this season it received 30 lbs.  $P_2O_5$  and 10·5 lbs. N as ammonium sulphate or bone-meal per morgen. The phosphates applied were Thomas slag, bone-meal superphosphate, and Curaçoa phosphate. In all cases the slag brought the lowest, and the superphosphate the highest yield, and from a money point of view the super- and Curaçoa phosphates were the most advantageous. E. W. P.

**Thomas Slag and other Phosphates as Manure for Moorlands.** By RIMPAU and others (*Bied. Centr.*, 1886, 732—742).—In the previous year, the phosphates failed to produce any definite result (*Abstr.*, 1886, 1069). The experiments have been repeated in the succeeding year without added manures, so as to obtain information regarding the after-effect of the manures. It appears, then, that the after-action of Thomas slag and precipitated phosphate are alike. A set of experiments similar to those already described (*loc. cit.*) have been made by Wagenheim, from which it appears that as a manure for rye, slag is as good as precipitated phosphate; moreover, P. Wagner's law, that so long as an increase is obtained by the employment of increased quantities of phosphate, that increase will be in direct ratio with the increase of manure, was corroborated.

Another corroboration of Wagner's law was also obtained when rye was grown, and a distinct advantage of slag over precipitated phos-

phate was noticed, in that the expenses were less with the former than with the latter. E. W. P.

**Superphosphate Manuring for Sugar-beet.** By A. NAUTIER (*Bied. Centr.*, 1886, 742—744).—It was found in the neighbourhood of Peronne, where the land was rich ( $P_2O_5$  0·34 per cent, N. 0·17,  $K_2O$  0·53), that the addition of manures (nitre, ammonia, oil-cake, and phosphate) was unnecessary, as instead of an increase in the crop which paid for the manure the case was exactly opposite; there was a deficiency and loss. Neither was the percentage of sugar in the juice appreciably altered. But, on the other hand, in poor land deficient in phosphates, a gain was obtained by the use of superphosphate and natural phosphates, yet the total yield was lower, although the quotient of purity was higher than on the richer soil.

E. W. P.

---

## Analytical Chemistry.

---

**Filters with Greased Edge.** By A. GAWALOVSKI (*Zeit. anal. Chem.*, 26, 51).—By soaking the edge of a filter with paraffin, wax, or fat (free from ash), the tendency which some precipitates have to creep over the edge is entirely removed. M. J. S.

**Method of Estimating Fluorine.** By A. CHAPMAN (*Chem. News*, 54, 287).—The ignited substance is pulverised and repeatedly treated with 10 per cent. hydrochloric acid, the combined extracts are made up to a definite volume, and an aliquot part treated with acid ammonium acetate, which precipitates calcium fluoride; the precipitate is washed, dried, ignited and weighed. As calcium phosphate is not precipitated under these circumstances, the method is well adapted for the analysis of commercial phosphates. D. A. L.

**Reagents for detecting Minimal Quantities of Active Oxygen.** By C. WURSTER (*Ber.*, 19, 3195—3205).—Tetramethylparaphenylenediamine,  $C_6H_4(NMe_2)_2$ , is converted by all oxidising agents into a blue-violet dye, only capable of existing as a salt,  $C_6H_4<\begin{smallmatrix} NMe_2Cl \\ NMe- \end{smallmatrix}>CH_2$ . This, when further oxidised, changes from red-violet to red, and finally becomes colourless. It can be reduced to the original base. Paper soaked with a solution of tetramethylparaphenylenediamine forms a very delicate test for active oxygen. It shows the presence of active oxygen in the air, in the neighbourhood of flames, in the sap of plants, and in the human skin. The moist paper is also coloured by silver oxide and by red-lead. Solution of copper sulphate or the dry salt, spongy platinum, wood charcoal, and many other powders, aldehyde, ethereal oils, some alcohols and acetone colour the paper. It is also coloured by most disinfectants in sunlight, by chlorophyll, and by some ferments.

Chloric and nitric acids do not colour the paper quickly; but when salts of these acids are treated with strong sulphuric acid the gases evolved rapidly oxidise the diamine.

When hydrogen peroxide and tetramethylparaphenylenediamine, both in the purest possible state, are brought together the solution is scarcely coloured; on adding paper or a chip of wood, an intense coloration is produced, which lasts for days. Very dilute nitrite solution (1 : 1000 or 1 : 10000) gives an intense coloration, but is decolorised again almost immediately. Even a solution of a nitrite diluted to 1 : 10,000,000 is slowly decolorised.

Dimethylparaphenylenediamine, when oxidised, yields a fine red dye; this changes to a violet or blue dye when kept, or when heated. When the free base is brought into contact with the skin, the latter is often coloured brown or black in a short time. Paper prepared with the diamine remains blue-violet for two or more hours in a mixture of hydrogen peroxide, and acetic or lactic acids; decolorisation takes place quickly on adding salt to the solution; this is probably due to the liberation of hydrochloric acid.

The oxidation of the methyl-derivatives of phenylenediamine is quantitative, and can be shown by potassium permanganate in hydrochloric acid solution.

N. H. M.

**Influence of Copper on the Estimation of Sulphur.** By W. F. BRUGMAN (*Chem. News*, 54, 290—291).—The author's experiments indicate that when copper is present in quantities not exceeding 1 per cent. it does not interfere with the working of the "hydrogen sulphide method" of estimating sulphur in iron and steel. There has been much difference of opinion on this point.

D. A. L.

**Eggerzt's Method of Estimating Sulphur in Iron.** By G. MÖLLER (*Chem. Centr.*, 1886, 489—490).—The author has reinvestigated this method, and finds the results to be unsatisfactory.

**Estimation of Sulphur in Coal and Coke.** By A. J. ATKINSON (*J. Soc. Chem. Ind.*, 5, 154—157).—The author's method is a modification of Nakamura's process of heating pulverised coal in contact with sodium carbonate, whereby the coal rapidly undergoes complete atmospheric oxidation, the combustion of the carbon being effected at a dull red heat over a spirit-lamp (compare *Trans.*, 1879, 785). The difficulty with which the heat from a spirit-lamp can be evenly distributed over the whole of the test, suggested to the author that the combustion could be more easily conducted in a muffle through which a gentle current of air is made to pass. The author has also made a series of experiments with the object of proving the applicability of this method to the estimation of the sulphur contained in pyrites, but the results have hitherto been far from satisfactory. If by some simple device, the complete oxidation of the sulphuric acid could be secured, the amount of this acid might be determined by finding the quantity of standard sulphuric acid required to neutralise the excess of sodium carbonate, and deducting that amount from the quantity

required to neutralise the whole of the sodium carbonate weighed out.  
D. B.

**Estimation of Sulphur and Impurities in Coal-gas.** By T. FAIRLEY (*J. Soc. Chem. Ind.*, 5, 283—286).—The author's process of estimating sulphur in coal-gas consists in using a very dilute solution of hydrogen peroxide, run in at the top of the referees' apparatus, and the plain flame under the trumpet without ammonium carbonate. The oxidising effect is very complete, even with solutions containing less than 1 per cent. of peroxide. The equation is  $\text{H}_2\text{O}_2 + \text{SO}_2 = \text{H}_2\text{SO}_4$ , and hence the liquid may either be titrated with standard alkali, or acidified and precipitated with barium chloride. The method may be used either intermittently or continuously. In the former case the sulphuric acid in the condensed liquid and washings may be determined either by titration, or precipitation, or both; and in the latter, the receiver being changed, the volume of gas required is burnt, and then the sulphuric acid is estimated in the liquid collected, without disturbing the rest of the apparatus. The estimations of carbonic anhydride and of ammonia in coal-gas are made by processes substantially the same as those described in text-books. Where the carbonic anhydride is over 1 per cent., approximately accurate results may be obtained by the use of Bunte's gas burette. When the gas has been purified by lime, the carbonic anhydride may fall under 1 per cent., and then a standard solution of barium hydroxide should be used, contained in an ordinary absorption apparatus arranged to give as small bubbles of gas as possible. After passing a measured volume of the gas through a measured quantity of the barium solution, and allowing the precipitated carbonate to settle, a portion of the clear liquid may be titrated. The loss of alkalinity gives the carbonic anhydride present in the gas.

D. B.

**New Reaction of Thiosulphates.** By L. L. DE KONINCK (*Zeit. anal. Chem.*, 26, 26).—A mixture of an alkaline thiosulphate with aqueous potash or soda yields an alkaline sulphide when treated with aluminium.  
M. J. S.

**Detection of Ammonia, Nitric or Nitrous Acids, and Thio-sulphuric Acid in a Mixture of Alkaline Salts.** By L. L. DE KONINCK (*Zeit. anal. Chem.*, 26, 26—27).—Aqueous soda is added, and the mixture boiled in a fractionating flask connected with a U-tube containing Nessler solution. When all the ammonia is expelled, aluminium foil is introduced, and the presence of the nitrogen acids is recognised by testing a second distillate for ammonia. Finally, the tests for a sulphide are applied to the residue in the flask (compare preceding Abstract).  
M. J. S.

**Determination of Ammonia in Arable Soil.** By W. KNOP (*Zeit. anal. Chem.*, 26, 1—9; compare Baumann, this vol., p. 82).—The determination of ammonia in soil by means of hypobromite is complicated by the fact that clay, especially when ferruginous, undergoes contraction when shaken with a strongly alkaline solution. This

contraction is quite unconnected with the absorption of oxygen, which occurs when humus is shaken with air and an alkali. The amount of the contraction is proportional to the quantity of alkali and the time of shaking. The addition of borax prevents it entirely.

A solution prepared as follows, whilst not containing sufficient free alkali to produce this contraction, decomposes ammonia readily. To an excess of calcium hydroxide 200 c.c. of water and 15 c.c. of bromine are added; the mixture is allowed to remain for several days that the solution may become saturated with lime; it is then filtered and mixed with a saturated solution of borax before use. If it is desired to render this solution more strongly alkaline, it is necessary to ascertain first the maximum amount of alkali which can be used without causing contraction. This may be done by shaking the earth with borax solution, and gradually increasing quantities of sodium hydroxide in a flask, closed with a cork, carrying a sealed capillary tube, the point of which is afterwards broken while in connection with the azotometer. The flask should have a thermometer inserted through a tubulus, and proper precautions against change of temperature must be taken.

M. J. S.

**Griess' Reaction for Nitrous Acid in Presence of Hydrogen Peroxide.** By C. WURSTER (*Ber.*, 19, 3206—3208.)—Fresh saliva failed to give Griess' colour reaction for nitrites, but coloured tetramethylparaphenylenediamine paper. This is accounted for by the presence of hydrogen peroxide which would oxidise the nitrite to nitrate, so that the coloration could only take place in presence of an excess of nitrite. The absence of nitric acid in fresh saliva is seen when saliva is added to two portions of metaphenylenediamine sulphate in glacial acetic acid, one of which is previously treated with a drop or two of ammonia; no coloration is produced in the solution free from ammonia, whilst that containing ammonia is soon more or less coloured, owing to the oxidation of the ammonia to nitrous acid by the hydrogen peroxide.

Saliva obtained from a large dog was found to contain much hydrogen peroxide, and to be free from nitrites and potassium thiocyanate.

N. H. M.

**Apparatus for Kjeldahl's Method of Nitrogen Determination.** By H. P. ARMSBY and F. G. SHORT (*Amer. Chem. J.*, 8, 323—326).—The distillation flask is closed by a rubber stopper with three holes. Through one hole passes a tube of half inch diameter, widening upwards to 1 inch, and about 4 inches long; sealed into the side of this is the exit tube, which is connected with a block-tin condenser; the top of the 1-inch wide tube is closed by a rubber stopper, through which passes a stoppered funnel whose stem reaches to the bottom of the flask, the remaining space in the wide tube is filled with glass beads, to stop any spray. The second hole serves for a small mercury valve to admit air in case of sudden absorption or cooling. The third hole carries a syphon tube reaching to the bottom of the flask, this serves to empty and clean the flask after each operation, so that the apparatus is never dismantled.

H. B.

**Determination of Phosphorus in Iron and Steel.** By P. VORWERK (*Zeit. anal. Chem.*, **26**, 51).—The modified method proposed by Huss (Abstr., 1886, 1073) yields results which are too low; the organic matters dissolved by the nitric acid render the precipitation of the phosphoric acid incomplete, a defect which is not removed by the quarter-hour's boiling, or by the addition of ammonium chloride.

M. J. S.

**Determination of Boric Acid.** By T. ROSENBLADT (*Zeit. anal. Chem.*, **26**, 18—23).—Boric acid can be completely volatilised by repeated distillation with dry methyl alcohol. The substance is placed in a dry flask fitted with a stopcock funnel and condenser. The lower end of the condenser is fitted by a cork into an empty flask, from which a double bent tube dips under ammonium carbonate solution. The substance is moistened with methyl alcohol, then a small excess of concentrated sulphuric acid is added, and a further quantity of methyl alcohol. This is distilled over into the lower flask, as are also several subsequently added quantities: 40 to 50 c.c. of the alcohol in 8 or 10 portions will carry over 0.3 gram of  $B_2O_3$  completely. The distillate is then mixed with ammonium carbonate and evaporated in a platinum basin, in which about 3 parts of magnesia for 1 of boric acid have been strongly ignited and weighed. The increase of weight gives the amount of  $B_2O_3$ .

Substances insoluble in acid require to be fused with alkaline carbonates. If containing fluorine, they must first be strongly ignited. If chlorides are present, an excess of silver sulphate must be added before distilling. The methyl alcohol employed must not darken or evolve sulphurous acid when heated with sulphuric acid.

The test determinations communicated are highly satisfactory. (Compare next Abstract.)

M. J. S.

**Separation and Estimation of Boric Acid.** By F. A. GOOCH (*Chem. News*, **55**, 7—10; compare preceding Abstract).—Boric acid is proved experimentally to be more volatile in methyl alcohol than in ethyl alcohol or in water. This volatility is diminished by the presence of water, hydrochloric acid, amyl alcohol or sulphuric acid; but the residue from the treatment of borax with hydrochloric, nitric, or acetic acid parts readily with its boric acid in the vapour of methyl alcohol; in the last case owing to the tendency of sodium acetate to become alkaline, the residue must be kept acid with acetic acid. For the retention of the boric acid thus volatilised, so as to weigh it after an ignition, magnesium oxide proved unsuitable, owing to its insolubility; lime, on the other hand, is quite efficient, but with lime, hydrochloric acid must not be used for decomposing the borate, as the chlorine of calcium chloride is not readily driven off by heat. On these facts the following method is based:—The substance dissolved in water and nitric acid, or acetic acid, or in the acids alone, is run into a retort connected with a condenser and receiver, and heated by means of a paraffin bath and distilled to dryness. The residue is treated six times successively with 10 c.c. of methyl alcohol, being evaporated to dryness after each addition; when nitric acid is used, a little water is added from time to time to break up the cake of

nitrate; when acetic acid has been used, a few drops of acetic acid are added with the fourth portion of methyl alcohol. In all cases the receiver contains a quantity of lime ignited and weighed before and after the distillation; any increase in the latter weighing is due to boric acid. When chlorides are present in the original substance it is best to dissolve it in nitric acid, and remove the chlorine by means of silver nitrate before distilling, although decomposition with acetic acid and direct distillation may be used successfully. The number of distillations required really depends on the quantity of boric acid present. A neat and convenient apparatus is described which may prove useful in other similar operations, besides this for which it was devised. Many experimental details of interest are also included in the original paper.

D. A. L.

**Absorption Tubes for Estimating the Carbonic Anhydride in Air.** By T. C. VAN NÜYS (*Amer. Chem. J.*, **8**, 315—323; compare Abstr., 1886, 835).—The carbonic anhydride is absorbed in two long tubes shaped like Guy-Lussac burettes, but provided at the bottom with an outlet and stopcock. They are filled with air free from carbonic anhydride, baryta-water is introduced, and the air to be analysed aspirated through; the tubes are then emptied and rinsed into a flask for titration. Full particulars are given of all the precautions necessary.

H. B.

**Microscopical Analysis.** By K. HAUSHOFER (*Jahrb. f. Min.*, 1887, **1**, Ref., 13—15).—A number of substances, when treated with hot, concentrated sulphuric acid in an assay tube (0.2 c.c. of acid to 10 mgrms. of the substance), are oxidised and partially dissolved. On cooling, anhydrous sulphates frequently separate out, the crystalline form of which, detected under the microscope, may be characteristic for certain metals. Thus, *copper* compounds give a green residue, which, under the microscope, is seen to consist of colourless or pale violet hexagonal plates (rhombic?), the plane angles of which measure  $120^\circ$ . *Iron* compounds give colourless, thin tablets, rhombic in appearance, with an acute plane angle of  $87^\circ$ . *Zinc* compounds give prisms with forked ends, suggesting the forms of gypsum crystals. *Mercury* compounds give a colourless crystalline powder; the crystals rarely have distinct forms; they are tabular crystals with a rhombic character. *Silver* compounds, with the exception of the halogen salts, give rhombic pyramids with an acute basal angle of  $77^\circ$ , and with indications of the planes of a dome, and of vertical pinacoids. Only a few of the *nickel* compounds occurring in nature give salts which crystallise distinctly. Nickel arsenide, gersdorffite, and ullmannite give forms resembling square prisms with a pyramid superimposed. Of the *manganese* compounds, manganese spar and manganese sulphide give rather large prisms with oblique terminal planes. On exposure to the air, a mass of smaller prisms is formed. Manganite, braunite and hausmannite give colourless prismatic crystals. *Arsenic* compounds give octahedra of  $\text{As}_2\text{O}_3$ , in addition to the sulphates. *Antimony* oxide and sulphide give colourless, prismatic crystals. All the *borates* occurring in nature are decomposed in concentrated sulphuric acid. On cooling, the boric acid separates out in

what seem to be hexagonal tablets. This method is not adapted for the detection of boron in tourmaline and axinite. B. H. B.

**Microchemical Tests.** By K. HAUSHOFER (*Jahrb. f. Min.*, 1887, 1, Ref., 15—17).—*Tellurium* treated with concentrated sulphuric acid gives an amaranth-red colour. On heating, the red colour disappears, and tellurous anhydride separates out on cooling in colourless, hexagonal tablets. The crystals are soluble in water, and on evaporation separate out again; the tellurous anhydride obtained by evaporation being rhombic.

*Selenium* dissolves in concentrated sulphuric acid with a leek-green colour, and on cooling gives a brick-red sediment of selenium.

*Bismuth* treated with boiling, concentrated sulphuric acid gives numerous very small prisms on cooling. On exposure to air, these rapidly dissolve, and acicular crystals grouped in the shape of a star are formed. These also disappear after a short time. After a few hours large, transparent, monoclinic tablets are formed.

Solutions containing 0.1 gram of *barium* chloride in 20 to 80 c.c., treated with 1 c.c. of concentrated hydrochloric acid, give, with dilute sulphuric acid, rectangular crystals which may be distinctly recognised. With *strontium*, very perfect, rhombic crystals are obtained.

On precipitating *lead* from boiling dilute solutions with sulphuric acid, the sulphate appears as sharply defined rhombic tablets. If this precipitate is washed and treated with a drop of hydrochloric acid, the characteristic long lamellæ and rhombic crystals of lead chloride are immediately formed. B. H. B.

**Titration of Zinc and Cadmium Sulphides with Iodine.** By P. v. BERG (*Zeit. anal. Chem.*, 26, 23—25).—The filter containing the washed sulphides is thrown, as soon as it is drained, into a bottle which contains about 800 c.c. of recently boiled water, and from which the air has been expelled by carbonic anhydride. The bottle is well shaken to break up the precipitate, otherwise the separated sulphur would partially protect the metallic sulphide. A moderate quantity of hydrochloric acid is added (which need not entirely dissolve the precipitate), and then an excess of iodine solution of known strength. The residual free iodine must, without loss of time, be titrated with thiosulphate. The whole operation takes about five minutes. The results obtained on known quantities ranged from 98.8 to 100.2 per cent. In the case of manganese, only about 95 per cent. was obtained. Cobalt and nickel sulphides are not attacked by the acid iodine solution. M. J. S.

**Valuation of Zinc-dust.** By F. WEIL (*Compt. rend.*, 103, 1013—1014).—The zinc-dust is mixed with a standard solution of cupric chloride containing 10 grams of metallic copper per litre, and when all the zinc has been dissolved, the liquid is poured off, strongly acidified with hydrochloric acid, and the excess of copper determined by means of a standard solution of stannous chloride (*Abstr.*, 1883, 509).

The copper solution is prepared by dissolving cupric oxide (from

the nitrate) in hydrochloric acid, and then adding ammonia until a very slight turbidity is produced. If the substances are mixed in a platinum dish, solution takes place rapidly. If a porcelain dish is used, a flat spiral of platinum wire must be placed in the liquid. In order to ascertain if all the zinc has been dissolved, the precipitate is touched with a clean platinum wire; if the wire acquires a red or black coating some zinc is still undissolved, but if it remains bright the reaction is complete.

C. H. B.

**Detection of Mercury in Organic Liquids.** By A. ALMÉN (*Arch. Pharm.* [3], 24, 1031).—This method is a modification of Reinsch's. In the liquid mixed with 8–10 per cent. hydrochloric acid a well-ignited copper or better brass wire is immersed, and the whole is heated gently during  $1\frac{1}{2}$  hours. The wire is then white if much mercury is present or dirty grey if less; it is dried on paper, placed in a small glass tube, which is sealed off a few mm. above the wire. On carefully heating so as to distil off the mercury, there appears close to the wire a reddish-brown non-volatile incrustation, then mercury beads, beyond yellow oil drops, and finally a little water. A lens or microscope may be necessary for the examination of the deposits. In the case of urine, a considerable quantity can be heated with aqueous soda, with or without sugar as a reducing agent; after settling, the test can be applied to a portion of the sediment.

J. T.

**Separation of Mercury and Palladium from one another, and from Lead, Copper, and Bismuth.** By T. ROSENBLADT (*Zeit. anal. Chem.*, 26, 15–18).—The sulphides of mercury and palladium are soluble in potassium thiocarbonate, whilst those of lead, copper, and bismuth are insoluble. A solution prepared by dissolving 1 part of sulphur in 2 parts of carbon bisulphide and adding 23 parts of aqueous potash of sp. gr. 1.13, will dissolve 20 grams of mercuric sulphide per litre.

The mixed sulphides are boiled for half an hour with a sufficient quantity of the thiocarbonate, and the insoluble sulphides are washed until the filtrate is colourless. From the solution, both mercury and palladium may be thrown down by hydrochloric acid, but a stream of carbonic anhydride precipitates the mercury only. The mercuric sulphide contains free sulphur, which, after drying, may be conveniently removed by extraction with carbon bisulphide in a Soxhlet's apparatus.

The results reported leave nothing to be desired as regards accuracy.

M. J. S.

**Estimation of Alumina and Iron Oxide in Mineral Phosphates and Manures.** By R. T. THOMSON (*J. Soc. Chem. Ind.*, 5, 152–154).—After considering the methods of separating the phosphates of aluminium and iron from acid solutions containing these substances in conjunction with calcium phosphate, the author gives a process for determining these compounds in commercial phosphates. Two or three grams of the substance is dissolved in hydrochloric acid, evaporated to dryness, the residue redissolved in hydrochloric acid, diluted, and filtered. The phosphates are then precipitated

either by ammonium acetate or by neutralisation with ammonia, soda, or potash. In the former case, a large excess of acetic acid should be used to ensure the complete removal of the lime. The precipitate is then collected on a filter and washed repeatedly with cold 1 per cent. solution of ammonium nitrate, containing di-ammonium hydrogen phosphate equivalent to 0.05 gram phosphoric anhydride per litre. It is then thoroughly washed with the same solution (hot), and finally once with water, then dried, ignited, and weighed. It may then be dissolved in hydrochloric acid, reduced with stannous chloride, and the iron determined by standard potassium dichromate. The result is calculated to iron phosphate, which is subtracted from the weight of the precipitate, and the remaining aluminium phosphate calculated to alumina. Test analyses gave good results.

If a high result is apprehended from the precipitation of calcium phosphate, the precipitate may be dissolved in hydrochloric acid, excess of caustic soda added, boiled, and filtered. The iron in the residue is then determined volumetrically; and the alumina in the filtrate, after acidifying with hydrochloric acid, by either of the above methods. It is advisable to add some phosphoric acid or ammonium phosphate to ensure the presence of an excess of the former sufficient to produce normal aluminium phosphate. When the mineral phosphates contain fluorides, it is best to heat the weighed portion of the sample with concentrated sulphuric acid until these compounds are decomposed and all the hydrofluoric acid is expelled. The residue is then treated with hydrochloric acid and the determination proceeded with.

D. B.

**Estimation of Nickel in Ores, Mattes, Slags, &c.** By T. MOORE (*Chem. News*, 54, 300).—After the separation of copper, arsenic, &c., in the usual manner, the strongly acid solution is diluted, and an excess of sodium phosphate added; any precipitate formed is redissolved by the aid of acid. The whole is boiled, and while boiling, sodium acetate is added until all the iron phosphate is precipitated, the boiling is continued for a minute, and the precipitate collected and washed with hot water containing a little sodium acetate and acetic acid. The filtrate is warmed and treated with potash and bromine. The precipitate is dissolved in warm, dilute sulphuric acid, made strongly alkaline with ammonia, and electrolysed. Metallic nickel is deposited, the small quantity of iron present which has escaped precipitation floats about as an insoluble oxide, and does not influence the results, whilst chromium and manganese remain in solution; part of the latter is deposited on the anode as peroxide (compare *Abstr.*, 1886, 921). The aluminium remains with the iron. When greater accuracy is required, the precipitation of the iron may be repeated.

D. A. L.

**Volumetric Determination of Chromium.** By W. J. SELL (*Chem. News*, 54, 299—300).—The author has devised a method of applying to analytical purposes the reaction between hydrogen peroxide and chromium oxides (see Martinon, *Abstr.*, 1886, 984). The aqueous solution of the substance to be analysed is treated with sufficient potash to dissolve the precipitate first formed, hydrogen

peroxide is then added, and the whole boiled briskly for at least 15 minutes, the chromic acid is then easily determined by any method in the resulting solution of the chromate formed. Aluminium and zinc do not interfere with the reaction, but with iron the results are low. The method was devised before the publication of the paper referred to. Another use for hydrogen peroxide is suggested for qualitative purposes. The ammonium precipitate in group III is dissolved in dilute nitric acid, poured into excess of potash containing hydrogen peroxide, boiled and filtered. The solution contains the aluminium and the chromium as chromate; the iron, &c., being precipitated.

D. A. L.

**Analysis of Chrome Paints.** By W. L. BROWN (*Chem. News*, **54**, 329—331).—Mixtures of lead chromate and sulphate, or chromate, sulphate and carbonate, are treated with hydrochloric acid for insoluble adulterants, whilst the solution is used for the chromium and sulphuric acid determinations. For lead, the paint is decomposed with concentrated sulphuric acid, and the lead, as in all succeeding cases, is weighed as sulphate. Red chromate of lead is decomposed with nitric acid and a few drops of alcohol added to facilitate the solution of the chromium. Chrome-green is treated with hydrochloric acid; lead, chromium, sulphuric acid, and sometimes iron, pass into solution, the Prussian blue, &c., remains as residue (it is sometimes slightly attacked). Any lead found in excess of that required by the chromium and sulphuric acid, is regarded as carbonate. Full details of separation, &c., are given in the paper.

D. A. L.

**Estimate of Chromate in the Presence of Dichromate.** By N. McCULLOCH (*Chem. News*, **55**, 2—3). As is well known, the blue coloration soluble in ether which results from the action of hydrogen peroxide on chromic acid is only produced with dichromates in acidified solutions, or with chromates to which acid has been added in excess of that required to convert them into dichromates. The following quick and ready method for estimating chromate in the presence of dichromate is founded on this basis. The substance, dissolved in a little water, is mixed with a few c.c. of hydrogen peroxide solution and covered with a layer of ether; standard sulphuric acid is run in gradually until after agitation the ether assumes a blue colour. From the quantity of acid used, the amount of chromate present is easily calculated.

D. A. L.

**Estimation of Tin and Lead in Alloys.** By O. WACHSMUTH (*Chem. Centr.*, 1886, 491).—For the rapid estimation of the composition of alloys of these two metals, the author recommends the determination of the specific gravities and melting points.

The specific gravities are not sensibly affected by the small admixture of antimony (2 to 5 per cent.), used in preparing many alloys. The specific gravities and melting points of mixtures of tin and lead, containing from 5 to 95 per cent. of each metal, are given.

C. F. C.

**Colour Reactions of Titanic, Niobic, Tantallic, and Stannic Anhydrides.** By L. LEVY (*Compt. rend.*, **103**, 1074—1076).—

various colour reactions given by these anhydrides with certain alkaloïds, phenols, and with hydroxybenzoic acids in presence of concentrated sulphuric acid are described. The colours disappear when water is added, except in the case of stannic anhydride, and the substances must be free from nitrates and nitrites. Silica, alumina, and zinc and uranium oxides give no similar colour reactions.

In order to detect the four anhydrides when mixed together, the substance is strongly heated with ammonium carbonate to remove nitrites and nitrates. Different portions are then mixed with strong sulphuric acid and one of the following reagents: morphine, a crimson colour indicates titanic anhydride; codeïne, a mauve colour indicates niobic anhydride; resorcinol, an amethyst colour, tantalic anhydride (green if much titanic and niobic anhydrides are present);  $\alpha$ -naphthol and a few drops of water, amethyst colour, stannic anhydride.

These reactions may be used in the reverse way to detect certain alkaloïds and phenols.

C. H. B.

**Colour Reactions of Arsenic, Arsenious, Vanadic, and Molybdic Anhydrides, and of Antimony and Bismuth Oxides.** By L. LEVY (*Compt. rend.*, **103**, 1195—1196).—A continuation of the author's previous experiments (preceding Abstract). In most cases the colours are destroyed or modified by the addition of water.

Arsenic anhydride mixed with catechol gives a grey-green colour, which changes to amethyst. In this way it can be distinguished from phosphoric anhydride, which gives no coloration, and from vanadic anhydride, which gives a dark green colour, becoming paler on addition of water. With arsenic anhydride, resorcinol and quinol give respectively a sepia and a yellowish coloration, and it is evident therefore that this reaction may be used to distinguish between these three isomeric dihydric phenols.

Vanadic anhydride with resorcinol gives a dark green coloration, which becomes violet on addition of water, and it can be distinguished by this reaction from molybdic and phosphoric anhydrides.

Bismuth oxide and catechol give a greenish coloration, which becomes deeper after the addition of water. Antimony oxide and arsenic anhydride give a flesh coloration under the same conditions.

Arsenites give a flesh tint with catechol, which distinguishes them from the arsenates, whilst  $\alpha$ -naphthol gives no coloration with any of the oxides similar to that which it gives with stannic oxide.

C. H. B.

**Post-mortem Detection of Chloroform.** By C. LUEDEKING (*Amer. Chem. J.*, **8**, 358—361).—The lungs or other viscera are made slightly alkaline by sodium carbonate, and heated on a water-bath in a flask, through which a current of air is passing. The escaping gases are passed through a short length of red-hot tube, and then tested with potassium iodide and starch paper. As the result of six experiments on dogs it is shown that chloroform may be detected at least four weeks after death, even when the carcasses have been exposed to the air at full summer's heat; during the decomposition no substances are formed which interfere with the above tests.

H. B.

**Estimation of Glycerol in Wine and Beer.** By SKALWEIT (*Chem. Centr.*, 1886, 541).—The author isolates the glycerol in the usual way, obtaining it in a concentrated form, in which, the aggregate weight having been determined, the percentage of glycerol is estimated by determining the coefficient of refraction in the Abbé instrument. Full details are given. C. F. C.

**Separation and Quantitative Estimation of Melitose (Raffinose) in Cane-sugar.** By C. SCHEIBLER (*Ber.*, 19, 2868—2874. Compare Abstr., 1885, 962.)—Further evidence has confirmed the formula  $C_{15}H_{32}O_{16} + 5H_2O$  for melitose. The best method of drying melitose is to place it in a Liebig's drying tube, heated at 70–80° in a water-bath, and so arranged that a small quantity of air, dried over sulphuric acid, enters it by a capillary tube, whilst a partial vacuum is maintained by a Bunsen pump. After one hour's drying under these conditions, so much water is removed that on raising the temperature of the bath to 100° to complete the dehydration, fusion does not occur. Melitose dried in this way melts at 118–119°; it is very hygroscopic, and in a moist atmosphere gradually absorbs the whole of the water removed by drying.

The author finds that melitose is far more soluble than cane-sugar in commercial absolute methyl alcohol, 100 c.c. of the alcohol dissolving 9.5 and 0.4 grams respectively at the ordinary temperature; on this property is based a method for its extraction from the molasses of beetroot sugar. The crystalline product, dried as described, is extracted with absolute methyl alcohol, and the syrupy residue obtained on distilling off the alcohol, is taken up with a little water, and purified by precipitation with ethyl alcohol.

A method for the quantitative estimation of melitose in cane-sugar has been devised, and is under investigation. According to the details given in the paper, commercial absolute methyl alcohol is saturated with cane-sugar at a known temperature, and the rotatory power of the solution is determined. A known weight of the impure cane-sugar, dried by the above method, is then extracted by 100 c.c. of the solution, the temperature being kept constant, and the rotatory power is again determined. From the increase in the rotation, the amount of melitose present can be calculated. W. P. W.

**Quantitative Estimation of Raffinose or Melitose.** By R. CREYDT (*Ber.*, 19, 3115–3119).—Raffinose can be determined either optically or gravimetrically after conversion into mucic acid. In the optical examination of cane-sugar and of raffinose, the amount is calculated by the subjoined formulæ—

$$Z = \frac{C - 0.493A}{0.827} \qquad R = \frac{A - Z}{1.57},$$

in which A = the amount of direct polarisation, B = the polarisation at 20° after inversion, C = the difference between B and A, Z = the percentage of cane-sugar, and R = the percentage of raffinose. This method is, however, not available in the presence of other optically active substances such as dextran or invert sugar. When these are

present, raffinose is best estimated by converting it into mucic acid by the following process:—

About 5 grams of dry substance is treated with 6.0 c.c. of nitric acid, sp. gr. 1.15, and the mixture evaporated to about one-third of its volume on the water-bath. After cooling, a known quantity of water is added, and the separation of the mucic acid assisted by the addition of a known weight of that acid, the whole being well stirred. The precipitate is then collected on a tared filter, dried, and weighed. The weight of the raffinose must be estimated from that of the mucic acid by aid of an empirical table which has been worked out by the author, but is not given in the paper.

A. J. G.

**Detection and Determination of Lactic Acid.** By R. PALM (*Zeit. anal. Chem.*, 26, 33—35).—Lactic acid, when mixed with lead acetate and alcoholic ammonia, gives a heavy, granular precipitate of the constant formula  $3\text{PbO}, 2\text{C}_3\text{H}_5\text{O}_3$ . To examine an animal or vegetable organ for free lactic acid, it is extracted with ether (if for a lactate, acidification with sulphuric acid precedes the extraction with ether), the ethereal solution is evaporated to a syrup, and this is treated with water. The filtered aqueous solution is mixed with lead acetate, and any precipitate produced is filtered off. On adding more lead acetate to the filtrate and then alcoholic ammonia, the lactate is thrown down free from foreign substances. It may be washed with alcohol, in which it is absolutely insoluble, and the amount of lactic acid in it may be ascertained from the loss on ignition. Minute traces of lactic acid may be thrown down with greater certainty by shaking the solution (prepared as above) with an excess of freshly precipitated lead hydroxide. The precipitate produced in either way yields pure lactic acid when decomposed by hydrogen sulphide and extracted with ether.

M. J. S.

**Use of Turmeric as an Indicator for Citric Acid.** By F. WATTS (*J. Soc. Chem. Ind.*, 5, 214—215).—When litmus is employed as an indicator in the determination of citric acid by alkalimetry, the results obtained are frequently too low, on account of the want of sharpness in the reaction. Warrington (this Journal, 1875, 925) recommends the preparation of a special litmus-paper, but even with this precaution the difficulty is not entirely removed. The author has obtained good results by using tincture of turmeric in place of litmus. Drops of this tincture are placed on a white tile, the liquid spreading out in bright yellow films. The slightest excess of alkali causes the development of the well-known red-brown colour. In using this indicator, much time is saved by employing litmus-paper to determine the near approach to neutralisation, proceeding with the addition of alkali until the litmus-paper is turned slightly blue, and determining the exact point of neutrality by means of the turmeric.

D. B.

**Determination of the Fatty Acids in Soap.** By B. SCHULZE (*Zeit. anal. Chem.*, 26, 27—28).—The soap is decomposed in a conical flask by dilute sulphuric acid. Ether is added to dissolve the fatty acids. The aqueous layer is then removed by a pipette. Water is

added, and is removed in the same way four times. A drop of barium chloride throws down any traces of sulphuric acid still left. The ethereal solution can then be poured off alone on to a filter, and the determination completed as usual.

M. J. S.

**New Method of Estimating Fat in Milk.** By A. CRONANDER (*Bied. Centr.*, 1886, 706—707).—By the new process, the fat in 40 samples can be estimated in six hours. 100 c.c. of milk is mixed and shaken up for an hour with 10 c.c. of aqueous potash (100 grams KHO in 500 c.c. H<sub>2</sub>O) and 30 c.c. of moist ether. After  $\frac{1}{2}$  to 1 hour, the ether will have dissolved out all the fat; the several ethereal solutions may then be simultaneously evaporated on a specially constructed water-bath at 60—65°, and finally heated at 80° for  $\frac{1}{2}$  hour. To measure the volume of the fat, the flasks containing the fat are fitted with corks, through which pass two tubes, of which the one graduated to fractions of cubic centimetres passes only just through the cork; the other passes nearly to the bottom of the flask. Water is then passed into the flask by the longer tube, so that the layer of fat rises and fills the graduated tube, where it is measured. This measurement gives volume per cent., from which the weight per cent. is calculated, according to the following table:—

| Vol. p. c. | Wt. p. c. | Vol. p. c. | Wt. p. c. |
|------------|-----------|------------|-----------|
| 1.0        | 0.89      | 2.5        | 2.22      |
| 1.5        | 1.34      | 3.0        | 2.67      |
| 2.0        | 1.78      | 3.5        | 3.12      |

The results are fairly accurate, but as the measurement is made at 35°, the percentage is slightly low (0.01—0.05 per cent.).

E. W. P.

**Butter Testing.** By J. SKALWEIT (*Analyst*, 11, 90—91).—It is suggested to employ dialysis in butter testing, inasmuch as the glycerides of the soluble butter acids dialyse much more quickly than the other glycerides contained in butter. The examination of the purified fat in an Abbe's refractometer is recommended as especially worthy of attention. The following tables gives the angles obtained by examining various fats at 20°, water = 1.333:—

|   |               |
|---|---------------|
| Butter olein.....                                   | 1.4635        |
| Olein from commercial oleic acid.....               | 1.4635        |
| Oleic acid.....                                     | 1.4639        |
| Genuine Gloucester butter (mean of two experiments) | 1.4655        |
| Cocoa butter.....                                   | 1.4680        |
| Lard.....   | 1.4690        |
| Butterine, Hanoverian (four experiments).....       | 1.4693—1.4712 |
| Butterine, English.....                             | 1.4733        |
| Cotton-seed oil { refined.....                      | 1.4748        |
| { crude.....  | 1.4732        |
| Cod-liver oil.....                                  | 1.4801        |
| Linseed oil.....                                    | 1.4835        |
| Margarine oil.....                                  | 1.4680        |
| Margarine, 1st quality.....                         | 1.4692        |

D. A. L.

**Butter Testing.** By H. HAGER (*Chem. Centr.*, 1886, 495).—The author recommends the Reichert-Meissl method of examining butter, the chief feature of which is a determination of the volatile fatty acids. The method is simpler and more expeditious than Hehner's. The butter is filtered and 5 grams are saponified with pure sodium hydroxide (2 grams) in presence of alcohol (80 per cent.). The volatile fatty acids are separated by decomposition with sulphuric acid and distillation, and estimated by titrating the distillate with decinormal alkali. The following table gives the number of c.c. of the latter required to neutralise the distillate in the case of certain typical fats:—

|                     |               |
|---------------------|---------------|
| Normal butter ..... | 26 to 31 c.c. |
| Oleomargarine ..... | 1.9     "     |
| Cocoa butter .....  | 7.4     "     |
| Pig's fat .....     | 0.6     "     |

C. F. C.

**Butter Analysis.** By F. W. A. WOLL (*Zeit. anal. Chem.*, 26, 28—33).—To ascertain the degree of accuracy with which the percentage of true butter in butterine could be determined by Köttstorfer's and Reichert's methods respectively, the author made mixtures of "oleo-oil" and genuine butter, containing 20, 40, 50, 60, and 80 per cent. of the latter, and analysed each mixture by both methods. The genuine butter employed being one requiring a low percentage of alkali (222.2—223.2 mgrms. per gram), the use of Köttstorfer's mean value, 227, indicated in all cases too low a percentage of real butter, the maximum error being 16.1, and the average error 6.5 per cent. Reichert's method (employing the mean factor 7.3) gave much closer numbers (maximum error 4.5 per cent.). (See *Abstr.*, 1879, 406, 983.)

A low specific gravity is a valuable indication of adulteration, most of the materials used in making butterine having a sp. gr. below 0.90536, whilst that of genuine butter is generally between 0.914 and 0.912.

The results of the examination of 37 samples of butter, butterine, and butterine materials are given.

M. J. S.

**Reichert's Method of Butter Analysis.** By H. B. CORNWALL and S. WALLACE (*Chem. News*, 54, 315—316).—Reichert's method is very highly recommended. The authors recognise the fact that the proportion of volatile fatty acid varies considerably in different pure butters, and are therefore of opinion that the products of single cows only should be taken into consideration when establishing standards. From this standpoint and from numerous observations, they consider that the minimum standard should not exceed 11 c.c. of decinormal alkali consumed in Reichert's method when 2.5 grams of fat are employed. Moreover, they note that there is no apparent connection between the number of c.c. of decinormal alkali used and any of the following conditions: season of the year, breed, food, age of cow, or time after calving.

The authors' average was 13.68 c.c. decinormal alkali. These results and conclusions differ from those obtained by Munier (*Abstr.*, 1883, 247).  
D. A. L.

**Carrot Colour in Butter.** By R. W. MOORE (*Analyst*, **11**, 163—164).—When fat coloured with carrot is dissolved in carbon bisulphide and mixed with alcohol, two layers form, the carbon bisulphide solution being yellow, the alcoholic colourless. On adding a drop of dilute ferric chloride, insufficient in itself to colour the alcohol, the carbon bisulphide becomes gradually decolorised, whilst the alcohol becomes distinctly yellow. Beef fat, mutton fat, olive oil, lard, and butter coloured with carrot all respond to this test. Natural uncoloured butter is not decolorised in this manner.  
D. A. L.

**A New Ureometer.** By J. MARSHALL (*Zeit. physiol. Chem.*, **11**, 179—180).—A new apparatus for the estimation of urea by means of the sodium hypobromite method is described and figured. It is a modification of that devised by Greene, the chief difference being that the graduated tube can be easily removed and cleaned.  
W. D. H.

**Separation of Nitrogenous Substances by Means of Phosphomolybdic Acid.** By A. HIRSCHLER (*Zeit. physiol. Chem.*, **11**, 25—40).—Phosphomolybdic acid precipitates proteïds, peptones, gelatin, xanthine, guanine, hypoxanthine, adenine, and creatinine. It does not precipitate aspartic acid, leucine, glycocine, urea, or creatine. In order to make quantitative analyses of nitrogen by Kjeldahl's method, it is not necessary that the phosphomolybdic acid should be first removed if excess has been employed. Proteïd, peptone, and propeptone are, moreover, completely precipitated by this reagent; this precipitate does not carry down with it any leucine or other substances which are not usually precipitated by the acid.

Applying this method for the detection and estimation of leucine in peptic digestion, the teaching of Hoppe-Seyler is confirmed, namely, that a small amount of leucine is formed from proteïd during that process, but much more slowly than in pancreatic digestion.

In experiments on the composition of the liver of animals (dogs) poisoned by phosphorus, it was found that in certain cases of typical phosphorus poisoning, the formation of amido-acids either does not take place at all, or only to a very slight extent.  
W. D. H.

**Opium Testing.** By E. DIETRICH (*Arch. Pharm.* [3], **24**, 1023—1024).—6 grams of air-dried opium powder is macerated with 60 c.c. of water with occasional shaking during 12 hours and then filtered; 50 c.c. of the filtrate is treated with 2 c.c. of normal ammonia, well mixed and immediately filtered through a ribbed filter. 44.2 c.c. of the filtrate, = 4 grams of opium, is placed in a tared Erlenmeyer's flask with 10 c.c. of ether and agitated with a swinging motion for a minute; 4 c.c. of normal ammonia is now added, well mixed by swinging, and

the flask allowed to remain six hours. The ether layer is now carefully passed through an 8 cm. filter; 10 c.c. of ether is added to the flask, shaken for a moment, and also passed through the filter. The crystals adhering to the flask are washed down by means of the aqueous solution in the flask, which is passed through the filter; the flask and filter are then twice washed with 5 c.c. of water saturated with ether. After well draining both filter and flask, they are dried at 100°, and the contents of the filter are brushed into the flask, which is dried and weighed until constant. In the case of opium extract, 3 grams is taken, dissolved in 42 c.c. of water, allowed to remain for an hour, treated with 2 c.c. of normal ammonia and filtered; 31.7 c.c. of the filtrate (= 2 grams of extract) is treated as above with 10 c.c. of ether and 4 c.c. of normal ammonia. In the case of *Tinctura opii* and *Tinctura opii crocata*, 50 grams of either is evaporated to one-half, the original weight made up with water, 2 c.c. of normal ammonia added, and filtered; 44.2 c.c. of the filtrate is treated as above. The method requires little time, is easily carried out, gives a sharp separation of the various constituents, gives very uniform results, and yields almost the whole of the morphine. J. T.

**Microchemical Detection of Tannin.** By J. W. MOLL (*Ann. Agronom.*, 12, 496).—Portions of the plant cut into small pieces are placed in a saturated solution of copper acetate (7 per cent.) and allowed to remain for 7—10 days. Sections are made and placed in a drop of acetate of iron of 0.5 per cent. strength for a few minutes, they are then washed with water and transferred to a glass containing alcohol in order to expel the air and to dissolve out the chlorophyll, afterwards they are placed in glycerol for observation. The tannin is precipitated by the copper acetate, and the precipitate is stained green or blue by the iron salt, so that these two classes of tannins can be readily distinguished. J. M. H. M.

**Tannin Determination.** By E. B. (*Zeit. anal. Chem.*, 25, 527—528).—The author having been unable to obtain the hide powder required for v. Schröder's method, has employed a solution of ferric acetate, which, when added in excess, throws down all the tannin and gives a clear filtrate fit for titration with permanganate in the usual way. The solution contained 48.2 grams of iron alum, 25 grams of sodium acetate, and 40 c.c. of 50 per cent. acetic acid in a litre. He requests chemists who are in the habit of using hide powder to make comparative determinations with this precipitant. M. J. S.

**Thalleioquinine Reaction.** By E. MYLIUS (*Chem. Centr.*, 1886, 602—603).—About 0.01 gram of the salt to be tested for quinine is treated on a watch-glass with about the same bulk of potassium chlorate and a drop of strong sulphuric acid; ammonia is then added in excess, and the whole stirred, when the solution assumes a dark-green colour. Less than a milligram of quinine can be easily detected by this reaction. L. T. T.

**Analysis of Pepper.** By C. HEISCH (*Analyst*, 11, 186—190).—It is noted that sand, &c., should be regarded as an adulterant of ground pepper, since almost all sand is removed when the peppercorns are properly cleansed before grinding. The organic matter of pepper should consist of not less than 50 per cent. of starch, which is easily distinguished under the microscope owing to the smallness of the grains; long-pepper starch-grains are, however, very similar to rice starch, but as long-pepper costs nearly as much as good black pepper, it would scarcely be used as an adulterant, and rice with its large proportion of starch could not well be mistaken for pepper. Results of several analyses of pepper are given, including water, ash, starch, alcoholic extract, piperine, &c.; the starch being estimated by boiling with 10 per cent. hydrochloric acid for three hours and polarising. (With regard to the last point, compare Harvey, this vol., p. 125.)

D. A. L.

**Hæmatoscopy; a new Method of Blood Analysis.** By HÉNOQUE (*Compt. rend.*, 103, 817—820).—The *hæmatoscope* is a small, wedge-shaped glass cell on which is etched a millimetre scale, by means of which the thickness of the layer of liquid at any point is ascertained. The blood to be examined is placed without dilution in the hæmatoscope, and the thickness of the layer which shows both absorption-bands of equal intensity is determined. The percentage of oxyhæmoglobin is then ascertained from special tables.

The *time of reduction* of oxyhæmoglobin is determined by examining the spectrum of the blood under the thumb-nail. With a direct vision spectroscope the first and sometimes the second band of oxyhæmoglobin can readily be seen. If a ligature is tied round the phalanx, the bands gradually disappear, and the time required for their disappearance after the ligature is tied, is called the time of reduction. This time varies from 25—90 seconds, the mean duration for a healthy person in a state of repose being 60 seconds.

*Activity of reduction* is measured in the following manner. In a healthy man, with blood containing about 14 per cent. of oxyhæmoglobin, the time of reduction is 70 seconds, from which it is calculated that 0.2 per cent. of oxyhæmoglobin is reduced per second. This quantity is taken as the unit activity of reduction, and the activity corresponding with various times of reduction and percentage of oxyhæmoglobin as determined by the methods just described is obtained by means of the expression—

$$\text{Activity of reduction } \epsilon = \frac{\text{quantity of oxyhæmoglobin}}{\text{time of reduction}} \times 5.$$

## General and Physical Chemistry.

---

**Distinction between Spectral Lines of Solar and Terrestrial Origin.** By M. A. CORNU (*Phil. Mag.*, 22, 458—463).—The dark lines of the solar spectrum are of two kinds. Those of one class (C, F, D, E, G, H, and the magnesium band *b* in the green) are of solar origin, and always present the same aspect: others (A, B, and band *a* in the red) are telluric, produced by selective absorption in the earth's atmosphere, and become broader and darker as the sun sinks towards the horizon. It is by this latter characteristic that they have been chiefly recognised hitherto.

The author's method of distinction is based on Fizeau's principle of the displacement of lines in the spectrum, when the source of light is in a state of absolute or relative motion. This displacement may be connected with the velocity by very simple expressions, and has been used to calculate the velocity of the source. In practice, the method consists in allowing the light from opposite edges of the solar disc (where of course the motions are opposed) to fall on the slit of the spectroscope; the telluric lines remain steady, while the solar lines appear to move. The motion is easily detected by noting the position of any line with respect to one of the particles of dust always found on the cross-wires. It becomes still more sensible when, by an arrangement which is figured and described, the collecting lens is caused to oscillate two or three times a second, so as to throw opposite edges of the sun's image alternately upon the slit. The solar lines are then distinguished at a glance.

The method has been applied to the anatomy of band *a*, and to ascertaining the telluric origin of some lines beyond  $\delta$ , and the solar origin of Kirchhoff's line 1474. Since this line oscillates, the vapour producing it must be carried round by the sun's rotation.

CH. B.

**Spectrum of Germanium.** By G. KOBB (*Ann. Phys. Chem.* [2], 29, 670—671).—The author has examined the spectrum of germanium by viewing in a six-prism spectroscope the spark of an induction-coil taken between terminals of platinum and germanium. The

| Wave-length. | Remarks.         | Wave-length. | Remarks.          |
|--------------|------------------|--------------|-------------------|
| 6336·0       | —                | 5131·0       | Bright, diffused. |
| 6020·0       | very sharp       | 4813·0       | Ditto.            |
| 5892·0       | ditto            | 4742·0       | Ditto.            |
| 5255·5       | —                | 4684·5       | Sharp, faint.     |
| 5228·5       | —                | 4291·0       | Faint, diffused.  |
| 5209·0       | —                | 4260·5       | Ditto.            |
| 5177·5       | bright, diffused | 4225·5       | —                 |
| 5134·0       | —                | 4178·0       | Ditto.            |

position of each line was determined by micrometric measurements of its distance from two neighbouring solar lines. The results are contained in the table (p. 313), in which wave-lengths are given in  $\frac{1}{10^{10}}$  metre.

A. H. F.

**Fluorescence of the Pigments of Fungi.** By A. WEISS (*Chem. Centr.*, 1886, 670—671).—The fluorescence of alcoholic extracts of fungi was examined by means of a cone of light. All gave a greater or less fluorescence, which was green with yellow or brown-coloured fungi, and blue with red or violet-coloured fungi. The ochre-yellow colouring matters of some *Agaricinæ* give, however, a sky-blue, and the red colouring matter of the heads of *Ammanita muscaria*, a green fluorescence. The spectrum of the blue fluorescent colouring matters of *Russula* shows a wide, very characteristic, black absorption-band in the green and yellow, a feeble one between the lines E and F, and a total absorption of the violet to the line G. The green-yellow band agrees in position with the band which is seen in the spectrum of a living red peony leaf, and also with that given by the blue colouring matter of many *Campanulæ*, after treatment with sulphuric acid. The more intense the colour of the extract, the more the absorption extends towards the red, so that with a thick layer of liquid the whole of the green and yellow is absorbed. The absorption in the violet is similar to that given by the red, blue, and violet leaf colouring matters of the *Phanerogamæ*. The green fluorescent colouring matters of fungi show a feeble absorption-band between E and F, and a wide absorption of the violet end of the spectrum, sometimes even the entire end of the spectrum as far as *b* is absorbed.

G. H. M.

**New Secondary Element.** By M. KALISCHER (*Phil. Mag.*, 21, 164).—The element consists of iron (or carbon) and amalgamated lead in contact with mercury, in a solution of lead nitrate. When charged, the iron (as anode) becomes passive and coated with lead peroxide, which protects it from the liquid. During discharge the peroxide is reduced. Electromotive force on open circuit = 2 to 2.5 volts; on closed circuit = 1.8 volts, falling slightly after a time. The lead plate must be occasionally renewed.

CH. B.

**Electromotive Force of a Constant Voltaic Cell with Moving Plates.** By A. P. LAURIE (*Phil. Mag.*, 21, 409—415).—Before accepting measurements of electromotive force it must be shown, by analysis of the products found in the cell, to what reactions it is really due. This can only be done when the current is passed for a long time, since the electromotive force observed by an electrometer, or by connecting for a short time through a high-resistance galvanometer, may be really due to impurities in the metal, or to a film of gas or oxide on its surface. Hence may arise the want of agreement in some cases between the electromotive forces observed by Wright and those calculated by him from the thermal data.

It is well known that the fall in electromotive force of a cell when the circuit is closed, due to alterations in the layers of liquid in con-

tact with the plates, may be prevented by keeping the liquid in motion. The author has measured the electromotive force of cadmium and platinum immersed in iodine solution, by means of a galvanometer, and finds that it remains constant for a long time when the cadmium plate is kept moving by clockwork. Its initial value was 1.084 volts (by the electrometer 1.076 volts). After two hours, it fell to 1.067 volts (by the electrometer 1.072 volts).

CH. B.

**Electromotive Force of Voltaic Cells having an Aluminium Plate as Electrode.** By A. P. LAURIE (*Phil. Mag.*, 22, 213—216).—Wright (Abstr., 1885, 721) has found that the electromotive force (0.538 volt) of zinc-aluminium cells (zinc in zinc sulphate, aluminium in potash alum) is opposite in direction to that calculated from the thermal data (0.938 volt); so also for other aluminium cells. The author attributes these contradictory results to the well-known property of aluminium in contact with air or water of becoming coated with oxide; and states that the abnormal electromotive force (measured by an electrometer) is reduced to 0.14 volt on cleaning the aluminium with sand-paper. When the aluminium plate is amalgamated, the electromotive force becomes *normal*, and equal to 0.46 volt; and the plate is speedily covered with a growth of oxide. Two aluminium wires, one cleaned, the other amalgamated, placed in a solution of aluminium sulphate, give an electromotive force = 1.08 volts.

Wright in reality measured the electromotive force between aluminium oxide on an aluminium plate and zinc; and the value obtained was probably due to the heat of formation of zinc sulphate—that of aluminium sulphate + that of aluminium oxide—that of water.

CH. B.

**Electrical Resistance of Soft Carbon under Pressure.** By T. C. MENDENHALL (*Phil. Mag.*, 22, 358—363).—The author describes experiments on this much disputed point, which prove, in his opinion, that a decided diminution occurs in the resistance of carbon when it is submitted to pressure, independently of any change in surface-contact between the carbon and the electrodes through which the current is introduced. For hard carbon, the change is slight, but greater than can be accounted for by any heating effect.

A disc of soft carbon, such as that used in Edison's tasimeter, showed a very great diminution in resistance when compressed between two columns of mercury. A pressure of 5 mm. of water caused a decided deflection in a sensitive galvanometer in circuit; and a pressure of 50 mm. of mercury reduced the resistance to one-half. If the initial pressure was considerable, the disc only slowly recovered its normal resistance after its removal.

Since hard carbon is much more porous than soft, the change should have been less with the latter than with the former, were the action entirely at the surface.

CH. B.

**Electrolysis of Silver and of Copper, and the Application of Electrolysis to the Standardising of Electric Current and**

**Potential Meters.** By T. GRAY (*Phil. Mag.*, **22**, 389—414).—This paper is chiefly of physical importance. The following points are, however, of general interest.

When the highest accuracy is required in electrochemical measurements, silver solutions are to be preferred to copper solutions; for although silver obtained by electrolysis is apt to be less coherent and less easy to manipulate than copper, it is not liable to oxidation and corrosion by the liquid. In ordinary measurements, however, copper is preferable.

In all cases thorough cleaning of the plates is of supreme importance; the best methods of effecting this are described at considerable length.

The size of the plates may vary within moderate limits for silver, and within wide limits for copper, without affecting the quality of the deposit, and rendering the processes of washing and weighing more difficult. For silver electrolysis, the author recommends a 5 per cent., or at most 10 per cent., solution of silver nitrate, and a cathode plate of not less than 200, nor more than 600 sq. cm. of surface per ampère of current. When the cathode is too small, the deposited metal is not adherent, and tends to grow out in crystals, especially from any sharp edge or corner. An anode plate slightly larger than the cathode is recommended; it should have a surface of at least 400 sq. cm. per ampère. Very small anode plates become black and spongy, and gas is evolved from the surface; but when the plates are large they remain bright, and may be weighed as a check on the weight of the cathode. When a silver anode has not been properly cleaned, the outer layer of metal is not dissolved, but remains as a loose skin. Between successive experiments, silver plates should be heated to redness in a spirit flame.

For the electrolysis of copper sulphate, the cathode plate should have a surface of at least 20 sq. cm. per ampère for short experiments, or 50 for experiments lasting some hours. The anode should expose at least 40 sq. cm. of surface per ampère; but the minimum size depends greatly on the degree of saturation of the copper solution. When this plate is too small, the passage of the current may be completely stopped after a time, owing to the metal becoming coated either with finely crystalline copper sulphate or with oxide. The loss from the anode never exactly equals the gain of the cathode; but when the current density does not exceed  $\frac{1}{200}$ th of an ampère per sq. cm., the anode may be weighed as a control. It never becomes black and inelastic like a silver anode; in other respects the two behave in a similar way.

The density of the copper sulphate solution may vary between 1.05 and 1.18. With weak solutions, the deposited copper is not very coherent.

A source of error in using copper lies in its corrosion by the liquid. This error is always trifling, and is a minimum for densities between 1.1 and 1.15. Copper plates are more readily corroded by neutral sulphate of copper solution than by a solution containing even 5 per cent. of sulphuric acid; and the action appears to be greater in a cell when the current is flowing than when it is not. A plate of copper immersed in pure sulphate solution at first loses weight by corrosion;

after a time it increases in weight owing to oxidation, and the increase finally becomes rapid owing to the formation of hydrated oxide.

The author gives 0.0003287 gram as the true amount of copper deposited by one coulomb of electricity. But for simple measurements of current the value may be taken as 0.000329 when the cathode has a surface of 50 sq. cm. For other sizes, this number may be corrected by means of a curve which is given. Direct determinations of the constant for silver were not very successful; but they seem to confirm the results obtained by Kohlrausch and by Lord Rayleigh.

CH. B.

**Electrolytic Polarisation produced by Small Electromotive Forces.** By C. FROMME (*Ann. Phys. Chem.* [2], 29, 497—544).—The polarisation of platinum plates in dilute sulphuric acid was measured during the flow of the polarising current, which was always so small as to produce no visible evolution of gases. Two forms of electrolytic cell were employed, the first open, containing two platinum electrodes in cells, joined by a tube containing a third, and a second form in which there were four equidistant electrodes contained in a glass tube. The acid employed varied in strength from 1 per cent. to 3 per cent., the amount of dilution not being found to produce any observable result. With the latter form of cell, the two middle electrodes were joined to the battery through a variable resistance, the two outer plates being for the purpose of measuring the potentials of the others by connection with a quadrant electrometer. In the first set of experiments, it was found that the maximum polarisation had occurred by the time the electrometer could be read, and the difference of potential was nearly equal to that obtained by joining the battery directly to the electrometer. Experiments with the open voltameter led to the conclusion that the difference of potentials between the plates remained nearly constant from the instant of making the current, but that the polarisation of the oxygen plate continuously *increased*, whilst that of the hydrogen plate *decreased*. In a voltameter free from air, the changes were similar, but in an opposite direction. The influence of a previous polarisation of the electrodes was examined, the battery being joined first in the same direction, and secondly in the reverse direction to that of the former current, and also the effect of polarisation of only one of the electrodes, this being effected by introducing temporarily a third electrode, and using it as an anode or cathode as required. By raising an electrode gradually out of the liquid, the effect of change of area was examined, and it was found that if either anode or cathode were raised so as to lessen its area of immersion, its polarisation was increased at the expense of the other.

Many other similar experiments were made, but without leading to any general conclusions, the author intending to extend the investigation, using gold and silver electrodes.

A. H. F.

**Expansion of Mercury between 0° and -39°.** By W. E. AYRTON and J. PERRY (*Phil. Mag.*, 22, 325—327).—By comparing the indications of a mercurial thermometer with those of a specially

constructed air thermometer (figured and described), the authors have found that the expansion of mercury from its freezing point to  $0^{\circ}\text{C}$ . is quite uniform; and that there is no critical point as in the case of water. Very great contraction, however, takes place when mercury passes from the liquid to the solid state. CH. B.

**Heats of Formation of Potassium Alkyl Oxides.** By DE FORCRAND (*Compt. rend.*, 104, 68—71).—*Potassium propyl oxide*,  $\text{C}_3\text{H}_7\text{OK}$ , is obtained from normal propyl alcohol in the same way as the methoxide and ethoxide. Heat of solution at  $12\text{--}15^{\circ} = +14\cdot92$  cal.

|   |                       |
|---|-----------------------|
| $\text{C}_3\text{H}_8\text{O}$ liq. + $\frac{1}{2}\text{K}_2\text{O}$ solid = $\text{C}_3\text{H}_7\text{OK}$ solid   |                       |
| + $\frac{1}{2}\text{H}_2\text{O}$ solid .....   | develops + 22·55 cal. |
| $\text{C}_3\text{H}_8\text{O}$ liq. + $\text{KHO}$ solid = $\text{C}_3\text{H}_7\text{OK}$ solid  |                       |

*Potassium isobutyl oxide*,  $\text{C}_4\text{H}_9\text{OK}$ , is obtained from fermentation isobutyl alcohol in a similar manner, and alters very rapidly when exposed to air. Heat of solution  $+17\cdot16$  cal. The thermal disturbances resulting from the reactions corresponding with those given in the case of the preceding compound are  $+20\cdot15$  cal.;  $-0\cdot34$  cal.;  $+1\cdot76$  cal.;  $+33\cdot53$  cal.; and  $+8\cdot89$  cal. respectively.

*Potassium amyl oxide*,  $\text{C}_5\text{H}_{11}\text{OK}$ , forms white, silky crystals, which alter rapidly when exposed to air. It was prepared from fermentation amyl alcohol. Heat of solution  $+13\cdot98$  cal. The thermal disturbances corresponding with the five reactions given above are  $+23\cdot27$  cal.;  $+2\cdot78$  cal.;  $-1\cdot35$  cal.;  $+36\cdot65$  cal.;  $+8\cdot59$  cal.

The values obtained with these three compounds agree closely with those previously obtained with the methyl and ethyl derivatives. The differences are greatest in the case of the heats of solution of the solid compound in an excess of the corresponding alcohol, and these differences indicate a greater or less degree of dissociation of the poly-alcoholic alcoholates.

The following table shows the heats of formation of these compounds from their elements. The values agree closely except in the case of the last two compounds, which, however, are not derived from normal primary alcohols:—

|  |                        |
|--|------------------------|
| $\text{K}$ solid + $\text{H}$ gas + $\text{O}$ gas = $\text{HOK}$ solid..  | develops + 104·32 cal. |

**Heat of Formation of Sodium Alkyl Oxides.** By DE FORCRAND (*Compt. rend.*, **104**, 169—172).—*Sodium propyl oxide* is obtained in white, deliquescent crystals by dissolving sodium in propyl alcohol and heating the product at  $200^\circ$  in a current of dry hydrogen. Heat of solution +  $13\cdot50$  cal. A solution of the metal in excess of propyl alcohol, when allowed to evaporate in dry air, deposits crystals of the compound  $\text{PrONa} + 2\text{PrOH}$ , analogous to the compounds obtained under similar conditions with the methoxide and ethoxide.

*Sodium isobutyl oxide* is obtained in a similar manner in white, deliquescent crystals, which alter slightly in dry air. Heat of solution at  $+10^\circ = 14\cdot25$  cal. If sodium is dissolved to saturation in isobutyl alcohol at  $150^\circ$  and the liquid allowed to cool, it deposits crystals of the trialcoholate,  $\text{C}_4\text{H}_9\text{ONa} + 3\text{C}_4\text{H}_9\text{OH}$ . The heat of solution of this compound is  $+17\cdot31$  cal., and hence

*Sodium amyl oxide*, prepared in a similar manner, alters when exposed to dry air, although not to the same extent as the potassium compounds. Heat of solution =  $+14\cdot21$  cal. An alcoholate,  $\text{C}_5\text{H}_{11}\text{ONa} + 2\text{C}_5\text{H}_{11}\text{OH}$ , can be obtained in crystals.

The table contains the thermal disturbances corresponding with the following five reactions, and the last column gives the heats of formations of the solid compounds from the solid and gaseous elements. The corresponding values for the hydroxide, methoxide, and ethoxide are also given :—

- (1.)  $\text{ROH liq.} + \frac{1}{2}\text{Na}_2\text{O solid} = \text{RONa solid} + \frac{1}{2}\text{H}_2\text{O solid.}$
- (2.)  $\text{ROH liq.} + \text{NaHO solid} = \text{RONa solid} + \text{H}_2\text{O solid.}$
- (3.)  $\text{RONa solid} + \text{H}_2\text{O liq.} = \text{ROH liq.} + \text{NaHO solid.}$
- (4.)  $\text{ROH liq.} + \text{Na solid} = \text{RONa solid} + \text{H gas.}$
- (5.)  $\text{RONa solid} + n\text{ROH liq.} = \text{RONa diss. in } n\text{ROH liq.}$

|                  | 1.     | 2.    | 3.    | 4.     | 5.     |         |
|------------------|--------|-------|-------|--------|--------|---------|
| Hydroxide .....  | +18·52 | +1·43 | +0·00 | +33·30 | + 9·78 | +102·30 |
| Methoxide .....  | +18·32 | +1·32 | +0·09 | +33·19 | +15·01 | + 95·22 |
| Ethoxide .....   | +17·35 | +0·25 | -1·19 | +32·13 | +12·40 | +102·73 |
| Propyl oxide.... | +17·66 | +0·65 | +0·78 | +32·52 | + 9·83 | + 99·56 |

| Amyl oxide. .... | +16·71 | -0·30 | +1·73 | +31·57 | —      | +124·58 |

The variations in the values are similar to those previously observed in the case of the corresponding potassium compounds.

C. H. B.

**Potassium Glyceroxide.** By DE FORCRAND (*Compt. rend.*, **104**, 116—118).—92 parts of glycerol are added to a concentrated solution of 39.1 parts of potassium in absolute ethyl alcohol. Combination takes place rapidly, and the compound  $\text{C}_3\text{H}_7\text{KO}_3, \text{EtOH}$  separates in transparent lamellæ, which seem to belong to the orthorhombic or monoclinic system. A further quantity of the crystals can be obtained by concentrating the mother-liquor; they are rapidly decomposed by moist air.

The heat of solution of the compound in water is  $-0.06$  cal.  $\text{C}_3\text{H}_8\text{O}_3$  liq. + KOH solid + EtOH liq. =  $\text{H}_2\text{O}$  solid +  $\text{C}_3\text{H}_7\text{O}_3\text{K}, \text{EtOH}$  solid, develops  $+18.53$  cal.

When heated at  $120^\circ$  in a current of dry hydrogen, the crystals lose alcohol and yield the glyceroxide  $\text{C}_3\text{H}_7\text{O}_3\text{K}$ . The heat of solution of this compound at  $+15^\circ$  is  $+0.18$  cal.

|  |                       |
|--|-----------------------|
| $\text{C}_3\text{H}_8\text{O}_3$ liq. + KHO solid = $\text{C}_3\text{H}_7\text{O}_3\text{K}$ solid                             |                       |
| + $\text{H}_2\text{O}$ solid .....   | develops + 15.84 cal. |
| $\text{C}_3\text{H}_7\text{O}_3\text{K}$ sol. + EtHO liq. = $\text{C}_3\text{H}_7\text{O}_3\text{K}, \text{EtOH}$              |                       |
| solid .....  | „ + 2.69 „            |
| $\text{C}_3\text{H}_8\text{O}_3$ liq. + $\frac{1}{2}\text{K}_2\text{O}$ solid = $\text{C}_3\text{H}_7\text{O}_3\text{K}$ solid |                       |
| + $\frac{1}{2}\text{H}_2\text{O}$ solid .....  | „ + 36.33 „           |
| $\text{C}_3\text{H}_8\text{O}_3$ liq. + K solid = $\text{C}_3\text{H}_7\text{O}_3\text{K}$ solid +                             |                       |
| H gas .....  | „ + 49.71 „           |

The last value is higher than that obtained in the case of the sodium compound, and approaches the corresponding value for phenol.

|   |                      |
|---|----------------------|
| $\text{C}_3\text{H}_8\text{O}_3$ liq. + EtOK diss. in $n\text{EtHO}$ liq. =             |                      |
| $\text{C}_3\text{H}_7\text{O}_3\text{K}, \text{EtOH}$ diss. in $n\text{EtOH}$ liq. .... | develops + 3.17 cal. |

The direct formation of the simple glyceroxide would likewise be exothermic, but the development of heat ( $+0.46$  cal.) would not be so great.

The values for potassium glyceroxide and its alcoholate are higher than those for the sodium compounds, except in the case of the heat developed by the union of the glyceroxide with the alcohol. This last result agrees with the fact that the alcoholate of potassium glyceroxide rapidly loses alcohol over sulphuric acid, whilst the sodium compound does not alter. The heats of formation of the two compounds from their elements are—

|   |                        |
|---|------------------------|
| $\text{C}_3$ (diamond) + $\text{H}_7$ gas + $\text{O}_3$ gas + Na solid |                        |
| = $\text{C}_3\text{H}_7\text{O}_3\text{Na}$ solid .....                 | develops + 209.42 cal. |
| $\text{C}_3$ (diamond) + $\text{H}_7$ gas + $\text{O}_3$ gas + K solid  |                        |
| = $\text{C}_3\text{H}_7\text{O}_3\text{K}$ solid .....                  | „ + 215.23 „           |
|   | C. H. B.               |

**Thermal Properties of Ether.** By W. RAMSAY and S. YOUNG (*Proc. Roy. Soc.*, **40**, 381—382).—In continuation of experiments on the physical constants of ethyl alcohol, the authors have made a similar study of ether, and numerical values have been obtained for the expansion of this liquid, the pressure of its vapour, and its compressibility in the gaseous and liquid states. From these results, the

densities of the saturated vapour and the heats of vaporisation have been deduced; the range of temperature of the observations is from  $-18^{\circ}$  to  $223^{\circ}$ . The saturated vapour of ether, like that of alcohol, has an abnormal density, increasing with rise of temperature and corresponding rise of pressure. The critical temperature of ether seems to be  $194^{\circ}$ , the critical pressure  $35.61$  atmospheres; the volume occupied by 1 gram of the substance at  $184^{\circ}$  is  $3.6$  to  $4$  c.c. V. H. V.

**Vapour-tension of Water from Salt Solutions.** By W. W. J. NICOL (*Phil. Mag.*, **22**, 502—516). In 1835, Legrand (*Ann. Chim. Phys.*, **59**, 423) examined the effect of various salts in solution on the boiling point of water, and found that salts might be divided into those for which the quantity of salt necessary to produce a rise of one-half degree diminishes with the concentration (NaCl, KCl, &c.); those for which this quantity is fixed ( $\text{KClO}_3$ ); those for which it increases with the concentration ( $\text{NaNO}_3$ ,  $\text{KNO}_3$ , &c.); those for which it first diminishes, then is constant for a few degrees, and finally increases rapidly up to the point of saturation. The last was the most general case.

Legrand's results were incomplete and defective, in so far that the temperature was variable. Wüllner's experiments (*Ann. Phys. Chem.*, **110**, 564) have added little to the subject. In the author's experiments, the temperature was kept constant, and the tension of the vapour observed. Four salts, NaCl, KCl,  $\text{NaNO}_3$ , and  $\text{KNO}_3$ , which crystallise without water, were examined as follows: From 2 to 25 molecular proportions of the salt were dissolved in 100 molecular proportions of water, and the solution heated to boiling under diminished pressure in a flask provided with a condenser, and containing a large quantity of zinc to prevent superheating. The pressure was then allowed to rise slowly until the boiling point, measured by a thermometer with its bulb completely immersed in the liquid, rose to  $70^{\circ}$ . At intervals of  $5^{\circ}$  from  $70^{\circ}$  to  $95^{\circ}$ , the pressure was observed, and the difference between this pressure,  $p'$ , and the vapour-tension of pure water,  $p$ , at the same temperature, also measured by a submerged thermometer, showed the "restraining effect" of  $n$  molecules of the salt. The quantity  $\frac{p-p'}{n}$  was the restraining effect for each molecule at the particular temperature. Tables of these values for the various temperatures are given, and from these the following conclusions may be drawn.

The restraining effect of each salt molecule increases with the concentration in the case of sodium chloride, and less markedly so in the case of potassium chloride. For sodium nitrate, it diminishes as concentration increases, and still more so for potassium nitrate.

Rise of temperature diminishes the restraining effect of sodium chloride, leaves that of potassium chloride unaffected, increases that of sodium nitrate, and still more increases that of potassium nitrate.

When both temperature and concentration increase, the salts form the same series; that is, there is diminution of the restraining effect of sodium chloride, less of that of potassium chloride, little or none of that of sodium nitrate, but marked increase of that of potassium nitrate.

When the solubility as a function of the temperature is considered, the same order is preserved. That of sodium chloride increases slightly with the temperature; that of potassium chloride rather more; that of sodium nitrate to a still greater extent; whilst that of potassium nitrate increases enormously.

There is clearly a connection between increase of solubility and restraining effect.

Some of these results are directly opposed to those obtained by Wüllner, who found that the total effect was in all cases in direct proportion to the amount of salt dissolved; but they agree satisfactorily with those of Tammann (Abstr., 1885, 862), with which the author compares them.

The author points out that these results are in accordance with his theory of solution (Abstr., 1884, 253). According to this, solution results from the tendency towards equilibrium of three forces, attraction of water for water, and of salt for salt (cohesions), and attraction of salt for water (adhesion). These three forces may be unequally affected by rise of temperature; and accordingly as difference between adhesion and the sum of cohesions at any temperature is

$> = <$  the same difference at a lower temperature, so is solubility  $> = <$  solubility at a lower temperature. Now the restraining effect per molecule is seen from the tables to be nearly the same for the four salts in *dilute* solution; or, for  $n = 2$ ,  $\frac{p - p'}{n}$  for NaCl = 4.25, for KCl = 3.8, for NaNO<sub>3</sub> = 4.25, for KNO<sub>3</sub> = 3.75. In *strong* solutions it is very different. Now the heat of solution is as follows:—NaCl = -1180, KCl = -4400, NaNO<sub>3</sub> = -5200, KNO<sub>3</sub> = -8500; regarding this as a measure of the work done in effecting a change of state, it is evident that the cohesion of the salts increases from sodium chloride to potassium nitrate. It may reasonably be supposed that concentration has but little effect on the attraction for water of a salt having small cohesion; but that it slowly diminishes this attraction when the cohesion is large, until saturation is reached. The influence of concentration is thus accounted for.

With regard to the effect of rise of temperature, it is evident that all three forces will be thereby diminished. If the cohesions be diminished a little more than the adhesion, the salt will be more soluble, and its restraining effect diminished at the higher temperature. But if the cohesions be large, and largely diminished by rise of temperature, the *comparative* value of the adhesion will be increased, and increase of restraining effect will result. CH. B.

**Vapour-tension of Sodium Acetate.** By H. LESCŒUR (*Compt. rend.*, 104, 60—63).—Sodium acetate and water will furnish three distinct systems, the first of which is prepared at the ordinary temperature with the crystallised salt  $\text{NaC}_2\text{H}_3\text{O}_2 + 3\text{H}_2\text{O}$ ; the second with the fused and dehydrated salt; and the third by heating the two first systems to complete solution, and then cooling the liquids. Determinations of the maximum vapour-tensions of the three systems at 20° indicate the existence of at least three isomeric systems, but as soon as the quantity of water present becomes sufficient for complete

solution, the three systems merge into one. It follows, therefore, that the differentiation takes place only at the moment of a change in the physical conditions of the systems.

The vapour-tension of a solution of sodium acetate diminishes regularly in proportion to the amount of anhydrous sodium acetate dissolved, and since, according to Wüllner, the diminution in the maximum vapour-tension is proportional to the weight of the compound actually existing in the system, it follows that the solution of sodium acetate contains the anhydrous salt almost exclusively.

The second system, which corresponds with the saturation of the solution, has a constant maximum vapour-tension of 12.4 mm., but when the composition of the system approaches that of the hydrate,  $\text{NaC}_2\text{H}_3\text{O}_2 + 3\text{H}_2\text{O}$ , the tension drops suddenly to 4.4 mm., and retains this value until dehydration is complete.

The maximum vapour-tension of the hydrated salt,  $\text{NaC}_2\text{H}_3\text{O}_2 + 3\text{H}_2\text{O}$ , increases with the temperature up to  $58^\circ$ , at which point the salt melts. The water is given off as a whole, and no intermediate hydrates are formed. The tension of dissociation of the hydrate is lower, and the maximum vapour-tension of its saturated solution is higher than the average tension of the aqueous vapour in the atmosphere, hence the hydrate is neither efflorescent nor deliquescent. As the vapour-tension of the saturated solution of anhydrous sodium acetate is lower than the average tension of atmospheric aqueous vapour, anhydrous sodium acetate is deliquescent.

These results explain Reischauer's observations concerning the hydration of sodium acetate (*Ann. Chim. Pharm.*, 95, 116).

C. H. B.

**Relation between the Theories of Capillarity and of Evaporation.** By J. STEFAN (*Ann. Phys. Chem.* [2], 29, 655–665).—Laplace has based his theory of capillarity on the assumption that there is a force of attraction between the particles of a liquid which decreases very rapidly with the distance, becoming insensible at a certain small distance known as the radius of molecular attraction. From this it follows that the molecular forces acting on a particle are in equilibrium so long as the distance of the particle from the liquid surface exceeds the above, but that if it is less, they have a resultant inwards, and consequently an expenditure of work is required to transfer liquid from the interior to the surface. Adopting Clausius' theory of evaporation, and assuming that the particles of a liquid do not differ from those of its vapour, it is shown that in the case of a plane surface the work done in moving a particle from the interior to the surface, is equal to that required to transfer it from the surface into the vapour above it. This work is equivalent to the heat required for the process. If the density of the liquid were uniform up to the boundary between it and its vapour, the equation  $p_2 - p_1 = \rho A$  would give the relation between  $p_2$ , the pressure in the interior,  $p_1$  the pressure at the surface,  $\rho$  the density, and  $A$  the mechanical equivalent of the latent heat of evaporation of the liquid, a relation which in the case of ether gives for  $p_2$ , 2574 atmospheres! Assuming that the density is a linear function of the pressure, a similar though

somewhat smaller result is obtained, as well as a value of  $p_2 = 2728$  atmospheres for carbon bisulphide. It is important, however, to mark that the above results are based on the assumption that no work is expended on the molecule itself in transferring it from the liquid to the vapour.

The author also explains on this theory the fact, first noticed by Sir W. Thomson, that the pressure of saturated vapour is less in the presence of a concave liquid surface, and greater in the presence of a convex, that when the surface is plane.

A. H. F.

**Coefficients of Affinity of Bases.** By W. OSTWALD (*J. pr. Chem.* [2], 35, 112—121).—In this paper, the author determines the coefficients of affinity of various bases by means of the rate of hydrolysis of ethyl acetate, and compares the results with those obtained from the corresponding coefficients of electrical conductivity. The following results were obtained:—

|                                       | Dynamical. | Electrical. |
|---------------------------------------|------------|-------------|
| Potash .....                          | 161·0      | 161·0       |
| Soda .....                            | 162·0      | 149·0       |
| Lithia .....                          | 165·0      | 142·0       |
| Thallium hydroxide ...                | 158·0      | 156·0       |
| Ammonia .....                         | 3·0        | 4·8         |
| Methylamine .....                     | 19·0       | 20·2        |
| Ethylamine .....                      | 19·0       | 20·5        |
| Propylamine .....                     | 18·6       | 18·4        |
| Isobutylamine .....                   | 14·4       | 15·2        |
| Amylamine .....                       | 18·5       | 18·6        |
| Allylamine .....                      | 4·0        | 6·9         |
| Dimethylamine .....                   | 22·0       | 23·5        |
| Diethylamine .....                    | 26·0       | 28·3        |
| Trimethylamine .....                  | 7·3        | 9·7         |
| Triethylamine .....                   | 22·0       | 20·2        |
| Piperidine .....                      | 27·0       | 27·0        |
| Tetraethylammonium<br>hydroxide ..... | 131·0      | 128·0       |

The discrepancies in the case of the feeble bases, ammonia and allylamine, are probably due to the difficulty of obtaining the coefficient of initial change by interpolation.

H. K. T.

**Influence of Heat on the Decomposition of Oxalic Acid by Ferric Chloride.** By G. LEMOINE (*Bull. Soc. Chim.*, 46, 289—294).—The author formerly investigated (Abstr., 1884, 381) the influence of sunlight on the progress of the reaction  $\text{Fe}_2\text{Cl}_6 + \text{H}_2\text{C}_2\text{O}_4 = 2\text{FeCl}_2 + 2\text{HCl} + 2\text{CO}_2$ . He now describes the action of heat on the same reaction. The aqueous solutions used contained 63 grams of crystallised oxalic acid and 162·5 grams ferric chloride respectively per litre. When equal volumes of these were solutions heated together in the dark, scarcely any action took place until the temperature reached  $50^\circ$ , the action then increased rapidly as the temperature was increased. At  $100^\circ$ , the evolution of gas

was at first rapid, gradually decreasing in the same ratio as the oxalic acid remaining undecomposed in the mixture decreased. Dilution with water very much increased the evolution of gas. The author considers this to be due to the action of the water in decomposing the ferric chloride, and thus assisting the formation of ferric oxalate, which is then further decomposed. Dilution with normal solutions of ferric chloride, ferrous chloride, or hydrochloric acid had scarcely any influence on the rate of reaction, the additional water in these cases not acting as if in the free state. Dilution with normal oxalic acid greatly increased the rate of reaction until enough oxalic acid had been added to form an acid ferric oxalate (the colour changing to green), but further addition of oxalic acid gradually diminished the rate of reaction. The author has not succeeded in isolating the acid oxalate which appears to be formed.

The influence of heat on this reaction seems, therefore, to be similar to that of light.

L. T. T.

**Theory of Fractional Precipitation.** By J. J. HOOD (*Phil. Mag.* [5], 21, 119—127). When the separation of the rarer closely allied earths is effected either by decomposition of the nitrates by heat, or by precipitation of highly dilute solutions by ammonia, the relative amount of each salt decomposed depends on its "basic power," or coefficient of resistance to decomposition; a quantity which may or may not vary with the temperature, and with the nature of the precipitant. In any separation, it is of importance to determine the conditions for the greatest difference of basic powers. In practice, the basic power,  $E$ , might be determined by measuring the intensity of the action when the same amount of precipitant is added to solutions each containing a definite mass of some sulphate (Ni, Co, Mn); or, by the action of the precipitant on a solution containing one or more of these sulphates, the relative values of  $E$  might be arrived at. In these cases,  $E$  might be regarded as a measure of the attraction of a particular base for a particular acid.

In the following theoretical investigation, no account is taken of secondary or inverse actions. Let the masses of two salts in solution be  $A$  and  $B$ , and let  $E$  and  $E'$  be the respective basic powers. Assuming that the rate of precipitation is proportional to the products of the active materials in solution, let  $x$  of  $A$  and  $y$  of  $B$  be precipitated at time  $t$ , and let  $p$  and  $q$  be quantities of precipitant consumed in each case. Then

$$\frac{dx}{dt} = \frac{1}{E}(A - x)(C - p - q) \text{ and } \frac{dy}{dt} = \frac{1}{E'}(B - y)(C - p - q),$$

from which

$$\left(1 - \frac{x}{A}\right)^E = \left(1 - \frac{y}{B}\right)^{E'} \text{ or } \frac{E}{E'} = \frac{\log\left(1 - \frac{y}{B}\right)}{\log\left(1 - \frac{x}{A}\right)}.$$

Thus the ratio  $\frac{E}{E'}$  should be calculable from a single experiment,

and should be independent of the time taken by the precipitate to form, and of the mode of addition of the precipitant. It can also be shown that the ratio of the less to the more basic material in the precipitate increases, the smaller the fraction precipitated; and if the ratio of the salts in solution be  $V$ , the maximum value of the preceding ratio will be  $\frac{E}{VE'}$  for an infinitesimal precipitate. If  $E = E'$ , no separation is possible; the experiments of Marignac (Abstr., 1884, 813) are not therefore decisive as regards the homogeneous character of the commoner elements.

Taking some observations by Mills and Bicket (Abstr., 1882, 689) on the precipitability of manganese and nickel sulphates by dilute sodium carbonate, the author finds the value of  $\frac{E}{E'} = 2.97$ ; that is, the former resists the decomposing action of sodium carbonate with a force 2.97 times greater than does the latter. Similarly for nickel and cobalt sulphates, precipitated by dilute aqueous soda (Mills and Smith, Abstr., 1879, 877)  $\frac{E}{E'} = 0.97$ . The separation of these two metals by fractional precipitation in this way would therefore be extremely tedious.

The author shows, however, that basic power is not related to atomic weight, as might be suspected. Debus (*Annalen*, **85**, **86**, and **87**) found that if a solution containing baryta and lime in the ratio  $\alpha$  is precipitated by carbonic anhydride, the ratio of the oxides in the precipitate is given by the equation  $\alpha = K\beta$ . For a *small* precipitate  $K = \frac{E}{E'}$  approximately.

CH. B.

**Halogen Carriers.** By L. MEYER (*J. pr. Chem.* [2], **34**, 502—504).—The author does not agree with Wildgerodt that the property of transferring halogens is a function of the atomic weights of the elements, provided they form the necessary combinations (compare this vol., p. 130). Thus antimony acts in this way, bismuth does not. The author maintains his view that a combination first takes place between the haloid compound and the substance acted on, that a combination then takes place between the halogen of the double compound and the hydrogen of the same, their places being taken by the free halogen. He quotes several reactions in support of his view.

H. K. T.

**Halogen Carriers.** By C. WILLGERODT (*J. pr. Chem.* [2], **34**, 547—550).—A reply to L. Meyer (preceding Abstract). The author points out the difference in the methods employed by himself and those used by Meyer and his pupils.

G. H. M.

**Indium and Gallium as Halogen Carriers.** By C. WILLGERODT (*J. pr. Chem.* [2] **35**, 142—144).—The author continues his researches on halogen carriers. With metallic indium in benzene, scarcely any chlorination took place until the indium had been converted into the chloride by the small quantity of hydrogen chloride formed. The

chlorination then proceeded rapidly. The product consisted almost entirely of paradichlorobenzene. With gallium, the chlorination commenced at once; mono- and di-chlorobenzene and a small quantity of benzene hexachloride were produced. The author regards these experiments as giving further evidence of his law that the halogen carrying power of an element is a function of its atomic weight provided it form the necessary combination. H. K. T.

**Expansion produced by Amalgamation.** By W. E. AYRTON and J. PERRY (*Phil. Mag.*, **22**, 327).—A brass bar, one foot long and three-quarters of an inch thick, rapidly became curved when it was amalgamated along one edge, this edge becoming convex; and on hammering the bar to straighten it the curvature increased. Very great force must be produced by amalgamation.

The authors think that the mercury amalgam used in polishing Japanese "Magic Mirrors" may assist in making the thin portions more convex than the thicker. CH. B.

**Oxy-acids of Iodine.** By C. W. BLOMSTRAND (*J. pr. Chem.* [2], **34**, 433—462).—A review of the evidence pointing to the pentavalent nature of iodine in periodic acid.

**Production of Ozone.** By J. J. THOMSON and R. THRELFALL (*Proc. Roy. Soc.*, **40**, 340—342).—Experiments were made with a view of ascertaining whether ozone is produced in an electric field, just not strong enough to permit of the passage of the spark through oxygen gas. The gas, before passing into the ozonising apparatus, was carefully dried and purified, and the issuing gas tested with paper soaked with a most sensitive solution of potassium iodide and starch, as also by the solution itself. Practically no ozone was produced.

It is further shown that no ozone is produced when a spark is passed through oxygen dried with the utmost care. V. H. V.

**Action of Sulphur on Ammonia and Metallic Bases in Presence of Water.** By J. B. SENDERENS (*Compt. rend.*, **104**, 58—60).—Contrary to Brunner's statement, an aqueous solution of ammonia of ordinary concentration acts gradually on sulphur at the ordinary temperature, with formation of a dark red liquid which contains a polysulphide and a thiosulphate. If this solution is exposed to the air, it deposits sulphur. The same products are formed according to Fluckiger, when sulphur is heated at 100° with ammonia in sealed tubes for several days.

Barium and calcium oxides likewise act on sulphur in the cold in

presence of water, forming a solution containing a polysulphide and a thiosulphate. When silver oxide or lead monoxide is heated with sulphur and water in a sealed tube at  $100^{\circ}$ , a sulphide and a sulphate are formed in accordance with the equation  $4MO + S_4 = 3MS + MSO_4$ . Both lead and silver oxides are slightly soluble in water, but similar reactions are obtained with triplumbic tetroxide, mercuric oxide, and cupric oxide. The formation of the sulphides under these conditions corresponds with a considerable development of heat. This is not, however, the only determining cause of the reaction, since ferric oxide is only very slightly affected by sulphur, and zinc oxide is not affected at all. The heats of formation of these oxides are, however, much higher than the heats of formation of the oxides of mercury, copper, &c., and it would seem therefore as if the decomposition of metallic oxides by sulphur in presence of water were partly conditioned by the absolute value of the heat of formation of the oxide.

C. H. B.

**Combination of Sulphuric Anhydride with Phosphoric and Iodic Anhydrides.** By R. WEBER (*Ber.*, **20**, 86—88).—When a mixture of pure sulphuric anhydride with phosphoric anhydride is heated in a right-angled tube at  $100^{\circ}$  for a short time, combination ensues, and, after decanting the fluid portion into the empty limb, and cooling, thin, transparent scales of a compound,  $P_2O_5 + 3SO_3$ , are obtained (this vol., p. 212); these can be freed from excess of sulphuric anhydride by carefully heating them at  $30^{\circ}$  and allowing them to drain. The compound readily decomposes when heated above  $30^{\circ}$ ; the residue, however, still retains some sulphuric anhydride at higher temperatures.

Sulphuric anhydride and iodic anhydride combine under similar conditions to form a compound,  $I_2O_5 + 3SO_3$ , sparingly soluble in sulphuric anhydride, and crystallising in lustrous, yellow scales. It is more stable than the phosphorus compound, and can be heated to  $60^{\circ}$  without decomposition; at higher temperatures, sulphuric anhydride distils off although the residue still retains a certain proportion at  $100^{\circ}$ .

W. P. W.

**Passage of Electric Discharge through Pure Nitrogen.** By J. J. THOMSON and R. THRELFALL (*Proc. Roy. Soc.*, **40**, 329—340).—It is observed that when a succession of electric sparks is sent through a sealed discharge tube containing nitrogen at a pressure less than 20 mm. of mercury, a permanent diminution of the nitrogen takes place, which ultimately reaches a maximum of 8 to 12 per cent. of the original volume if the pressure be 8 mm., but only 2 to 3 per cent. with a pressure of 16 mm. A considerable time is required before this maximum value is attained, and the ratio of this diminution to the original volume is independent of the volume of the discharge tube, the extent of its surface, and the substance of the electrode, whether platinum or aluminium. If the tube is maintained at a temperature of over  $100^{\circ}$  for several hours, the gas regains its original volume.

The apparatus is described in full, as also the method used for the preparation of the nitrogen, the determination of the quantity of

oxygen contained in the gas and the elimination of hydrogen from the electrodes as evidenced by spectroscopic examination. It was proved that the gas used contained less than 1 part in 800 of oxygen, whilst the contraction observed would require the presence of 15 per cent. of hydrogen if this gas combined with the nitrogen to form ammonia, whereas only the minutest traces of hydrogen could be detected by means of the spectroscope. The authors incline to the hypothesis that an allotropic modification of nitrogen is produced by the sparking, and the phenomena of the contraction of volume and expansion on heating are analogous to those observed in the case of ozone. It is further noticed that when the discharge passes through nitrogen, whose pressure has been diminished by sparking, it shows a greater tendency to produce a beautiful golden colour than when it passes through a tube recently filled. No attempts have thus far been made to ascertain the chemical properties of this modified gas.

V. H. V.

*Note.*—G. S. Johnson, in a pamphlet entitled "Elementary Nitrogen," has described the production of an allotropic modification of this gas under conditions somewhat similar to those mentioned above.—V. H. V.

**Hydrated Silicon Phosphate.** By P. HAUTEFEUILLE and J. MARGOTTET (*Compt. rend.*, **104**, 56—57).—If a concentrated solution of phosphoric acid containing about one quarter of the quantity of silica required to saturate it, is heated at 125° for 7 or 8 days, it deposits concretions which gradually increase in size. They are separated from the mother-liquor by pouring the hot liquid on to a previously heated porous plate, and are dried by exposure to dry air for about a week. The spherical globules thus obtained have the composition  $\text{SiO}_2 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ . When suspended in sulphuric acid, they act strongly on polarised light, showing black crosses with the arms in the principal planes of the Nicols. Under the microscope, the concretions are seen to be formed of concentric cones of prismatic crystals with their principal axes radiating from the centre. The silicon phosphate decomposes rapidly in moist air, and dissolves completely in water at 0°, but is decomposed by water at the ordinary temperature, with separation of gelatinous silica.

C. H. B.

**Action of Carbon Tetrachloride on Metallic Oxides.** By E. DEMARÇAY (*Compt. rend.*, **104**, 111—113).—Niobic anhydride is slowly attacked by vapour of carbon tetrachloride at 220°, but very rapidly at 440°, the products being niobic chloride, carbonic chloride, and carbonic anhydride. Titanic oxide is also very readily attacked at 440°, and in fact titanium tetrachloride can readily be prepared by the action of carbon tetrachloride vapour on fragments of rutile heated to dull redness in a somewhat long, hard glass tube. When titanic oxide and carbon tetrachloride are heated together in sealed tubes, it is found that the reaction really occurs in three phases, which are severally represented by the equations  $\text{TiO}_2 + \text{CCl}_4 = \text{TiOCl}_2 + \text{COCl}_2$ ;  $\text{TiOCl}_2 + \text{COCl}_2 = \text{TiCl}_4 + \text{CO}_2$ ;  $\text{TiOCl}_2 + \text{CCl}_4 = \text{TiCl}_4 + \text{COCl}_2$ . Titanium oxychloride is a yellow crystalline solid.

In addition to carbonic anhydride and carbonyl chloride, which are formed with all the oxides, some carbon hexachloride and free chlorine are amongst the products of this reaction.

Chromic, aluminium, and tantalic oxides are readily attacked under similar conditions. Zirconia is only slowly attacked at  $440^{\circ}$ , but rapidly at dull redness. Silica is scarcely affected even at the higher temperature.

Zircons are not attacked by carbon tetrachloride. Certain opaque Swedish specimens became transparent after heating in the vapour, most probably in consequence of the removal of small quantities of titanium, niobium, &c.

C. H. B.

**Action of Carbon Tetrachloride on Chromyl Dichloride and Ferric Phosphate.** By H. QUANTIN (*Compt. rend.*, 104, 223—224).—Nickel and cobalt oxides, and tungstic and molybdic anhydrides are readily converted into chlorides when heated in the vapour of carbon tetrachloride. At the same time, this process has no advantages over the method of preparing anhydrous chlorides by the action of a mixture of chlorine and carbonic oxide on the respective oxides. Silicon dioxide and boron trioxide are not affected in either case.

The author has previously found that carbonic oxide decomposes chromyl dichloride into chromic oxide and chromic chloride. A similar reaction takes place between chromyl dichloride and carbon tetrachloride, as expressed by the equation  $2\text{CrO}_2\text{Cl}_2 + 4\text{CCl}_4 = \text{Cr}_2\text{Cl}_6 + 4\text{COCl}_2 + 3\text{Cl}_2$ . Some carbonic anhydride is also formed.

When carbon tetrachloride vapour is passed over heated ferric phosphate, violet vapours are produced, and if these are passed over a column of granular potassium chloride heated at  $200^{\circ}$ , the ferric chloride is absorbed, and yellow crystals are deposited on the cold part of the tube; these crystals are very hygroscopic, and have an irritating odour; their aqueous solution deposits carbon tetrachloride and contains hydrochloric acid and phosphoric acid. Analysis shows that the crystals are phosphorus pentachloride. With more basic phosphates the reaction is similar, but it seems to be different with the phosphate  $3\text{P}_2\text{O}_5, 2\text{Fe}_2\text{O}_3$ .

When a boat or dish is used, a somewhat large excess of carbon tetrachloride is required for complete decomposition. It is therefore better to mix the ferric phosphate with carbon from sugar and place the mixture in a layer in front of a layer of potassium chloride.

C. H. B.

**Sodium Carbonate.** By W. SMITH and W. B. HART (*J. Soc. Chem. Ind.*, 5, 643—644).—The authors have investigated an alleged reaction, on which is based a recently patented process for manufacturing sodium carbonate directly from sodium sulphate, and draw the following conclusions from the results of their researches:—(1.) No action takes place at a dull red heat when carbonic oxide comes in contact with sodium sulphate in a glass tube, even in presence of moisture. (2.) At a bright red heat, in presence of moisture, sodium sulphite and sulphide are produced. (3.) At a bright red heat, moreover, the silica of the glass reacts with the sulphite and sulphide, especially in presence of moisture, yielding silicate, sulphurous

anhydride, and hydrogen sulphide. (4.) From the fact that no sulphurous anhydride could be detected but only hydrogen sulphide, it is inferred that reduction by carbonic oxide tends, under the circumstances named, to convert the sulphate directly to sulphide. (5.) The proportion of this reduction is very small, even at a bright red heat. (6.) No carbonate was formed under any of the conditions mentioned. (7.) In absence of moisture and with carbonic anhydride in slight excess over that necessary to form a volume equal to that of the carbonic oxide in the gas mixture, a bright red heat being employed, no reduction of sulphate took place. (8.) Carbonic oxide at a bright red heat and in presence of moisture, reduces sulphurous anhydride to sulphur. If moisture is excluded this reduction does not proceed quite so easily.

D. B.

**Occasional Products in the Soda Manufacture.** By C. RAMMELSBURG (*J. pr. Chem.* [2], 35, 97—111).—The following compounds were obtained from the hearth of a Leblanc soda-ash furnace.

Aluminium calcium silicate combined with calcium sulphide,  $2\text{CaS}, 6\text{Ca}_3\text{SiO}_5, \text{Al}_2\text{SiO}_5$ , yellow or green, transparent, prismatic crystals;  $a:c = 1:0.58318$ . Calcium silicate,  $\text{CaSiO}_3, \text{Ca}_2\text{SiO}_4 + \text{H}_2\text{O}$ , small, hard, white, pointed prisms. White octahedral crystals, which in a few days fell to powder, and consisted of calcium hydroxide mixed with carbonate.

In an iron clearing-vat, crystals were found having the composition,  $\text{Na}_2\text{CO}_3, \text{CaCO}_3 + 5\text{H}_2\text{O}$ , and identical with gay-lussite.

H. K. T.

**Influence of Heat on the Combination of Water of Crystallisation with Sodium Monosulphide.** By C. GÖTTIG (*J. pr. Chem.*, [2], 35, 89—91).—The author has previously shown that when hydrated sodium sulphide separates from alcoholic soda treated with hydrogen sulphide, products with varying percentages of water of crystallisation are obtained. Experiments described in the present paper confirm this, and show that the percentage of water of crystallisation depends not only on the strength of the alcohol, but also on the temperature at which the sulphide is prepared. At temperatures between  $17^\circ$  and  $22^\circ$ , a hydrate containing 6 mols.  $\text{H}_2\text{O}$  was formed; at  $41^\circ$  to  $45^\circ$ , a hydrate containing  $5\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ .

N. H. M.

**Silver Ammonio-nitrate.** By H. N. DRAPER (*Pharm. J. Trans.*, [3], 17, 487—488).—The precipitate first formed when ammonia is added to a solution of silver nitrate, is silver oxide, which is soluble in ammonium nitrate. Therefore only a small proportion of the silver is at any time precipitated, and if any free nitric acid is present, ammonia fails to produce any precipitate. A further addition of ammonia results, as is well known, in the formation of silver ammonio-nitrate.

D. A. L.

**Action of Non-metals on Solutions of Silver and Cupric Nitrates.** By J. B. SENDERENS (*Compt. rend.*, 104, 175—177).—Powdered selenium acts more readily than sulphur on boiling aqueous solutions of silver nitrate, reduction being almost complete,

even when the solution is somewhat concentrated. The reaction takes place in accordance with the equation  $4\text{AgNO}_3 + 3\text{Se} + 2\text{H}_2\text{O} = 2\text{Ag}_2\text{Se} + \text{SeO}_2 + 4\text{HNO}_3$ . If the substances are heated together in sealed tubes, the action is almost complete, but a certain quantity of silver selenite is formed, and dissolves in the hot liquid, but separates in white needles on cooling.

The action of powdered tellurium at  $100^\circ$  is similar to that of selenium but somewhat less rapid. In sealed tubes, however, the precipitation of the silver by tellurium is always complete, and if the tellurium is in excess, the nitric acid which is formed is decomposed with production of nitrogen peroxide even in dilute solutions.

Silver nitrate in solution is completely, although slowly, reduced by selenium and tellurium at the ordinary temperature. Cupric nitrate is not affected under the same conditions, but is partially reduced by tellurium on heating.

The reduction of silver nitrate by arsenic yields arsenious and not arsenic acid, and takes place in accordance with the equation  $3\text{AgNO}_3 + \text{As} + 3\text{H}_2\text{O} = \text{Ag}_3 + \text{H}_3\text{AsO}_3 + 3\text{HNO}_3$ . The precipitate is free from arsenic.

The action of amorphous phosphorus on solutions of silver and copper nitrates respectively is represented by the equations  $5\text{AgNO}_3 + \text{P} + 4\text{H}_2\text{O} = 5\text{Ag} + \text{H}_3\text{PO}_4 + 5\text{HNO}_3$ , and  $5\text{Cu}(\text{NO}_3)_2 + \text{P}_6 + 8\text{H}_2\text{O} = \text{Cu}_5\text{P}_4 + 2\text{H}_3\text{PO}_4 + 10\text{HNO}_3$ . A solution of copper nitrate yields the compound  $\text{Cu}_5\text{As}_2$  when treated with arsenic. Solid iodine acts on silver nitrate solution in the dark in accordance with the equation  $5\text{AgNO}_3 + \text{I}_6 + 3\text{H}_2\text{O} = 5\text{AgI} + \text{HIO}_3 + 5\text{HNO}_3$ , and the action of bromine is represented by the equation  $\text{AgNO}_3 + \text{Br}_2 + \text{H}_2\text{O} = \text{AgBr} + \text{HBrO} + \text{HNO}_3$ , as previously stated by J. Spiller and Schönbein.

C. H. B.

**Reaction between Barium Carbonate and Sodium Sulphate under the Influence of Pressure.** By W. SPRING (*Bull. Soc. Chim.*, **46**, 299—302).—The author has already shown (*Bull. Soc. Chim.*, **44**, 166) that when an intimate mixture of sodium carbonate and barium sulphate is subjected to intense pressure, a considerable amount of double decomposition occurs. He has now studied the reverse action. When finely powdered dry sodium sulphate and barium carbonate are intimately mixed in molecular proportions and the mixture subjected to pressure, a considerable quantity of barium sulphate is produced. If the mixture is shaken for some time in a dry flask, about 50 per cent. of the barium carbonate is found to have become converted into sulphate. If the mixture is subjected to a single pressure of several thousand atmospheres, the percentage of barium sulphate is increased to about 60 per cent. Subjected to thrice repeated pressure—the compressed mass being re-powdered before each renewed pressure—the percentage of barium sulphate is increased to about 70 per cent., and after six similar renewals of pressure to about 73 per cent. If the mixture under ordinary atmospheric pressure is allowed to remain untouched, no further increase of barium sulphate takes place, but if the mixture is maintained under pressure the formation of barium sulphate increases until a limit of about 80.5 per cent. is reached.

When fragments of the compressed cylinders were heated at  $160^{\circ}$  for some hours and then again analysed, the percentage of barium sulphate was found to have been very much diminished. The author intends further to investigate this influence of heat; and also the double decomposition of mixtures of dry substances under ordinary pressures. He finds that when dry copper sulphide is shaken with dry silver nitrate, double decomposition takes place. L. T. T.

**Calcium Silicostannate.** By L. BOURGEOIS (*Compt. rend.*, **104**, 231—233).—Three parts of silica and four parts of stannic oxide are heated with an excess of calcium chloride to bright redness for about eight hours, and the cooled mass extracted with water. If the time of fusion has been short, the residue is a mixture of tridymite and cassiterite, but if the reaction has proceeded further the residue consists of calcium silicostannate, whilst if the heating has been too far prolonged, the products are calcium bisilicate and calcium stannate.

*Calcium silicostannate*,  $\text{CaO}, \text{SiO}_2, \text{SnO}_2$ , analogous to sphene, is obtained as a brilliant white powder consisting of monoclinic prisms somewhat less birefractive than those of sphene; sp. gr. 4.34. They are not attacked by acids, potassium hydrogen sulphate, or solutions of alkalis, and are less fusible than sphene.

A mixture of silica, stannic oxide, and titanin oxide, with calcium chloride, yields similar crystals, which contain all three of the dioxides. Crystals of cassiterite form on the upper part of the crucible, and if the action is prolonged icositetrahedrons of the composition  $3\text{CaO}, \text{Al}_2\text{O}_3, 3\text{SiO}_2$  are formed by the action of the fused mixture on the crucible. C. H. B.

**Solubility of Gypsum in Solutions of Ammonium Salts.** By S. COHN (*J. pr. Chem.* [2], **35**, 43—56).—Droeze has already shown (this Journal, 1877, ii, 112) that the solubility of gypsum in solutions of salts decreases with the concentration of the salt solution, except in the case of ammonium nitrate solution, when the solubility first increases and then decreases. The author has determined the solubility of gypsum in solutions of different ammonium salts of varying strength. The results of several experiments point to the following conclusions:—1. The irregularity observed by Droeze in the case of ammonium nitrate exists also in the case of the chloride, but not in the case of the sulphate; this difference is possibly due to a chemical reaction taking place with the gypsum. 2. Ammonium sulphate increases the solubility of gypsum, probably forming readily soluble double salts. 3. Ammonium chloride, nitrate, and acetate, increase the solubility of gypsum by double decomposition, readily soluble calcium salts being formed. 4. The decomposition of the gypsum by the ammonium salts increases with decreasing concentration. 5. Gypsum dissolves most readily in ammonium acetate, then in nitrate, chloride, and sulphate. 6. This order holds good for the readiness with which gypsum is decomposed by the salts.

The methods employed in preparing the solutions and determining the amount of gypsum are described. N. H. M.

**Crystallography of Cadmium Borotungstate.** By G. LINCK (*Zeit. Kryst. Min.*, **12**, 442—446).—Two kinds of crystals are obtained from the concentrated solution of cadmium borotungstate, which, according to Klein (Abstr., 1881, 1168), has the composition  $9\text{WO}_3 \cdot \text{B}_2\text{O}_3 \cdot 2\text{CdO} + 18\text{H}_2\text{O}$ . The crystals which separate out first are of a bright yellow colour and tabular in form (Analysis I); whilst the others are of a yellowish-brown colour, and have a pyramidal form (Analysis II). Analysis gave the following results:—

|     | H <sub>2</sub> O at<br>100°. | H <sub>2</sub> O at<br>red heat. | CdO. | WO <sub>3</sub> . | B <sub>2</sub> O <sub>3</sub> . | Total. |
|-----|------------------------------|----------------------------------|------|-------------------|---------------------------------|--------|
| I.  | 8.18                         | 4.18                             | 9.33 | 76.27             | 2.04                            | 100.00 |
| II. | 8.03                         | 3.80                             | 9.52 | 76.51             | 2.14                            | 100.00 |

Neither of the salts analysed correspond with Klein's formula, in that they contain much less water of crystallisation and more chemically combined water.

The yellow crystals belong to the monosymmetric system; the axial ratio being  $a : b : c = 1.3321 : 1 : 1.1383$ ;  $\beta = 57^\circ 47'$ . The forms observed were  $0\text{P}$ ,  $\infty\text{P}\infty$ ,  $\infty\text{P}\infty$ ,  $\text{P}\infty$ ,  $\text{P}\infty$ ,  $6\text{P}\infty$ .

The brown crystals belong to the asymmetric system;  $a : b : c = 0.6261 : 1 : 0.4398$ .  $\alpha = 114^\circ 56'$ ;  $\beta = 92^\circ 47'$ ,  $\gamma = 94^\circ 57'$ . The following planes were observed:— $0\text{P}$ ,  $\infty\text{P}\infty$ ,  $\infty\text{P}\infty$ ,  $\infty\text{P}\frac{5}{4}$ ,  $\infty\text{P}'$ ,  $\text{P}$ ,  $\frac{1}{2}\text{P}$ .  
B. H. B.

**Higher Oxides of Copper.** By T. B. OSBORNE (*Amer. J. Sci.* [3], **32**, 333—342).—The various coloured hydrated oxides of copper obtained by treating cupric hydroxide with hydrogen peroxide, are all mixtures in varying proportions of the brown dioxide,  $\text{CuO}_2 \cdot \text{H}_2\text{O}$ , with cupric hydroxide. The author has also experimented on the so-called sesquioxide, obtained by the action of alkaline solutions of hypochlorites on copper compounds, but has not obtained any conclusive results.  
A. J. G.

**New Elements in Gadolinite and Samarskite.** By W. CROOKES (*Proc. Roy. Soc.*, **40**, 502—509).—An account of the differentiation in the absorption and the phosphorescent spectra obtained by the process of systematic fractionation of the earths present in gadolinite and samarskite. By the evidence of absorption spectra, Welsbach has concluded that didymium is separable into two elements, designated præsodymium and neodymium, which give green and rose-red salts respectively. The method adopted by the author does not lead to the same conclusion, although it is suggested that didymium can be resolved in more than one direction according to the method adopted. Evidence has, however, been afforded of a blue line,  $\lambda 451.5$ , characteristic of the element named dysprosium by Boisbaudran, as also of absorption-bands  $\lambda 475$  and  $\lambda 443$ , which can be obtained separate from  $\lambda 451.5$ , and thus belong to some element.

By systematic fractionation, and examination of the various portions by the phosphorescent spectrum method, it is shown that the spectrum bands hitherto considered to belong to yttria vary in intensity among themselves, as also that the element called  $\text{Y}\alpha$  or gadolinium,

by Marignac, is probably composed of at least four simpler substances. The spectrum of this  $Y\alpha$  is that of yttria with the chief characteristic, namely, the citron band, left out, and with the double green band of samaria added to it. A provisional list is given of eleven elements, inclusive of ytterbium and gadolinium, with the mean wave-lengths of their dominant band.

Attention is also drawn to the delicacy of the phosphorescent spectrum method as applicable to substances which have been approximately separated but not yet completely isolated by chemical processes. In accuracy, it is unsurpassed by spectrum analysis; in economy, it possesses the advantage that the specimen examined is not destroyed, whilst continued experience confirms its trustworthiness.

V. H. V.

*Note.*—For a further account of the experiments described above and the theoretical conclusion drawn therefrom, compare the address of the author to the Chemical Section of the British Association, Report, 1886.—V. H. V.

**Chemistry of Manganese and of Fluorine.** By O. T. CHRISTENSEN (*J. pr. Chem.* [2], 35, 57—82; comp. Abstr., 1886, 854).—When chlorine is passed into absolute ether containing pure manganese peroxide in suspension and cooled by means of water, the liquid acquires after some time a violet colour so intense that it appears almost black and opaque. If the treatment with chlorine is prolonged, and the cooling insufficient, a reduction takes place, and manganous chloride gradually separates. The mixture should be shaken frequently, and kept from much light. If the dark liquid is poured off, a substance is obtained partly soluble in ether with intense violet colour; the insoluble residue is unchanged manganese oxide. The ether poured off, gives after some hours an abundant separation of manganous chloride, and loses its colour. When strong hydrochloric acid (sp. gr. 1.19) is shaken with absolute ether, two layers are obtained, the lower, a solution of ether in hydrochloric acid, and the upper, a solution of hydrochloric acid in ether. When these are treated separately with manganese peroxide, the ethereal hydrochloric acid solution acquires a green, whilst the hydrochloric acid containing ether acquires a violet colour. Hence the colour appears to depend on the amount of water present (comp. Nicklès, *Ann. Chim. Phys.* [4], 5, 161).

A number of experiments are described which were made to determine the valency of the manganese in the compounds obtained by the action of hydrochloric acid on manganese peroxide. The result points to the formula  $Mn_2Cl_6$ . When the reaction takes place at  $10^\circ$ , more chlorine is taken up, and it is probable that the compound  $MnCl_4$  is formed.

Manganese sesquioxide,  $Mn_2O_3$ , yielded the same chloride,  $Mn_2Cl_6$ , when treated with ether containing hydrochloric acid.

Manganese fluoride,  $Mn_2F_6 + 6H_2O$ , is obtained in the pure state by dissolving artificial manganese peroxide in hydrofluoric acid; the product is filtered through spongy platinum, evaporated down and kept over sulphuric acid.

Manganese potassium fluoride,  $4\text{KF}, \text{Mn}_2\text{F}_6 + 2\text{H}_2\text{O}$ , is prepared by treating manganous hydroxide (Otto, *Annalen*, **93**, 372) with pure dilute hydrofluoric acid; the product is filtered and treated with excess of potassium fluoride, when a rose-coloured, crystalline precipitate is formed. This is washed with water containing hydrofluoric acid, and dried on platinum. It is decomposed by water at the ordinary temperature. Hydrochloric acid decomposes it with a dark colour; when the solution is treated with water, the solution becomes transparent and bright yellowish-red. The salt dissolves in sulphuric acid, yielding an amethyst-coloured liquid, which becomes red on the addition of water. The solution in phosphoric acid is red. The salt is identical with the one to which Nicklès (*Compt. rend.* **65**, 107) ascribed the formula  $2\text{KF}, \text{MnF}_4$ . The salt,  $2\text{KF}, \text{MnOF}_2$ , is obtained by adding manganese tetrachloride to a boiling solution of potassium fluoride; it is probably identical with Nicklès' salt,  $4\text{KF}, \text{Mn}_2\text{OF}_4$ .

The salt,  $4\text{KF}, \text{Mn}_2\text{F}_6 + 2\text{H}_2\text{O}$ , was also prepared by heating manganese peroxide with hydrogen potassium fluoride, and by precipitation from a solution of potassium fluoride with a solution of manganese peroxide in hydrofluoric acid. N. H. M.

#### Action of Potassium Permanganate on Sodium Thiosulphate.

By M. GLÄSER (*Monatsh. Chem.*, **7**, 651—654).—According to Hönig and Zatzek (*Abstr.*, 1886, 504), a boiling neutral solution of sodium thiosulphate is not completely oxidised to sulphate by potassium permanganate. Experiments in which sodium thiosulphate was boiled with solutions of permanganate, show that when 1 c.c. of the solution contains 0.007487 gram of permanganate, and the boiling is continued for 15 to 20 minutes, 1.98 to 2.69 per cent. of the thiosulphate is not oxidised to sulphate, whilst when concentrated solution of permanganate is employed, the oxidation is complete. In alkaline solution, and at the ordinary temperature, the oxidation is almost, but not quite, complete.

The compound manganite formed in the reaction is stable, and is not decomposed by cold or hot water. Numerous analyses confirm the formula  $\text{KH}_3\text{Mn}_4\text{O}_{10}$ , previously assigned to it. The author adheres to the equation previously suggested by him (*Abstr.*, 1885, 957), and considers that it holds good whether the reaction takes place in the boiling concentrated solution of permanganate or in a more dilute solution. N. H. M.

**Compounds of Stannic Oxide.** By A. DITTE (*Compt. rend.*, **104**, 172—175).—Stannic hydrate, produced by the action of alkalis on a solution of stannic chloride, dissolves readily in warm dilute sulphuric acid (1 : 8), forming a limpid solution, which when concentrated until it contains not more than 3 or 4 vols. of water to 1 vol. of sulphuric acid, deposits at first colourless, radiating needles, then rhomboidal lamellæ, and eventually hexagonal prisms with two parallel faces largely developed. All the crystals have the composition  $\text{SnO}_2 \cdot 2\text{H}_2\text{SO}_4$ .

The same compound is obtained by the action of sulphuric acid

of suitable concentration on the hard, vitreous hydrate  $\text{SnO}_2 \cdot 2\text{H}_2\text{O}$ , obtained by dissolving gelatinous stannic hydrate in ammonia, and evaporating the liquid; on metastannic acid obtained by treating the metal by nitric acid; and on strongly heated anhydrous stannic oxide. In the last case the rate of solution is very slow. The form of the crystals varies in the manner already described with the relative proportions of acid and water in the liquid.

The crystals are decomposed by water, but the stannic oxide is kept in solution by the sulphuric acid which is liberated, and a precipitate is only obtained when water is added in such quantity that the liquid does not contain more than about 43 grams of sulphuric acid per litre. The crystals are very deliquescent, and form a colourless, transparent liquid when exposed to the air; this solution does not crystallise on evaporation, but forms a hard, vitreous mass. If, however, some sulphuric acid is added to the liquid, crystals of  $\text{SnO}_2 \cdot 2\text{H}_2\text{SO}_4$  are readily obtained. They dissolve readily in dilute sulphuric acid, especially on heating, are not affected by ether, but are decomposed by alcohol with removal of sulphuric acid.

If the sulphuric acid is not in large excess, but has dissolved a considerable proportion of stannic oxide, it forms a transparent jelly on cooling, which is sometimes opalescent. This liquefies when heated, but gelatinises again when cooled. The jelly is strongly acid, and does not become crystalline even after several weeks. If, however, it is mixed with an excess of ether, it yields a precipitate of slender, white needles of the compound  $\text{SnO}_2 \cdot \text{H}_2\text{SO}_4$ . This compound dissolves in cold water, and the solution is at first limpid, but soon becomes turbid, owing to the separation of gelatinous stannic hydrate.

A compound of the same kind containing selenic acid is readily obtained by dissolving gelatinous stannic oxide in a warm solution of selenic acid, and evaporating to a syrup. When the liquid is cooled, it deposits transparent rhomboïdal lamellæ or hexagonal prisms of the composition  $\text{SnO}_2 \cdot \text{H}_2\text{SeO}_4$ . These crystals are hygroscopic, and are decomposed by excess of water, with separation of stannic hydrate. This compound is formed even in presence of a large excess of selenic acid.

Titanic and zirconic oxides yield similar products. C. H. B.

**Titanium.** Part II. By O. v. D. PFORDTEN (*Annalen*, **237**, 201—235).—The yellow colour of titanium tetrachloride is due to the presence of vanadium oxychloride. This impurity may be removed by treatment with sodium amalgam. The pure chloride is a colourless liquid boiling between  $135^\circ$  and  $136^\circ$ . It is not decomposed by dry oxygen, but fumes in moist air. Titanium tetrachloride is miscible with alcohol, and on the addition of water the solution remains clear. A yellow precipitate is formed when the chloride is poured into hydrochloric acid; it is soluble in an excess of acid. Titanium chloride does not conduct electricity.

A gelatinous modification of hydrated titanic oxide is occasionally obtained by fusing titanium dioxide with potassium carbonate, and adding hydrochloric acid to the aqueous solution of the product. When sodium amalgam is left in contact with titanium tetrachloride,

a black deposit of the dichloride or a violet deposit of the trichloride is slowly formed on the surface of the amalgam.

The dichloride dissolves in water and in alcohol with a brown coloration, but it is insoluble in ether. On exposure to the air, the aqueous solution deposits titanous acid; the alcoholic solution remains clear, but contains organic chlorine products. With potassium thiocyanate and ether, titanium dichloride exhibits a delicate and characteristic reaction; the ether acquires a dark-brown colour. Robinson and Hutchings (*Amer. Chem. J.*, **6**, 74) describe a method of preparing metallic titanium by the action of sodium on titanous chloride in sealed tubes at 130°. The author finds that this reaction yields a considerable quantity of titanium dichloride, but little if any metallic titanium.

Titanium trichloride mixed with dichloride is precipitated when sodium amalgam is added to a solution of the tetrachloride in hydrochloric acid. The powder dissolves in water, forming a violet solution. When sodium amalgam acts on a solution of potassium titanofluoride and hydrochloric acid, a green solution is produced which does not contain any dichloride. On the further addition of sodium amalgam, the solution becomes colourless, and finally deposits a black precipitate of  $\text{Ti}(\text{OH})_2$ . If the solution contains only a small quantity of acid, the sesquioxide is precipitated.

The three chlorides exhibit the following reactions:—

| Soluble in           | $\text{TiCl}_2$ . | $\text{TiCl}_3$ .         | $\text{TiCl}_4$ .    |

Titanium sesquioxide is not formed as Ebelmann states (*Ann. Chim. Phys.* [3], **20**, 394) by the action of hydrogen on titanium dioxide at a red heat. The product has the composition of  $\text{Ti}_7\text{O}_{12}$ . W. C. W.

**Vanadates of the Alkaline Earths.** By O. MANASSE (*Chem. Centr.*, 1886, 773—774).—The *normal barium salt*,  $\text{BaV}_2\text{O}_6 + \text{H}_2\text{O}$ , is obtained by adding barium chloride to a solution of the normal potassium salt. Precipitated from the acid potassium salt, it is often obtained as a yellowish-white powder mixed with orange-red crystals. An *acid barium salt*,  $\text{Ba}_3\text{V}_{10}\text{O}_{28} + 19\text{H}_2\text{O}$ , is formed by precipitating the acid potassium salt with a soluble barium salt. The precipitate first formed slowly changes into red-yellow crystals, mixed with the yellowish-white powder of the preceding salt, the solution gradually becomes quite colourless. It is soluble in water to the extent of 1 in 5000. The salt is obtained in beautiful, red, prismatic crystals, when equivalent amounts of potassium divanadate and barium chloride are mixed with a large excess of acetic acid. *Barium orthovanadate*,  $\text{Ba}_6\text{V}_2\text{O}_8$ , cannot be obtained, owing to its great instability; it is decomposed into barium pyrovanadate and barium hydroxide at the time of its formation.

**Strontium Salts.**—The *normal salt*,  $\text{SrV}_2\text{O}_6 + 4\text{H}_2\text{O}$ , is described, and also *acid salts*, having the composition  $\text{Sr}_3\text{V}_6\text{O}_{23} + 14\text{H}_2\text{O}$ ,  $\text{Sr}_5\text{V}_{14}\text{O}_{39} + 30\text{H}_2\text{O}$ , and  $\text{SrV}_8\text{O}_{21} + 11\text{H}_2\text{O}$ . When potassium divanadate and strontium chloride are allowed to crystallise together, the following double salts are obtained:— $\alpha$  and  $\beta$ ,  $\text{K}_8\text{V}_{14}\text{O}_{39} + 20\text{H}_2\text{O} + 3(\text{Sr}_4\text{V}_{14}\text{O}_{39} + 20\text{H}_2\text{O})$ ;  $3(\text{Sr}_4\text{V}_{14}\text{O}_{39} + 30\text{H}_2\text{O}) + \text{K}_8\text{V}_{14}\text{O}_{39} + 30\text{H}_2\text{O}$ ; and a  $\gamma$ -salt,  $\text{K}_8\text{V}_{14}\text{O}_{39} + 18\text{H}_2\text{O} + \text{Sr}_4\text{V}_{14}\text{O}_{39} + 18\text{H}_2\text{O}$ , and also  $\text{K}_4\text{V}_{10}\text{O}_{27} + 12\text{H}_2\text{O}$ .

**Calcium Salts.**—The *normal salt*,  $\text{CaV}_2\text{O}_6 + 4\text{H}_2\text{O}$ , is obtained by allowing a mixture of normal potassium vanadate and calcium chloride to evaporate. The *acid salt*,  $\text{Ca}_3\text{V}_6\text{O}_{23} + 15\text{H}_2\text{O}$ , is formed when equivalent amounts of potassium divanadate and calcium chloride are mixed with excess of acetic acid. The *tetравanadate*,  $\text{CaV}_4\text{O}_{11} + 6\text{H}_2\text{O}$ , is obtained in red crystals by evaporating potassium divanadate and calcium chloride. Other salts prepared were:— $\text{Ca}_3\text{V}_{14}\text{O}_{38} + 7\text{H}_2\text{O}$ ,  $\text{Ca}_3\text{V}_{16}\text{O}_{43} + 26\text{H}_2\text{O}$ , and  $\text{CaV}_4\text{O}_{11} + 4\text{K}_2\text{V}_4\text{O}_{11} + 22\text{H}_2\text{O}$ , potassium calcium tetравanadate.

**Magnesium Salts.**—The *normal salt*,  $\text{MgV}_2\text{O}_6 + 6\text{H}_2\text{O}$ , is prepared by boiling finely powdered vanadic acid with excess of magnesium carbonate. *Acid salts*,  $2(\text{Mg}_2\text{V}_6\text{O}_{17}) + 19\text{H}_2\text{O}$  and  $\text{Mg}_3\text{V}_{10}\text{O}_{28} + 28\text{H}_2\text{O}$ , were also prepared.

When a few drops of nitric or sulphuric acid is added to these salts, a hydrate of vanadic acid,  $\text{H}_2\text{V}_2\text{O}_6$ , is formed, which is much more soluble than the crystallised vanadic acid.

The author determined the vanadic acid in the above salts by reducing the acid and titrating with permanganate. He found that the reduction of vanadic acid is best effected by hydrogen sulphide, or by sulphurous anhydride with a simultaneous passage of carbonic anhydride.

A compound,  $\text{V}_8\text{O}_{17}$ , was obtained as a dark blue or black powder with metallic lustre, by dissolving vanadic acid containing oxide in potassium hydroxide. It can be regarded as a mixture of  $\text{V}_2\text{O}_5 + 3\text{V}_2\text{O}_4$ , or of  $\text{V}_4\text{O}_9 + 2\text{V}_2\text{O}_4$ .

G. H. M.

**Valency of Bismuth.** By A. MICHAELIS (*Ber.*, **20**, 52—54).—See this vol., p. 368.

**Action of Hydrogen Peroxide on Bismuth Salts.** By K. HASEBROEK (*Ber.*, **20**, 213—218).—When commercial (3 per cent.) hydrogen peroxide, rendered alkaline with ammonia (or potash), is added to a bismuth salt and the mixture gently warmed, evolution of oxygen occurs and a characteristic orange-yellow precipitate of bismuth pentoxide is formed; the reaction is of such delicacy that 1 part of bismuth in 100,000 can be detected by its means. To obtain the pentoxide in the pure state, it is necessary to work in an atmosphere free from carbonic anhydride, otherwise absorption of the gas and formation of bismuthyl carbonate takes place. The air-dried bismuth pentoxide contains less water than corresponds with 1 mol.  $\text{H}_2\text{O}$ ; it is a bright orange-yellow, amorphous powder, insoluble in water and alkalis, but soluble in dilute acids, solutions of varying shades of red being formed when dilute nitric and sulphuric acids are used as solvents. When heated with alkalis or alone, it becomes brown, and by further heating melts to form crystalline bismuth trioxide. Treated with hydrochloric and sulphuric acids, it evolves chlorine and oxygen respectively, whilst hydrogen peroxide is readily decomposed by it.

W. P. W.

**Atomic Weight of Gold.** By G. KRÜSS (*Ber.*, **20**, 205—210).—The collective results obtained in a determination of the atomic weight of gold are given. Two salts were employed, the neutral auric chloride,  $\text{AuCl}_3$  (in solution), and potassium gold bromide,  $\text{KAuBr}_4$ . The gold chloride was obtained by passing chlorine over finely divided gold; to remove excess of chlorine, the product was exposed for a day to air dried by passage over sulphuric acid and phosphorus pentoxide, then allowed to remain for several weeks over frequently renewed soda-lime, and finally decomposed by water into a solution of neutral auric chloride. The potassium gold bromide was prepared by adding finely divided gold to potassium bromide and bromine in aqueous solution; the salt is anhydrous and only very slightly hygroscopic.

| Number of experiments made with each method. | Ratio determined.  | Atomic weight. | Difference between the maximum and minimum values found. |
|--|--|----------------|--|
| 8  | Solution of neutral auric chloride ... $\text{Au} : \text{Cl}_3$ | 196·622        | 0·101  |
| 4  | Potassium gold bromide .....                                     |                |  |
|  | ..... $\text{Au} : \text{Br}_3$                                  | 196·619        | 0·110  |
| 4  | Ditto ..... $\text{Au} : \text{KBr}$                             | 196·620        | 0·134  |
| 5  | Ditto ..... $\text{Au} : \text{Br}_4$                            | 196·743        | 0·225  |
| 9  | Ditto ..... $\text{Au} : \text{KBr}, \text{Br}_3$                | 196·741        | 0·306  |
| 30   | Mean ....  | 196·669        | 0·175  |

The values found for the atomic weight ( $O = 15.96$ ) are given in the table (p. 340).

The author adopts the value 196.64 as that of the atomic weight of gold.  
W. P. W

**Sublimed Auric Chloride.** By G. KRÜSS (*Ber.*, 20, 211—213).—When a continuous current of dry chlorine is passed over powdered gold, and the temperature gradually raised, it is found that at  $140^\circ$  a small quantity of reddish-brown vapour is formed which condenses to a yellowish-red sublimate; if the temperature is kept constant the sublimation soon ceases, and the gold is entirely converted into aurous auric chloride. When the temperature is raised to  $180$ — $190^\circ$  this compound decomposes, chlorine is evolved, and green aurous chloride and a small quantity of volatile gold chloride are formed. At  $220$ — $230^\circ$  a small quantity of gold chloride again volatilises, whilst the aurous chloride decomposes into gold and chlorine, and at  $300^\circ$  the gold, contrary to Debray's statement (*Compt. rend.*, 69, 985), remains unaltered in the current of chlorine. On allowing the temperature to fall these changes take place in the reverse order. The amount of volatile gold chloride, which analysis shows to be auric chloride,  $AuCl_3$ , and not a higher chloride as stated by Prat (*Compt. rend.*, 70, 840), is very small; thus, 100 repetitions of the process with a layer of powdered gold 30—35 cm. long, yielded less than 0.12 gram of auric chloride in the form of a sublimate consisting of lustrous, reddish-brown needles.  
W. P. W.

## Mineralogical Chemistry.

**Amorphous Carbon (Graphitoid) in the Saxon Erzgebirge.** By A. SAUER (*Zeit. Kryst. Min.*, 12, 527).—Amorphous carbon is widely distributed throughout the mica schists and phillites of the Erzgebirge. It is not identical with graphite or with anthracite. The author finds that it is identical with the amorphous carbon described by Inostranzeff (*Abstr.*, 1881, 357), and suggests for the substance the name of graphitoid. The analysis gave the following results:—

| Ash.  | C.    | H <sub>2</sub> O. | H.   | Total. |
|-------|-------|-------------------|------|--------|
| 73.85 | 24.85 | 1.01              | 0.06 | 99.77  |

B. H. B.

**Crystallisation of Native Copper.** By E. S. DANA (*Amer. J. Sci.*, 32, 413—429).—This elaborate memoir is based on a careful study of the beautiful collection of 60 specimens of native copper from Lake Superior, in the possession of Mr. C. S. Bement. The author also had the use of a large number of specimens belonging to the cabinets of Professor G. J. Brush, and of the Yale College

Museum. The paper is accompanied by illustrations of 54 varieties of crystalline forms of native copper. The planes observed by the author are :  $\infty O\infty$ ,  $\infty O$ ,  $O$ ,  $\infty O4$ ,  $\infty O\frac{5}{2}$ ,  $\infty O2$ ,  $\infty O\frac{3}{2}$ ,  $3O3$ ,  $2O2$ ,  $1\frac{1}{2}O\frac{3}{2}$ ,  $11O\frac{1}{6}$ ,  $6O4$ . Of these, the trisoctahedron  $2O2$ , and the hexoctahedra  $11O\frac{1}{6}$  and  $6O4$ , are new to the species.

B. H. B.

**Crystallographic Notes.** By W. G. BROWN (*Amer. J. Sci.*, **32**, 377—380).—1. *Artificial Copper Crystals*.—In a cell of a Calland gravity battery which had remained undisturbed for three months, there was found attached to the insulating wire coming from the copper plate, at the point where it passed the zinc plate, a pendant mass consisting almost entirely of copper crystals. The crystals were evidently accidentally formed by electrolysis. The upper part of the mass consists of spongy dendritic copper, whilst the lower and larger portion consists of definite copper crystals. By far the greater number of the crystals are twins, either according to the spinel law, twinning plane an octahedral face, or the twinning plane is that of a trapezohedron forming polysynthetic twins.

2. *Artificial Crystallised Cuprite*.—On the outside of the spongy portion of the copper described above, there is a purple layer of crystals of cuprous oxide. Individually, they are of a dark ruby-red colour; the forms present being combinations of the octahedron and cube. Another example of crystallised cuprous oxide was found on a German-silver camp spoon picked up on the site of a magazine constructed in 1863, on Morris Island, South Carolina. The short time in which the crystals have formed seems a noteworthy feature of this occurrence. The spoon could not have been exposed more than 20 years.

3. *Crystallised Cerussite*.—At Morris Island, among the *débris* of a battle-field, a dozen Minié balls were picked up. Upon various parts of the surface of these were patches of lead carbonate, sometimes amorphous and sometimes acicular. The balls had not been fired. It is possible that the formation of the carbonate was hastened by the rapid oxidation of the lead by the nitre of the gunpowder of the cartridge in the presence of moisture.

B. H. B.

**Mineralogical Notes.** By A. GENTH (*Zeit. Kryst. Min.*, **12**, 487—492).—The author gives descriptions and analyses of the following minerals:—1. Native tin from the Aberfoil River, New South Wales; 2. Joseite and tetradymite from San José, Minas Geraes; 3. Galenobismuthite containing selenium from Falun, Sweden; 4. Silver bismuth glance from Lake City, Colorado; 5. Cosalite from the Alaska and Gladiator mines in Ouray Co., Colorado; 6. Beegerite from the Treasury Vault mine, Summit Co., Colorado; 7. Fahlerz from the Governor Pitkin mine, Lake City, Colorado; 8. Polybasite from the Terrible Lode mine, Clear Creek Co., Colorado; 9. Arsenical pyrites from North Alabama; 10. Brucite from Berks Co., Pennsylvania; 11. Ilmenite and oligoclase from the Carter mine, North Carolina; 12. Topaz from Stoneham, Maine; 13. Orthoclase from French Creek, Chester Co., Pennsylvania; 14. Muscovite pseudomorphs after nepheline from Wakefield in Canada; 15. Stilp-

nomelane from Antwerp, New York; 16. Calamine from the Bertha mine, Pulaski Co., Virginia; 17. Titanite from Statesville, North Carolina; 18. Vanadinite from Wanlockhead, Scotland; 19. Annabergite from the Gem mine, Silver Cliff, Colorado. B. H. B.

**Mineralogical Notes.** By E. S. DANA (*Amer. J. Sci.*, **32**, 386—390).—The author gives the results of a crystallographical investigation of the following minerals:—

1. *Columbite* from Standish, Maine.—The results of the author's examination of this mineral have already been published (this vol., . 20).

2. *Diaspore* from Newlin, Pennsylvania.—The crystal examined is the finest ever found at the locality. It is prismatic in habit and showed the following planes:— $\infty P\infty$ ,  $\infty P\bar{2}$ ,  $\infty P\bar{2}$ ,  $\infty P\bar{5}$ , and  $\frac{3}{2}P\bar{5}$ ; the last pyramid being new to the species. On crystals of diaspore from Chester, Massachusetts, the author has observed the planes  $1P\frac{5}{2}$  and  $1P\bar{2}$ , new to the species.

3. *Zincite*.—The knowledge of the crystals of zinc oxide has hitherto rested on observations of artificial crystals, the native mineral showing usually only massive forms. The cabinet of Mr. C. S. Bement contains several specimens of zincite from Stirling Hill, New Jersey, showing distinct crystals. The angles measured show a fair agreement with the angles of the artificial forms.

4. *Sulphur*.—A specimen of native sulphur from Rabbit Hollow, in the cabinet of Professor Brush, is interesting on account of the complexity of its form. Fifteen planes were observed; of these  $\frac{3}{5}P\bar{5}$  and  $\frac{1}{4}P$  are new to the species. B. H. B.

**Copper Mineral from Sunnerskog, Sweden.** By G. LINDSTRÖM (*Zeit. Kryst. Min.*, **12**, 512—513).—The mineral is dark indigo-blue, with a blue streak and faint metallic lustre. Analysis gave the following results:—

| Cu.   | S.    | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | Insol. | Total. |
|-------|-------|----------------------------------|------|--------|--------|
| 74.29 | 24.22 | 0.10                             | 0.59 | 0.51   | 99.71  |

A mineral analysed by Hahn, and named carmenite, had the same composition. It was, however, regarded by Dana as an impure copper glance, mixed with covelline. B. H. B.

**Galenobismuthite containing Selenium from the Falun Mine.** By M. WEIBULL (*Zeit. Kryst. Min.*, **12**, 511—512).—Galenobismuthite containing selenium was first observed in the quartz at the Falun Mine in Sweden. Its occurrence is of practical importance, as it has been proved that the native gold is always accompanied by this mineral at Falun. The mineral has a perfect cleavage; H. = 3. Thin plates are flexible, but scarcely elastic. The colour is a steel grey; sp. gr. 6.97. Analysis gave the following results:—

| Bi.   | Pb.   | Cu.  | Fe.  | S.   | Se.   | Total. |
|-------|-------|------|------|------|-------|--------|
| 49.73 | 24.62 | 0.77 | 0.61 | 9.82 | 13.61 | 99.66  |

The formula is thus  $PbS, Bi_2S_3 + PbS, Bi_2Se_3$ . The mineral is

probably isomorphous, with the lead-bismuth glance described by H. Sjögren.

This mineral has also been analysed by A. Genth (*Zeit. Kryst. Min.*, **12**, 487—488), the mean of five analyses giving the following results, after 3·96 to 8·8 per cent. of impurities had been subtracted :—

| Bi.   | Pb.   | Ag.  | S.   | Se.   | Total. |
|-------|-------|------|------|-------|--------|
| 49·88 | 27·88 | 0·33 | 9·75 | 12·43 | 100·27 |

B. H. B.

**Emmonsite, an Iron Telluride.** By W. F. HILLEBRAND (*Zeit. Kryst. Min.*, **12**, 492—493).—This new mineral from Colorado occurs in yellowish-green scales in a hard brown, vein-mass, consisting of lead carbonate, quartz, and a brown substance containing iron and tellurium. The mineral is probably monosymmetric. The quantity of mineral available for analysis was very small. Three analyses of the brown substance gave the results under I, II, III; an analysis of the green particles carefully picked out, but still not pure, gave the results under IV. The mean results, probably the most correct, are given under V, 0·53 per cent. of selenium having been subtracted :—

|                | I.    | II.   | III.  | IV.   | V.    |
|----------------|-------|-------|-------|-------|-------|
| Te(Se) . . . . | 59·77 | 59·15 | 59·05 | 59·14 | 58·75 |
| Fe . . . . .   | 14·00 | 14·06 | 14·90 | 14·20 | 14·29 |

In Analysis I, 3·28 per cent. of water was found, and in Analysis IV 1·94 of ZnO and 0·56 of CaO. The mineral is a ferri-telluride. It has been named in honour of Mr. S. J. Emmons, of the U.S. Geological Survey.

B. H. B.

**Elpasolite, a New Mineral.** By W. J. CROSS and W. J. HILLEBRAND (*Zeit. Kryst. Min.*, **12**, 495).—This is a new Colorado mineral, named after the county (El Paso) in which it was found. It occurs in cavities in massive pachnolite, in the form of compact masses, on which are planted indistinct, isometric crystals. Analysis gave the following results :—

| Al.   | Ca.  | Mg.  | K.    | Na.  | F.      | Total. |
|-------|------|------|-------|------|---------|--------|
| 11·32 | 0·72 | 0·22 | 28·94 | 9·90 | (46·98) | 98·08  |

The determination of the alkalis is only an approximation, and the fluorine is calculated on the assumption that it is completely combined with metals. It is suggested that the mineral should be regarded as a cryolite, in which two-thirds of the potassium is replaced by sodium.

B. H. B.

**Gearksutite from Ivigtut, Greenland.** By A. E. NORDENSKIÖLD (*Zeit. Kryst. Min.*, **12**, 513—514).—The mineral is, according to the author, of recent formation, being due to the action of calcareous water on the water circulating in the fissures of the cryolite deposit. Analysis gave results identical with those obtained by Cross and Hillebrand (*Abstr.*, 1884, 21), the formula being  $\text{CaF}_2 + (\text{AlF}_3)(\text{AlH}_3\text{O}_3) + \text{H}_2\text{O}$ .

B. H. B.

**Chemical Composition of Ralstonite.** By S. L. PENFIELD and D. N. HARPER (*Amer. J. Sci.*, **32**, 380—385).—Analyses of the rare mineral ralstonite have been published by Nordenskiöld, Penfield, and Brandt. The authors have now made an analysis of a specimen of ralstonite associated with thomsenolite from Arksut Fjord, Greenland, the results being as follows:—

| Mg.  | Na.  | K.   | Ca.  | Al.   | F.    | H <sub>2</sub> O. | Total. |
|------|------|------|------|-------|-------|-------------------|--------|
| 4·39 | 4·27 | 0·12 | 0·03 | 24·25 | 39·91 | 18·73             | 91·70  |

The ratio of  $(\text{MgNa}_2\text{K}_2) : \text{Al} = 1 : 3$  nearly. This ratio being assumed to be correct, the ratio of the fluorine necessary to unite with the metals should be 11, whereas only 7·56 was found. The assumption that hydroxyl replaces fluorine not only makes up for the deficiency in the analysis, but also leads to a very satisfactory ratio. The assumption is also well supported by actual experiment. Using the actual water of crystallisation and hydroxyl determinations, and determining the fluorine by difference, the latter part of the analysis would be as follows:—

| F.    | OH.   | H <sub>2</sub> O. |
|-------|-------|-------------------|
| 40·79 | 15·78 | 10·37             |

Assuming these conclusions to be correct, the mineral is an isomorphous mixture of  $(\text{MgNa}_2)\text{Al}_3\text{F}_{11}, 2\text{H}_2\text{O}$  and  $(\text{MgNa}_2)\text{Al}_3(\text{OH})_{11} + 2\text{H}_2\text{O}$ .  
B. H. B.

**Brucite from the Ural.** By A. A. LÖSCH (*Zeit. Kryst. Min.*, **12**, 514).—The mineral occurs with chlorite, calcite, perowskite, forsterite, and waluewite at the Nikolaje-Maximilianoffski Mine; sp. gr. = 2·388. Analysis gave the following results:—

| MgO.  | FeO. | H <sub>2</sub> O. | CO <sub>2</sub> . | Total. |
|-------|------|-------------------|-------------------|--------|
| 69·03 | 0·76 | 30·15             | 0·09              | 100·03 |

B. H. B.

**Artificial Production of Zincite and Willemite.** By A. GORGEU (*Compt. rend.*, **104**, 120—123).—When zinc sulphate is gradually heated to bright redness, it yields zinc oxide in small crystals which are more readily obtained if the zinc salt is mixed with an equivalent quantity of an alkaline sulphate. Decomposition is then less rapid and the crystals separate in the fused mass. Before decomposition is complete, the product is cooled and extracted with water, when zinc oxide is left in heavy, transparent, nacreous, greenish-yellow or greenish, hexagonal prisms which, like the crystals of zincite, belong to the hexagonal system. In hardness and sp. gr. (5·5) the artificial crystals are identical with the natural oxide. Zinc nitrate also yields good crystals if only heated to partial decomposition, and the crystals are also obtained by heating equal parts of zinc fluoride and potassium fluoride in presence of aqueous vapour.

Willemite,  $\text{SiO}_2, 2\text{ZnO}$ , is obtained when an intimate mixture of zinc sulphate with 0·5—1 equivalent of an alkaline sulphate and one-thirtieth of their weight of hydrated silica is heated for an hour

at a temperature sufficient to cause a slight but regular evolution of sulphurous anhydride. The fused mass is treated with water, which leaves a residue of tridymite and basic zinc sulphate with strongly birefractive crystals of willemite, which form hexagonal prisms with obtuse rhombohedral terminations. In hardness (5·5), sp. gr. (4·25), and general properties, the artificial crystals are identical with those of the natural mineral. Calcined silica and sand will give the same results, but the action is much slower.

No acid zinc silicate was obtained even with an excess of silica.

When a mixture of zinc chloride and an alkaline chloride with silica is heated in presence of water-vapour, crystals of the composition  $\text{SiO}_2 \cdot 2\text{ZnO}$ , are obtained, but their exact form could not be determined.

C. H. B.

**Goslarite from Montana.** By R. PEARCE (*Zeit. Kryst. Min.*, **12**, 494).—Goslarite occurs in long, acicular crystals in some old workings, 400 feet deep, in the Gagnon Mine, Butte City, Montana. Analysis gave the following results:—

| $\text{SO}_3$ . | ZnO.    | CuO. | MnO, FeO. | $\text{H}_2\text{O}$ . | Total. |
|-----------------|---------|------|-----------|------------------------|--------|
| 28·09           | (27·56) | 0·12 | 0·30      | 43·93                  | 100·00 |

B. H. B.

**Place of Spodiosite in the Mineral System.** By A. SJÖGREN (*Zeit. Kryst. Min.*, **12**, 512).—In consequence of the chemical and crystallographical resemblance between spodiosite and kjerulfine, the author suggests that the two minerals may be isomorphous compounds, thus:—

|                  |  |
|------------------|--|
| Kjerulfine ..... | $\text{Mg} \cdot \text{F} \cdot \text{PO}_4$   |
| Spodiosite ..... | $\text{Ca}_2 \cdot \text{F} \cdot \text{PO}_4$ |

The planes of spodiosite calculated from the axial ratio of kjerulfine would be  $\infty\text{P}$ ,  $\infty\text{P}\infty$ ,  $-2\text{P}$ ,  $+2\text{P}$ ,  $4\text{P}\infty$ .

B. H. B.

**Sarkinite, a New Manganese Arsenate.** By A. SJÖGREN (*Zeit. Kryst. Min.*, **12**, 514).—This mineral occurs in veins of white calcite at Pajsberg, in Sweden. It has a greasy lustre, and is of a bright flesh colour, hence its name, from *σάρκινος*, *fleshy*.  $\text{H} = 4$  to 5. Sp. gr. = 4·14 to 4·15. The mineral is brittle, giving a bright red powder. On heating, the powder becomes first grey, then black, and, when strongly ignited, a brownish-black. The crystalline system is unknown, probably monosymmetric. The mean of two analyses gives the following figures:—

| $\text{As}_2\text{O}_5$ . | $\text{P}_2\text{O}_5$ . | $\text{CO}_2$ .        | MnO.   | FeO.   | CaO. | MgO. |
|---------------------------|--------------------------|------------------------|--------|--------|------|------|
| 41·60                     | 0·21                     | 0·76                   | 51·60  | 0·13   | 1·40 | 0·98 |
|                           | PbO.                     | $\text{H}_2\text{O}$ . | Insol. | Total. |      |      |
|                           | 0·25                     | 3·06                   | 0·38   | 100·37 |      |      |

B. H. B.

**Polyarsenite, a New Mineral.** By L. J. IGELSTRÖM (*Zeit. Kryst. Min.*, **12**, 515).—The mineral was found at the Sjö mine, in the parish of Grythyttå, Örebro, Sweden. It is a hydrated manganese

arsenate, of a reddish-yellow colour, translucent, massive, and without distinct cleavage, or crystal planes. It occurs with hæmatostibiite (a manganese antimoniate) in calcite veins in a mass of tephroite. Sp. gr. = 4·085. Analysis gave the following results:—

| H <sub>2</sub> O. | CO <sub>2</sub> . | As <sub>2</sub> O <sub>5</sub> . | Sb <sub>2</sub> O <sub>5</sub> . | MnO.  | FeO.  | CaO. | MgO. | Total. |
|-------------------|-------------------|----------------------------------|----------------------------------|-------|-------|------|------|--------|
| 3·15              | 3·51              | 39·23                            | 1·37                             | 49·88 | trace | 2·85 | 0·77 | 100·76 |

Formula: (MnO)<sub>4</sub>As<sub>2</sub>O<sub>5</sub> + H<sub>2</sub>O.

B. H. B.

### Crystallised Vanadinite from Arizona and New Mexico.

By S. L. PENFIELD (*Amer. J. Sci.*, **32**, 441—443).—The crystals of vanadinite from Pinal Co., Arizona, are small, seldom over 1 mm. in length, of a deep red colour, and usually show the very simple combinations mentioned by W. P. Blake (*Amer. J. Sci.*, **22**, 410). A few highly modified crystals were found possessing pyramidal hemihedral forms, which are of interest because these forms have rarely been observed in this species. From the best measurements, the axial ratio  $a : c = 1 : 0·71121$  was obtained. This agrees closely with the ratios given by Schabus,  $1 : 0·71157$ , and by Vrba,  $1 : 0·7112177$ . The measured angles agree closely with those calculated from the axial ratio. The crystals contain but a trace of As<sub>2</sub>O<sub>5</sub>.

The crystals from the Sierra Grand Mine, Lake Valley, New Mexico, are straw-yellow in colour. The crystals give distinct V<sub>2</sub>O<sub>5</sub> and As<sub>2</sub>O<sub>5</sub> reactions, thus corresponding exactly with the description given by F. A. Genth and G. vom Rath of the species named by them *endlichite*. The axial ratio was found to be  $a : c = 1 : 0·7495$ . The measured angles do not agree well with those calculated from the axial ratio. The presence of As<sub>2</sub>O<sub>5</sub> in the mineral must therefore tend to increase the length of the vertical axis.

B. H. B.

**Columbite from Colorado.** By W. P. HEADDEN (*Zeit. Kryst. Min.*, **12**, 494).—A mineral, hitherto regarded as tin ore, from Turkey Creek, Jefferson Co., Colorado, is found to be columbite rich in manganese. Sp. gr. 5·48. Analysis gave the following results:—

| Nb <sub>2</sub> O <sub>5</sub> . | WO <sub>3</sub> + SnO <sub>2</sub> . | FeO. | MnO.  | Total. |
|----------------------------------|--------------------------------------|------|-------|--------|
| 77·83                            | 1·00                                 | 9·92 | 11·23 | 99·98  |

B. H. B.

**Phosphoric Anhydride in Felspar.** By G. LINDSTRÖM (*Zeit. Kryst. Min.*, **12**, 513).—The author gives two analyses of felspar from Tammela and Skogböle in Finland. They present nothing worthy of note, with the exception of the phosphoric anhydride found by the author. In one case the percentage is 0·72, and in the other 0·58. Thin sections of the mineral analysed were found to contain a small quantity of apatite. The author is, however, of opinion that the phosphoric anhydride must also be present in some other less soluble compound.

B. H. B.

**Lithia Micæ.** By F. W. CLARKE (*Amer. J. Sci.*, **32**, 353—361).  
1. *The Lepidolites of Maine.*—In the western part of Maine, there are

a series of veins of albitic granite containing lithia mica and coloured tourmalines. The localities, in the towns of Rumford, Paris, Norway, Hebron, and Auburn, are all within a narrow belt of 40 miles in length. Analyses of the lepidolite gave the following results:—

|                                      | 1.<br>Purple.<br>Rum-<br>ford. | 2.<br>Foliated.<br>Paris. | 3.<br>Granu-<br>lar.<br>Hebron. | 4.<br>Border.<br>Auburn. | 5.<br>Granu-<br>lar.<br>Auburn. | 6.<br>White.<br>Norway. | 7.<br>Brown.<br>Norway. |
|--------------------------------------|--------------------------------|---------------------------|---------------------------------|--------------------------|---------------------------------|-------------------------|-------------------------|
| SiO <sub>2</sub> .....               | 51·52                          | 50·92                     | 48·80                           | 49·62                    | 51·11                           | 49·52                   | 50·17                   |
| Al <sub>2</sub> O <sub>3</sub> ..... | 25·96                          | 24·99                     | 28·30                           | 27·30                    | 25·26                           | 28·80                   | 25·40                   |

The foregoing analyses of several distinct types of lepidolite from five distinct localities indicate a great consistency of composition. In most of the analyses, the water and fluorine appear to vary reciprocally, suggesting the ordinary replacement of the latter element by hydroxyl. With this assumption, the formula for lepidolite may be written Al<sub>2</sub>LiKF<sub>2</sub>Si<sub>3</sub>O<sub>9</sub>; a formula generally accepted, but which now rests upon the basis of a wider range of analytical data.

2. *The Iron-lithia Micas of Cape Ann, Massachusetts.*—Cryophyllite, a remarkable mica from this locality, was described by Cooke in 1867 (*Amer. J. Sci.*, **43**, 217), who also analysed an associated lepidomelane, to which Dana afterwards gave the name of annite. The cryophyllite varies considerably in external character, and three well-marked types of it were analysed. They may be described as follows:—I, broadly-foliated, brilliant, blackish-green; II, paler, dull-green, less lustrous, apparently altered; III, an aggregation of minute, hexagonal pyramids,

dark-green, almost granular in appearance. The analytical results were as follows:—

|                                      | I.     | II.    | III.   | IV.    |

The three samples were sensibly identical, and not very different from the material analysed by Cooke. The integrity of the species seems to be clear; and it cannot be identified with zinnwaidite. Empirically, as deduced from the new analyses, the formula may be written  $R'_6Al_2F_2(SiO_3)_5$ .

With the annite, quite unexpected results were obtained (Analysis IV). The material was black, brilliant, broadly foliated, and seemed to be very pure. The analytical results clearly show that this mica and that analysed by Cooke are entirely distinct, and the question is raised whether the Cape Ann granite may not contain a series of complex isomorphous mixtures.

**Lucasite, a New Variety of Vermiculite.** By T. M. CHATARD (*Amer. J. Sci.*, **32**, 375—377).—A distinct variety of the vermiculite-group has been found among the minerals occurring with corundum at Corundum Hill, North Carolina. The name *lucasite* has been given to it in honour of Dr. H. S. Lucas, well known in connection with corundum mining in the Southern States. The mineral was found in a corundum vein. It is foliated, compact, also disseminated; cleavage, basal; colour, yellowish-brown; lustre, submetallic, somewhat greasy; easily decomposed by concentrated hydrochloric acid, the silicic acid separating in pearly scales. When heated, it gives off much water and exfoliates with considerable force. Under the microscope, it was found to be biaxial and negative, but the angle between the optic axes, as seen in a cleavage plate split off parallel to the base, is uniformly small. On rotating the section, although the cross is plainly distorted into two hyperbolæ, they do not com-

pletely separate from each other. Analysis of the air-dried mineral gave the following results:—

|                   |                    |                                  |                                  |                                  |        |      |
|-------------------|--------------------|----------------------------------|----------------------------------|----------------------------------|--------|------|
| H <sub>2</sub> O. | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Cr <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO.   | MnO. |
| 10·76             | 39·81              | 12·99                            | 0·54                             | 5·29                             | 0·11   | 0·05 |
|                   | CaO.               | MgO.                             | K <sub>2</sub> O.                | Na <sub>2</sub> O.               | Total. |      |
|                   | 0·14               | 24·83                            | 5·76                             | 0·20                             | 100·48 |      |

Water determinations gave the following results:—H<sub>2</sub>O at 100°, 3·78; H<sub>2</sub>O at red heat, 6·98. Total, 10·76. B. H. B.

**Lamellar Thomsonite.** By A. LACROIX (*Compt. rend.*, 104, 234—235).—This mineral occurs in a small vein in the labradoric porphyrite at Bishopston, Scotland.

It exists in nacreous, white lamellæ with a rose tint, the ordinary cleavage of thomsonite having become micaceous. These lamellæ are grouped at all angles. The cleavage lamellæ unite parallel with their elongation along the edge (100) (010), and there are also traces of cleavage along (100) and (001). The plane of the optical axes is parallel with (001), and the positive bisectrix is normal to the easy cleavage (010), the maximum birefractive power being 0·027. Under the microscope, the mineral is found to consist of thin plates irregularly superposed like those of zeolites. It has the composition RO, Al<sub>2</sub>O<sub>3</sub>, 2SiO<sub>2</sub> + H<sub>2</sub>O, R being calcium and sodium, sp. gr. 2·34. When heated before the blowpipe, it yields a white enamel, and it is easily decomposed by hydrochloric acid with gelatinisation.

C. H. B.

**White Epidote from the Beagle Canal, Terra del Fuego.** By A. LACROIX (*Compt. rend.*, 104, 235—236).—The mineral forms white needles which cleave parallel with the direction of the elongation. They are monoclinic prisms elongated along the edge (001) (100). The plane of the optical axes is parallel with the face (010), and the positive bisectrix is normal to one face of the zone (001) (100), the separation of the two axes being about 75°, and the maximum birefractive power 0·04. The mineral contains many cavities with liquid enclosures. When heated to redness, it becomes brown, and forms a semi-agglutinated powder, which melts to a brown scoria before the blowpipe. It is scarcely attacked by boiling acids, but gelatinises with hydrochloric acid after being strongly heated.\* The mineral has the sp. gr. 3·21 at 5°, and the composition SiO<sub>2</sub>, 37·95; Al<sub>2</sub>O<sub>3</sub>, 30·38; FeO, 7·83; CaO, 20·34; MgO, 0·93; loss on heating 2·64, which agrees with the formula 6RO, 4Al<sub>2</sub>O<sub>3</sub>, 9SiO<sub>2</sub>. The high proportion of alumina and the state of oxidation of the iron are especially noteworthy. In external appearance, the mineral strongly resembles zoisite.

C. H. B.

**Critical Examination of some Minerals.** By A. LACROIX (*Compt. rend.*, 104, 97—99).—*Pterolite*, from the island of Lövö, is

\* I have observed the same behaviour in the case of several English specimens of epidote. See Green's *Physical Geology*, p. 128.—C. H. B.

an association of green pyroxene with black mica. The latter is uniaxial and pleochroic, being deep brown along *ng*, and reddish-yellow along *np*. The mineral also contains numerous grains of blue sodalite, rhombohedrons of calcite or dolomite, and intrusions of other minerals. It has no claim to be regarded as a distinct mineralogical species.

*Villarsite*, from Traverselle, is not a distinct species, but is merely normal peridot cracked in all directions and more or less completely converted into secondary products. In some specimens, the conversion into chrysotile is complete. It resembles serpentine in being a product of the disintegration of olivine.

*Grangesite*, from Grangesberg, has a composition very similar to that of ripidolite. It forms thin, greenish-brown, isotropic plates, but cannot be regarded as a distinct species.

*Gamsigradite*, from Gamsigrad, has the optical properties of hornblende, and is pleochroic, being bottle-green along *ng*, greenish-brown along *nm*, brownish-yellow along *np*. The rock in which it occurs is an amphibolic dacite containing labradorite and amphibole.

C. H. B.

**Paragonite Schist from the Ural.** By A. ARZRUNI (*Zeit. Kryst. Min.*, 12, 531).—The author describes a paragonite-schist from the Nizne-Issetsk district, where it occurs interstratified in the chlorite schist. It is filled with inclusions of a colourless, rhombic mineral, which, in its optical characters, is intermediate between zoisite and epidote. In crystalline system, twinning, and cleavage it is identical with zoisite, but in respect of the position of the plane of the optic axes, the character of the double refraction, and the dispersion of the optic axes, it is identical with epidote.

B. H. B.

**Gaseous Constituents of Meteorites.** By G. ANSDALL and J. DEWAR (*Proc. Roy. Soc.*, 40, 549—559).—Few analyses have hitherto been made of the gaseous constituents of meteorites, whether of the iron, stony, or carbonaceous classes; the results obtained have shown the presence, in variable proportion, of carbonic oxide and anhydride, hydrogen and methane. The investigation comprises a re-examination of a well-known meteorite, the analysis of several meteoric stones, and an examination of a graphite nodule taken from the interior of an iron meteorite, which is compared with graphites of celestial and terrestrial origin. Analytical results are given of specimens of the Dhurmsala, Pultusk, and Mocs meteorites and of pumice stone. In the former, carbonic anhydride was the largest constituent (about 65 per cent.), whilst marsh-gas in considerable quantity was found in all, and water was evolved, probably in part combined originally in some form, and not entirely absorbed from the atmosphere. A sample of the Dhurmsala meteorite, from which the gases had been removed, was exposed for different periods to a damp atmosphere; water, carbonic oxide and anhydride, and nitrogen were found to be absorbed; the total water given off after this exposure was less than that obtained in the first process of heating.

A sample of celestial graphite was examined and compared with specimens from Borrodale, Siberia, and Ceylon, as also with a partly

decomposed gneiss from Canada; the former gave off about twice as much gas as the latter.

Experiments are quoted to show that this large quantity of gas occluded in celestial graphites cannot be explained by any special absorptive power possessed by the variety of carbon. The hydrogen appears to exist in some combined form, but it is not shown whether the methane is entirely present as such in the meteoritic graphite or is subsequently formed during the heating process.

From the Orgueil meteorite, a typical specimen of the carbonaceous class, sulphur and sulphurous acid, together with ammonium salts, were obtained.

V. H. V.

**Hot Springs at Wiesbaden.** By R. FRESENIUS (*J. pr. Chem.* [2], 35, 122—131).—The author makes a full analysis of the solid and gaseous constituents of the water from these springs, and compares it with a similar analysis made in 1849.

The alkaline chlorides and the sulphates have not altered; on the other hand, calcium and magnesium compounds have slightly decreased, whilst silica and iron and manganese oxides have increased. The amount of solid matter delivered yearly by the springs is calculated.

## Organic Chemistry.

---

**Derivatives of Erythrene.** By E. GRIMAUX and C. CLOEZ (*Compt. rend.*, 104, 118—120).—The hydrocarbon  $C_4H_6$ , isolated from the liquid obtained by the compression of coal-gas, yields a tetrabromide crystallising in long, brilliant needles, which melt at  $116^\circ$ , and are almost insoluble in cold alcohol, but dissolve in about 30 times their weight of boiling alcohol of  $85^\circ$ . When heated on a water-bath with alcoholic potash, half the bromine is removed as potassium bromide, and the other product distils over with the alcohol. If water is added to the distillate, an oily liquid separates and rapidly polymerises to a solid, which dissolves only in boiling ethylene bromide. This liquid probably has the composition  $C_4H_4Br_2$ . If ether is added immediately after precipitation with water, the oily liquid is dissolved and the solution is stable, but if the ether is volatilised, the residue quickly polymerises. When the ethereal solution is mixed with bromine, it yields long, brilliant prisms of the composition  $C_4H_4Br_2, Br_2$ , which melt at  $69^\circ$ , volatilise in small quantities without decomposition, and are slightly soluble in alcohol, but dissolve readily in ether. The properties of this compound agree with those of the bromide described by Henninger, and it follows that the hydrocarbon obtained from coal-gas is identical with Henninger's erythrene, and is vinyl-acetylene,  $CH_2 : CH : CH : CH_2$ . The name erythrene indicates its relation to erythrol, and may conveniently be retained.

The tetrabromide obtained by Caventou from the hydrocarbons

formed by the pyrogenic decomposition of amyl alcohol, does not seem to be identical with erythrene bromide, since the former decomposes without volatilising, whilst the latter distils completely although with partial decomposition.

Erythrene from coal-gas combines with hypochlorous acid, forming a compound which is soluble in ether, alcohol, or water.

C. H. B.

**Triethyl Carbinol.** By S. BARATAEFF and A. SAYTZEFF (*J. pr. Chem.* [2], 34, 463—467).—Triethyl carbinol is obtained by bringing together diethyl ketone (1 mol.), ethylic iodide (3 mols.), and excess of zinc. At the end of a week, the mass is treated with water, the zinc oxide dissolved in sulphuric acid, and the liquid distilled. A colourless liquid of camphor-like odour boiling at 141—143° (uncorr.) is obtained. Sp. gr. at 20° = 0·84016 (water at 20° = 1). The acetate is an oil boiling at 160—163°.

Triethyl carbinol when oxidised with chromic mixture gives diethyl ketone, heptylene, propionic and acetic acids, and carbonic anhydride. The triethyl carbinol obtained as above is identical with that obtained by Nachapetian from zinc ethyl and propionic chloride (this Journal, 1871, 1035).

H. K. T.

**Dipropyl Carbinol.** By D. USTINOFF and A. SAYTZEFF (*J. pr. Chem.* [2], 34, 468—472).—Butyrone, propyl iodide, and zinc are allowed to react as in the previous paper. On treating with water and distilling, *dipropyl carbinol* is obtained as a colourless liquid boiling at 154—155°. Sp. gr. at 20° = 0·82003 (water at 20° = 1). The acetate boils at 170—172°. With chromic mixture, the dipropyl carbinol is oxidised first to butyrone, and then to propionic and butyric acids.

H. K. T.

**Action of Silver Acetate on Tetrabromodiallyl Carbinol Acetate.** By W. DIEFF (*J. pr. Chem.* [2], 35, 17—21).—Saytzeff obtained (*Annalen*, 185, 138), by the action of silver acetate on the compound  $\text{OH}\cdot\text{CAc}(\text{CH}_2\cdot\text{CHBr}\cdot\text{CH}_2\text{Br})_2$ , a product which he took to be the acetate of an alcohol of the formula

The author repeated the experiment, and determined the number of acetyl-groups by heating the compound with alcoholic potash. The numbers obtained corresponded with the formula of a triacetyl-compound,  $\text{C}_7\text{H}_{11}\text{O}(\text{OAc})_3$ . This compound was also prepared by heating the alcohol (obtained by saponifying the acetate) with an excess of acetic anhydride at 145° for 12 hours. The sp. gr. of the triacetyl-compound at 0° = 1·18013 (water at 0° = 1). When saponified by means of baryta, it yields the compound  $\text{C}_7\text{H}_{11}\text{O}(\text{OH})_3$ . The latter is a viscous syrup, readily soluble in water and alcohol. It is identical with the compound which Saytzeff (*loc. cit.*) obtained by saponifying the ether with alcoholic solution of hydrogen chloride.

N. H. M.

**Erythrol.** By A. COLSON (*Compt. rend.*, 104, 113—115).—The heat of solution of erythrol at 18° is -5·2 cal., and at 9° -5·12 cal.

The heat of neutralisation is affected by the degree of dilution of the solution. The value obtained for the first equivalent of potash was  $+0.66$  cal., and for the second equivalent  $+0.44$  cal. The thermochemical results are not in accord with the generally accepted symmetrical constitution of erythrol.

When erythrol is treated with phosphoric bromide, it yields a bromhydrin,  $C_4H_6Br_4$ , which melts at  $112^\circ$ , dissolves in 10 parts of boiling ether, and is identical with the crotonylene tetrabromide described by Henninger. If heated with bromine in sealed tubes at  $175^\circ$ , it yields a mixture of a solid and a liquid product. The solid has the composition  $C_4H_4Br_6$ , and crystallises in nacreous plates which melt at  $167$ – $169^\circ$ , and dissolve readily in chloroform, but are only slightly soluble in alcohol or ether; sp. gr. about  $3.4$ .

The liquid compound is an isomeride of the solid product. It dissolves easily in chloroform or ether, but is only slightly soluble in alcohol; sp. gr. about  $2.9$  at  $15^\circ$ . When heated with dilute potash in sealed tubes at  $120$ – $130^\circ$  for several hours, it yields a potassium salt which resembles potassium hydrogen tartrate in appearance, but the angles of the crystals are different, and the crystals have no action on polarised light. Its solutions give no precipitate with salts of calcium or silver, but a precipitate is formed with salts of lead. This compound is in all probability the potassium salt of erythric acid, and this supposition is confirmed by the weight of lead salt obtained from a given weight of the potassium salt.

It would seem, therefore, that the liquid is the unsymmetrical  $CBBr_3 \cdot CHBr \cdot CHBr \cdot CH_2Br$ , whilst the solid is the symmetrical

This result requires confirmation, but it is evident that the complete hydrolysis of the bromine-derivatives of crotonylene is possible, since the acid obtained was free from bromine. C. H. B.

**Glucose and the Saccharification of Starch.** By L. CUISINIER (*Chem. Centr.*, 1886, 614).—The sugar found in the soluble part of barley- or maize-meal consists for the most part of dextrose. If this dextrose is formed by the action of diastase, then the ferment must exert a different action on raw starch from what it does on boiled starch. The dextrose may, on the other hand, be formed by another special ferment present in the living grain. This latter view of the case is, according to the author's experiments, the correct one. The ferment present in ungerminated grain converts starch slowly into dextrose. The dextrose so formed is readily crystallisable on concentrating the liquid, the crystals obtained consisting almost exclusively of fermentable sugar contaminated with not more than 1 to 2 per cent. of dextrin. J. P. L.

**Action of Saliva on Starch.** By E. BOURQUELOT (*Compt. rend.*, 104, 71–74).—Potato-starch, free from glucose, was heated with water to a definite temperature, cooled down to the ordinary temperature, and then mixed with saliva. When fermentation was complete, the reducing power of the liquid was determined by means of Fehling's

solution. The saliva acts only on the starch which has undergone hydration, and it was found that the hydrating action of water begins at about  $53^{\circ}$ , and increases somewhat irregularly up to  $74^{\circ}$ , beyond which point an increased temperature exerts no sensible effect.

In a second series of experiments, the water and saliva were mixed together, heated up to a definite temperature, the starch added, the temperature maintained for about  $3\frac{1}{2}$  hours, and the reducing power of the liquid was then determined. The results show that saliva acts on starch at a temperature below that at which water alone exerts any hydrating action. Feebly acid or alkaline liquids, or solutions of sodium chloride or phosphate have no action on amylose at temperatures below  $53^{\circ}$ , and saliva in which the ferment has been destroyed by boiling is scarcely more active. It follows that it is the diastase in the saliva which assists the hydrating action of the water.

At the temperature at which water alone begins to convert starch into a hydrate saccharifiable by saliva at the ordinary temperature, water mixed with saliva has a more energetic action than when water and saliva are allowed to act successively in the way described. The difference diminishes, however, as the temperature approaches  $58^{\circ}$ , at which point the two actions are equal. At higher temperatures, the action is greater if the water alone is heated, and the saliva is afterwards added to the cooled liquid, than when the saliva and water are heated together, since the high temperature destroys the diastase in the saliva.

C. H. B.

**Starch Granules.** By E. BOURQUELOT (*Compt. rend.*, 104, 177—180).—Potato-starch was heated with saliva and water at different temperatures for different periods of time. At temperatures below  $57^{\circ}$ , the amount of reduction increases with the temperature and also with the time, but is not proportional to the latter. At temperatures above  $57^{\circ}$ , however, the action continues to increase with the temperature, but attains its maximum in about five hours, and proceeds very little further even if the experiment is prolonged to 30 hours.

The hydrating action of water alone increases with the temperature, and is practically complete after five hours, increasing but little if the experiment is continued for 30 hours. The hydrating action of the water is independent of the mass of the water.

It is a general rule that a reaction effected on a single carbon compound is proportional to, or in direct relation to, the time, especially if the action is of the nature of hydration. The divergence from this rule observed in the case of starch and water indicates that starch granules are composed of a complex mixture of carbohydrates, and not only of one or two compounds (granulose and amylose). Possibly these different compounds are polymerides of one original substance. This view is similar to that held by many physiologists concerning the different layers of cellulose which constitute cell-walls.

C. H. B.

**Inosite.** By MAQUENNE (*Compt. rend.*, 104, 225—227).—Walnut leaves are extracted methodically with about four times their weight of water, and the boiling solution is precipitated first with milk of

lime, then with lead acetate, and finally with basic lead acetate, which forms an insoluble compound with the inosite. The last precipitate is washed with water, decomposed by hydrogen sulphide, and the solution concentrated to a syrup. The boiling liquid is then mixed with 7 or 8 per cent. of concentrated nitric acid, which destroys nearly all the foreign matter without attacking the inosite, and, after cooling, a mixture of 4—5 vols. of alcohol with 1 vol. of ether is gradually added to the nearly colourless liquid. Inosite is thus separated as a colourless flocculent precipitate, which is recrystallised from dilute acetic acid, dissolved in water, again treated with nitric acid, and again precipitated with alcohol and ether. A small quantity of calcium sulphate, which always occurs in the product, is decomposed by adding barium hydroxide, and the barium is removed by means of ammonium carbonate, the product being finally recrystallised from water. The yield is about 2.94 grams per kilo. of leaves.

Anhydrous inosite has the composition  $C_6H_{12}O_6$ , whilst the crystals have the composition  $C_6H_{12}O_6 + 2H_2O$ ; they lose all their water at  $110^\circ$ . Inosite does not volatilise without decomposition, but its molecular weight can be determined by Raoult's cryoscopic method, that is, by determining the freezing point of its aqueous solution. The freezing point of a solution of 2.5 grams of inosite in 100 grams of water is  $-0.29^\circ$ , whilst the calculated value for  $C_6H_{12}O_6$  is  $-0.27^\circ$ .

Inosite is only slightly soluble in cold, but very soluble in warm water. It is insoluble in alcohol, ether, and glacial acetic acid, but dissolves readily in dilute acetic acid, from which it can be easily crystallised. It melts at  $217^\circ$  without carbonisation, and boils with slight decomposition in a vacuum at  $319^\circ$ . When heated in the air, it burns readily. Solutions of inosite are optically inactive, both when freshly prepared and after they have been in contact with *Penicillium glaucum* for six weeks. Inosite is not attacked by boiling dilute acids or alkalis, does not reduce copper solutions, and is not acted on by ammoniacal silver nitrate alone, but in presence of sodium hydroxide it yields a mirror of metallic silver. It does not combine with sodium hydrogen sulphite, is not reduced by sodium amalgam, and is not sensibly affected by halogens in the cold. When heated with bromine and water at  $100^\circ$ , it yields brown products precipitable by salts of barium and similar to those obtained in Scherer's reaction. These compounds contain no bromine, and are oxidation-products which can be more readily prepared by the action of nitric acid.

No acid containing six carbon-atoms can be obtained from inosite, nor will it split up into oxy-acids of the acetic series. It is neither an aldehyde nor a ketone, and contains neither double bonds nor lateral chains; hence, it can only be a hexhydric hexa-secondary alcohol, with a constitution represented by the symbol—

which agrees with its optical inactivity.

C. H. B.

**Preparation of Isobutylamines.** By H. MALBOT (*Compt. rend.*, 104, 63—65).—When isobutyl chloride is heated with an equivalent

quantity of ammonia dissolved in water or isobutyl alcohol, it yields the three isobutylamines, the tri-isobutylamine being formed in largest proportion. If aqueous ammonia is used, the composition of the product is monisobutylamine, 1 part; di-isobutylamine, 4 parts; tri-isobutylamine, 5 parts. This result differs from that obtained by Reimer (*Ber.*, 3, 756) by acting on isobutyl bromide with ammonia dissolved in ordinary alcohol.

C. H. B.

**Separation of Mono- and Di-isobutylamines by Means of Ethyl Oxalate.** By H. MALBOT (*Compt. rend.*, 104, 228—231; see preceding Abstract).—In the first fraction, which is rich in monisobutylamine, it is necessary to produce the maximum quantity of di-isobutyloxamide without neglecting to collect the two oxamates which are also formed. In the second fraction, rich in di-isobutylamine, the bases are converted into oxamates, which are then separated by a method more perfect than distillation.

The operations by which these changes are effected are: (1) Ethyl oxalate is added to the *aqueous* solution of the bases, and the primary bases are thus converted into oxamides; (2), the mixture of anhydrous bases, poor in primary bases, is poured into ethyl oxalate, and primary and secondary bases are thus converted into oxamates; (3), the tertiary bases are separated by distillation, and the oxamates are saponified by calcium hydroxide at a moderate temperature, the calcium oxamates being separated by crystallisation.

*Di-isobutyloxamide* forms short, acute lamellæ, which are almost insoluble in boiling water, but crystallise from boiling alcohol in long, brilliant, slender needles which melt at 167°, and sublime slowly at this temperature without decomposition.

*Calcium isobutyloxamate* is obtained by heating the anhydrous isobutylamine with ethyl oxalate, and then treating the product, which boils at 160°, with calcium hydroxide. It crystallises from alcohol in anhydrous needles.

*Calcium di-isobutyloxamate*, formed in a similar manner, is separated from the preceding compound by fractional crystallisation, since it is more soluble in alcohol, from which it crystallises in slender, flexible, silky needles.

C. H. B.

**Syntheses of Guanylcarbamide.** By E. BAMBERGER (*Ber.*, 20, 68—71).—Guanylcarbamide can be obtained by methods similar to those employed in the synthesis of carbamide, guanidine being substituted for ammonia. Thus, the base is formed when an intimate mixture of guanidine carbonate (1 part) and urethane (2 parts) is heated at 160° until alcohol ceases to distil over,  $\text{NH}_2\text{COOEt} + (\text{NH}_2)_2\text{C}:\text{NH} = \text{NH}_2\text{CO}\cdot\text{NH}\cdot\text{C}(\text{NH})\text{NH}_2 + \text{EtOH}$ . At the same time, sparingly soluble decomposition products of guanidine, showing properties similar to those of ammeline, ammelide, and melanurenic acid, are formed, with evolution of ammonia; the guanylcarbamide can be separated from these by extracting the melt with water, and converting the base into the copper-derivative. Another synthesis, which for its success depends on the observance of several minute precautions, can be effected by heating at about 180° an intimate mixture of potassium

cyanate and guanidine hydrochloride. From an aqueous solution of molecular proportions of these salts and of hydrochloric acid in the cold, guanylecarbamide cannot be separated, although it seems to be formed since the solution gives the copper reaction of the base.

*Guanylecarbamide nitrate*,  $C_2N_4H_6O, HNO_3$ , crystallises in white needles, the *aurochloride* in sparingly soluble, long, golden-yellow needles.

*Guanidine cyanurate*,  $CN_3H_3(CNOH)_3$ , obtained by adding guanidine carbonate to a boiling solution of cyanuric acid, crystallises in silky needles.

W. P. W.

**Preparation of Alkylamidoformic Chlorides and Alkyl Isocyanates.** By L. GATTERMANN and G. SCHMIDT (*Ber.*, 20, 118—121).—When a stream of phosgene gas is passed over dry ethylamine hydrochloride heated at  $250\text{--}270^\circ$ , *ethamidoformic chloride*,

is formed in almost theoretical quantity. It is a colourless liquid, boiling at  $92^\circ$ , and having a very pungent odour. During the distillation, there is a dissociation into hydrogen chloride and ethyl isocyanate, but on cooling the chloride is re-formed. This compound is decomposed by water into ethylamine hydrochloride and carbonic anhydride. This substance is identical with that obtained by Habich and Limpricht by the action of hydrochloric acid on ethyl isocyanate, and by the distillation of diethylcarbamide hydrochloride. When the above chloride is distilled over quicklime, ethyl isocyanate is formed in almost the theoretical proportion.

This chloride, when treated with toluene and aluminic chloride, yields *paratoluy lethamide*,  $C_6H_4Me \cdot CO \cdot NHEt$ , which crystallises in colourless, glistening needles, melting at  $96^\circ$ ; this, when heated with strong potash, yields paratoluic acid. When benzene is substituted for toluene in the above reaction, *ethylbenzamide*,  $Ph \cdot CO \cdot NHEt$ , is formed, which forms glistening needles, melting at  $67^\circ$ , and boiling at  $258\text{--}260^\circ$ .

Methylamine hydrochloride and phosgene gas yield *methamidoformic chloride*,  $NHMe \cdot COCl$ . This crystallises in scales, melts at  $90^\circ$ , and boils (with dissociation) at  $93\text{--}94^\circ$ . In its properties and reactions, it resembles the ethyl-derivative. With toluene and aluminic chloride, it gives *paratoluylmethamide*,  $C_6H_4Me \cdot CO \cdot NHMe$ . This is soluble in water, crystallises in colourless plates, and melts at  $143^\circ$ .

The above reactions appear to be generally applicable for the preparation of substituted amidoformic chlorides and of alkyl isocyanates.

L. T. T.

**Convenient Method for Preparing Brominated Fatty Acids.** By A. MICHAEL (*J. pr. Chem.* [2], 92—95).—The chlorides of monobasic fatty acids are heated in a flask with the calculated amount of carefully dried bromine and about 50 c.c. of carbon bisulphide, until no more hydrogen bromide is evolved. The product is poured into water, partially distilled, and converted into the ethereal salt by treatment with absolute alcohol. From butyric acid, nearly the theoretical amount of ethyl  $\alpha$ -bromobutyrate was obtained. The method works

well in the case of monobasic fatty acids, but not so well with succinic chloride, owing to the instability of the bromine-derivative when warmed. N. H. M.

**Behaviour of Acetic Acid and some of its Derivatives towards Phosphorus Pentachloride.** By A. MICHAEL (*J. pr. Chem.* [2], 35, 95—96).—When acetic chloride (40 grams) is boiled with phosphorus pentachloride (200 grams) for some weeks, mono- and tri-chloroacetic acids are formed (probably also some dichloroacetic acid). Much acetic and phosphoric chlorides remained unchanged.

When chloroacetic acid and phosphorus pentachloride (1 mol. to 4 mols.) are heated for two days, perchlorethylene is formed, together with higher boiling substances, probably tetra- and penta-chlorethane.

Phosphorus pentachloride and phenoxyacetic acid react violently when brought together in the cold. The product consists of trichlorophenoxyethylene (Abstr., 1886, 614) and a substance crystallising in rhombic prisms melting at 151—152°. The latter has the composition of a chlorophenoxyacetic acid. N. H. M.

**$\beta$ -Dimethacrylic Acid.** By D. USTINOFF (*J. pr. Chem.* [2], 34, 478—485).—The salts of  $\beta$ -dimethacrylic acid (Semljanitzin and Saytzeff, Abstr., 1879, 618) are described. The sodium salt,  $C_5H_7O_2Na$ , forms white, opaque, effloresced crystals. The calcium salt,  $(C_5H_7O_2)_2Ca$ , forms bundles of long, silky crystals belonging to the rhombic system, soluble in water and alcohol. The barium salt,  $(C_5H_7O_2)_2Ba + 2H_2O$ , nodular groups of prismatic crystals. The zinc salt,

crystallises in rhombic plates. The copper salt,  $(C_5H_7O_2)_2Cu + 2H_2O$ , crystallises in efflorescent rhombic plates. The lead salt,  $(C_5H_7O_2)_2Pb + H_2O$ , forms bundles of needles, and the silver salt,  $C_5H_7O_2Ag$ , is a crystalline powder. When  $\beta$ -dimethylacrylic acid is treated in ethereal solution with bromine, it forms a dibromide,  $C_5H_8Br_2O_2$ ; this is a crystalline substance melting at 105—106°. The salts and bromine compound of  $\beta$ -dimethylacrylic acid distinguish it from its isomerides, angelic, methylcrotonic, and allylacetic acids.

H. K. T.

**Acids from Drying Oil.** By K. HAZURA (*Monatsh. Chem.*, 7, 637—638).—When linoleic acid is oxidised with potassium permanganate in alkaline solution, *linusic acid*,  $C_{18}H_{36}O_7$ , is formed. It crystallises in lustrous needles, very sparingly soluble in water, and melts at 188°.

The acid contained in hemp-oil yielded a *tetrabromo-derivative* melting at 114—115°, and a *hexabromo-derivative* melting at 177°; the latter compound is amorphous. The analyses of the two compounds make it probable that the formula of the original acid is  $C_{18}H_{32}O_2$ , and not  $C_{16}H_{28}O_2$ . N. H. M.

**Methoxydiallylacetic Acid and its Salts.** By S. BARATAEFF (*J. pr. Chem.* [2], 35, 1—6).—Methoxydiallylacetic acid (Abstr., 1885, 512) is readily soluble in alcohol, ether, and hot water. The

ethyl salt boils at 214—216°. Sp. gr. = 0.96228 at 28° (water at 20° = 1). Determinations of the refractive power of the ethyl salt point, according to Brühl's law, to the presence of two double affinities; this was confirmed by the formation of a *bromine-derivative*,  $C_{11}H_{18}O_3Br_4$ , by the action of bromine on the salt. *Barium methoxydiallylacetate* crystallises with 2 mols.  $H_2O$  in needles, rather readily soluble in water; the *calcium salt* forms slender crystals, more sparingly soluble than the barium salt; the *zinc salt* crystallises in microscopic, slender needles, very soluble in water; the *lead salt* (with  $6\frac{1}{2}$  mols.  $H_2O$ ) separates from its solution when slowly evaporated at 10°, in large, triclinic prisms, rather sparingly soluble in water, and more soluble in alcohol. The *copper salt*, with 1 mol.  $H_2O$ , separates from the warm aqueous solution in bright green, oily drops, which solidify on cooling; the *silver salt* separates in thin threads, rather soluble in water.

N. H. M.

**Oxalic Acid from the Residue of Spiritus Ætheris Nitrosi.** By H. FRICKHINGER (*Arch. Pharm.* [3], 24, 1065—1068).—By taking alcohol of 0.812 sp. gr. instead of 0.832, as given in the German Pharmacopœia, almost the whole of the liquid may be distilled over, and there is much less free acid to contend with in the distillate. The nitric acid is not sufficient in amount to completely oxidise all the products of the reaction. The residue from the first distillation, amounting to about 2 per cent. of the original charge, is wine-yellow, strongly acid, and has a specific gravity of 1.10. It contains no nitric acid, but, on the contrary, a large quantity of oxalic acid, which can be economically converted into ammonium oxalate. If this residue is poured into nitric acid of 1.35 sp. gr., and allowed to stand for some weeks, crystals of oxalic acid separate out from the grass-green liquid obtained. The mother-liquor becomes again colourless on warming for some time. The rectified ether is perfectly neutral in reaction; at first the sp. gr. of the distillate is 0.835, then 0.840, 0.845, and 0.850, at which point it remains until the rectification suddenly ceases.

J. T.

**Preparation of Ethyl Oxalate.** By E. SCHATZKY (*J. pr. Chem.* [2], 34, 500—501).—A better yield of the oxalate is obtained by maintaining the mixture of oxalic acid and alcohol in ebullition for some hours, then distilling off any ethyl formate formed, adding more alcohol, and again boiling. By this means 56.03 per cent. of the theoretical yield is obtained.

H. K. T.

**Action of Ethyl Iodide and Zinc on Ethyl Malonate.** By C. DAIMLER (*Ber.*, 20, 203—204).—When a mixture of ethyl malonate (1 mol.) and ethyl iodide (2 mols.) is heated with zinc, ethane is evolved, and ethylic ethylmalonate is obtained; the yield amounts to 90 per cent. of that required by theory. The author finds that ethylmalonic acid yields two barium salts, one  $(C_5H_7O_4)_2Ba + H_2O$ , which crystallises in hemispherical aggregates, and is converted into barium butyrate at 100°, and a second,  $C_5H_6O_4Ba + \frac{1}{2}H_2O$ , which forms slender, lustrous prisms, very sparingly soluble in water. When, in the above reaction, 4 mols. instead of 2 mols. of ethyl iodide are

employed, an almost quantitative yield of ethyl diethylmalonate is obtained.  
W. P. W.

**Action of a Mixture of Allyl and Ethyl Iodides and Zinc on Ethyl Oxalate.** By S. BARATAEFF (*J. pr. Chem.* [2], 35, 7—16).—A mixture of ethyl oxalate (1 mol.), allyl iodide (1 mol.), and ethyl iodide (2 mols.) was added by drops to finely granulated zinc in a retort kept cold by means of ice. The contents of the retort were left for 24 hours, and then heated in a water-bath for 10 hours. The product was then treated with sulphuric acid to dissolve the zinc oxide, and distilled. The oil so obtained was fractionally distilled, and was found to consist of a mixture of ethylic diethyloxalate and diallyloxalate. The reaction is analogous to that which takes place between allyl and ethyl iodide, zinc and ethyl formate (Kanounikoff and Saytzeff, this Journal, 1877, ii, 298).  
N. H. M.

**Diallyloxalic Acid.** By E. SCHATZKY (*J. pr. Chem.* [2], 34, 485—500).—The following data were obtained for the optical relations of diallyloxalic acid:—

For a 7·08 per cent. solution in benzene at 18·6°—

$$D^d = 0.88981, n_d = 1.494830, n_\beta = 1.151107, A = 1.475135.$$

$$B = 0.849372, \frac{n_d - 1}{D} = 0.55611, \frac{A - 1}{D} = 0.53397.$$

For the acid—

$$\frac{n_d - 1}{D} = 0.4487, P \frac{n_d - 1}{D} = 69.99, R_d = 64.6. \text{ Difference } 5.39.$$

$$\frac{A - 1}{D} = 0.42991, P \frac{A - 1}{D} = 67.07, R_A = 63.07. \text{ Difference } 4.00.$$

The ammonium, sodium, potassium, lithium, silver, calcium, barium, magnesium, lead, copper, cadmium, and zinc salts have been prepared.

Ethyl diallyloxalate combines with bromine, forming a yellowish-brown liquid of the formula  $C_{10}H_{16}Br_4O_3$ .

Diallyloxalic acid when treated with bromine gave a neutral substance, crystallising in microscopic needles, insoluble in water, soluble in alcohol, ether, and benzene, and melting at 42—43°. The substance is scarcely acted on by sodium carbonate; with potassium hydroxide no definite results were obtained. It is probably a tri-bromolactone formed from the tetrabromodiallyloxalic acid by removal of hydrogen bromide. Diallyloxalic acid combines with hydrogen chloride, forming a thick liquid,  $OH \cdot C(C_3H_6Cl)_2 \cdot COOH$ .

Diallyloxalic acid is converted by concentrated hydriodic acid into iododiallylacetic acid, from which diallylacetic acid can be obtained by means of sodium amalgam, hence diallyloxalic acid has the formula  $OH \cdot C(C_3H_5)_2 \cdot COOH$ .  
H. K. T.

**Action of Ethyl Chloracetate and Zinc on Ethyl Oxalate.** By R. FITTIG and C. DAIMLER (*Ber.*, 20, 202—203).—When a mixture of ethyl oxalate (1 mol.) and ethyl chloracetate (2 mols.) is heated with

zinc at  $100^{\circ}$  for several days, a dark-brown zinc compound is obtained, which is readily decomposed by water with formation of a bright yellow, amorphous substance, but when treated with dilute sulphuric acid, and extracted with ether, yields a thick oil, probably identical with 'Wislicenus' ethyl oxalacetate (this vol., p. 234), and a colourless, well crystallised compound, *ethyl ketipate* (ketone-adipate),  $C_{10}H_{14}O_6$ . This is a salt of a bibasic ketonic acid, whose constitution is probably either  $COOEt \cdot CH_2 \cdot CO \cdot CO \cdot CH_2 \cdot COOEt$  or  $COOEt \cdot CO \cdot CH_2 \cdot CO \cdot CH_2 \cdot COOEt$ . It melts at  $76-77^{\circ}$ , is decomposed by boiling water, and is readily soluble in ether, chloroform, alcohol, benzene, and carbon bisulphide. Ferric chloride colours the alcoholic solution an intense red. With phenylhydrazine, a compound,  $C_4H_4(N_2C_6H_5)_2(COOEt)_2$ , is obtained, crystallising from chloroform in yellow needles. Aqueous barium and calcium hydroxides precipitate white insoluble compounds of the formula  $C_{10}H_{12}O_6Ba(or\ Ca) + H_2O$ . By the action of bromine, according to the conditions of the experiment, there is obtained either a tetrabromo-substitution-derivative,  $C_4O_2Br_4(COOEt)_2$ , crystallising in yellow prisms, or a partially saponified compound of the formula  $C_4O_2H_2Br_2(COOH)COOEt$ , forming colourless crystals.

*Ketipic acid* is a white powder, insoluble in ordinary solvents, and is very unstable. When heated, it decomposes into carbonic anhydride and a yellow liquid, which boils at  $78-79^{\circ}$ , and has an odour resembling that of quinone. W. P. W.

**Nitration of  $\alpha$ -Thiophenic Acid.** By M. RÖMER (*Ber.*, **20**, 116—118).—When  $\alpha$ -thiophenic acid is gradually added to concentrated nitric acid at  $50^{\circ}$ , *nitro- $\alpha$ -thiophenic acid*,  $NO_2 \cdot C_4SH_2COOH$ , is formed. This acid exists in two modifications, the one crystallising in long, thin, colourless needles melting at  $145-146^{\circ}$ , the other in compact crystals melting at  $125^{\circ}$ . From an aqueous solution, the needles crystallise out first, and afterwards the compact variety. By recrystallisation, the latter modification is always partially, sometimes wholly, converted into the needles, whilst when placed under water, the needles are gradually changed into the compact variety. This behaviour resembles that of dinitrothiophen. With a trace of soda, both modifications of the acid give a magenta-red coloration which is destroyed by excess of alkali. The *silver salt* forms colourless needles; the *ethyl salt* colourless needles, melting at  $70-71^{\circ}$ , and subliming unchanged; the *copper salt* forms bluish-green hydrated prisms.

L. T. T.

**Constitution of Benzene.** By A. BAEYER (*Ber.*, **19**, 1797—1810; see also this vol., p. 370), by J. THOMSEN (*Ber.*, **19**, 2944—2950), and by A. LADENBURG (*Ber.*, **20**, 62—65).—Theoretical papers: an account of the arguments brought forward will be found in the present number of the Transactions (A. K. Miller, *Trans.*, 1887, 208—215).

**Chlorination of Toluene.** By E. SEELIG (*Annalen*, **237**, 129—181).—The trichlorotoluenes have already been described by the author (*Abstr.*, 1885, 769). Pure orthochlorotoluene can be obtained

by taking advantage of the facts that orthochlorotoluene is more easily converted into the sulphonic acid than the para-compound, and also that calcium and sodium orthochlorotoluene-sulphonates are less soluble than the corresponding para-salts. The sulphonic acid when decomposed by superheated steam, yields orthochlorotoluene. The pure compound boils at  $156^{\circ}$  under 750 mm. pressure. The chief product of the chlorination of orthochlorotoluene is  $\alpha$ -dichlorotoluene,  $C_6H_3MeCl_2$  [1 : 2 : 3]. Parachlorotoluene is completely converted into  $\beta$ -dichlorotoluene [ $Me : Cl_2 = 1 : 2 : 4$ ].

$\alpha$ -Dichlorotoluene boils at  $195$ — $199^{\circ}$  and  $\beta$ -dichlorotoluene boils at  $194$ — $198^{\circ}$ . The former yields a dinitro-derivative melting at  $121$ — $122^{\circ}$ .  $\beta$ -Dinitrodichlorotoluene crystallises in prisms, and melts at  $101$ — $102^{\circ}$ . The  $\alpha$ -diamine crystallises in needles and melts at  $137^{\circ}$ ; the  $\beta$ -diamine melts at  $110^{\circ}$ , and is deposited from light petroleum in long needles.

$\beta$ -Dichlorobenzyl chloride and aldehyde are obtained from  $\beta$ -dichlorotoluene. The aldehyde melts at  $71^{\circ}$ , and boils between  $231^{\circ}$  and  $235^{\circ}$ . On oxidation, it yields dichlorobenzoic acid [1 : 3 : 4].  $\beta$ -Dichlorocinnamic acid is deposited from weak alcohol in needles, and melts at  $228^{\circ}$ .  
W. C. W.

**Nitrochlorotoluene and Chlorotoluidine.** By H. GOLDSCHMIDT and M. HÖNIG (*Ber.*, 20, 199—201).—*Nitrochlorotoluene*,

obtained by diazotising nitrotoluidine,  $C_6H_3Me(NH_2) \cdot NO_2 [= 1 : 2 : 5]$ , crystallises in needles, melts at  $44^{\circ}$ , boils without decomposition at  $248^{\circ}$  under 711 mm. pressure, and is readily soluble in ether.

*Chlorotoluidine*,  $C_6H_3MeCl \cdot NH_2$  [ $Me : Cl : NH_2 = 1 : 2 : 5$ ], is formed when the nitro-compound is reduced with tin and hydrochloric acid. It melts at  $83^{\circ}$ , boils at  $239^{\circ}$  under 715 mm. pressure, and is identical with Wroblewsky's chlorotoluidine and that obtained when orthochlorotoluene is nitrated and reduced (*Abstr.*, 1886, 1022). The *hydrochloride* crystallises in long, slender needles; the *acetyl-derivative* crystallises from benzene in colourless scales melting at  $89^{\circ}$ ; and the *phenylthiocarbamide* forms small, white granules melting at  $108$ — $109^{\circ}$ .  
W. P. W.

**Synthesis of Cyanphenine.** By P. KLASON (*J. pr. Chem.* [2], 35, 82—84). **Remarks.** By E. v. MEYER (*ibid.*, 84—85).—By the action of potassium on ethyl cyanide, Kolbe and Frankland (*Annalen*, 65, 281) obtained ethane together with cyanethine. In a similar manner Hofmann obtained cyanphenine from benzonitrile, and Bayer cyanmethine from acetonitrile (*Ber.*, 1, 198, and 2, 319). It is, therefore, probable that these compounds have an analogous constitution.

Cyanphenine is obtained by dissolving pure cyanuric chloride in pure ether, and adding the calculated amount of bromobenzene and sodium. It is filtered, the ether distilled off, and the residue treated with water and crystallised, first from glacial acetic acid and then from alcohol. The chief product of the reaction is *diphenyl-*

*cyanine chloride*,  $(\text{CN})_3\text{ClPh}_2$ ; this is more soluble than cyanphenine, and crystallises in groups of needles melting at  $136^\circ$ . The formation of cyanphenine in the above reaction shows it to be a triphenyl-cyanuric compound.

v. Meyer refutes Klason's view that cyanethine and cyanmethine are cyanuric compounds. Cyanmethine and cyanethine are both converted by the action of nitrous and hydrochloric acids into hydroxy-bases, the hydroxyl taking the place of amidogen. Ethyl and methyl cyanides contain hydrogen-atoms more loosely combined than in phenyl cyanide; hence it is conceivable that in polymerising, hydrogen-atoms disunite in the case of the fatty cyanides, whilst phenyl cyanide polymerises without shifting of hydrogen to cyanur-phenyl,  $(\text{CN})_3\text{Ph}_3$ .  
N. H. M.

**Quinol and its Derivatives.** By A. BAESSLER (*Chem. Centr.*, 1886, 671—672).—*Amidodimethylquinol*,  $\text{C}_6\text{H}_3(\text{OMe})_2\text{NH}_2$ , is prepared by reducing mononitrodimethylquinol in acetic acid solution with sodium amalgam. It melts at  $81$ — $82^\circ$ . The chloride crystallises in white needles, which deliquesce in the air; the platinochloride forms a brown precipitate. From the aqueous solution of the base, iron chloride on warming throws down greenish plates with a strong metallic lustre, which dissolve in water with a red colour. From the hydrochloric acid solution, potash precipitates the substance in black flocks; solutions of silver salts are reduced, giving a mirror. *Acetamidodimethylquinol*,  $\text{C}_6\text{H}_3(\text{OMe})_2\text{NHAc}$ , is formed by dissolving the base in acetic anhydride. It crystallises in brilliant scales, and melts at  $91^\circ$ . *Nitracetamidodimethylquinol*,  $\text{NO}_2\cdot\text{C}_6\text{H}_3(\text{OMe})_2\text{NHAc}$ , is prepared by slowly adding the preceding compound to fuming nitric acid. It melts at  $164^\circ$ .

*Dimethylquinoltrimethylammonium iodide*,  $\text{C}_6\text{H}_3(\text{OMe})_2\text{NMe}_3\text{I}$ , is obtained by heating the substance with methyl iodide and methyl alcohol in sealed tubes at  $150^\circ$ . It melts at  $202^\circ$ . The chloride melts at  $172^\circ$ ; the platinochloride is a beautiful, yellow, crystalline precipitate.

*Dimethylquinolphenylthiocarbamide*,  $\text{NHPh}\cdot\text{CS}\cdot\text{NH}\cdot\text{C}_6\text{H}_3(\text{OMe})_2$ , formed by adding phenylthiocarbamide in excess to an alcoholic solution of amidodimethylquinol, melts at  $137^\circ$ . The *thiocarbamide-derivative* of amidodimethylquinol,  $\text{CS}[\text{NH}\cdot\text{C}_6\text{H}_3(\text{OMe})_2]_2$ , melts at  $109^\circ$ .

*Azodimethylquinol*,  $[\text{C}_6\text{H}_3(\text{OMe})_2]_2\text{N}_2$ , is formed when nitrodimethylquinol is reduced by sodium amalgam in alkaline solution, or by the action of alcoholic potash and zinc-dust on the mononitro-compound. It forms red needles, and melts at  $140^\circ$ . It dissolves in strong hydrochloric acid with a dark blue colour, in strong sulphuric acid with a violet colour, which afterwards changes to blue and green, with partial decomposition; with alcoholic bromine solution, it forms *dibromazodimethylquinol*, which melts at  $220^\circ$ .

*Hydrazodimethylquinol*,  $\text{C}_6\text{H}_3(\text{OMe})_2\text{NH}\cdot\text{NH}\cdot\text{C}_6\text{H}_3(\text{OMe})_2$ , is obtained together with the preceding substance by the reaction given above.

*Tetramethoxydiamidodiphenyl*,  $\text{NH}_2\cdot\text{C}_6\text{H}_2(\text{OMe})_2\cdot\text{C}_6\text{H}_2(\text{OMe})_2\cdot\text{NH}_2$ , is

obtained when the mixture of the azo-compound and the preceding substance is treated with warm hydrochloric acid. It melts at  $210^{\circ}$ . The chloride is easily soluble in water: the platinochloride quickly becomes brown in the air. With phenylthiocarbamide, it forms a compound,  $C_{12}H_4(OMe)_4(NH \cdot CS \cdot NHPh)_2$ , which melts at  $184^{\circ}$ ; acetic anhydride gives the *diaceto-compound*,  $C_{12}H_4(OMe)_4(NHAc)_2$ , which melts at  $251^{\circ}$ , and gives golden-yellow plates when treated with nitric acid. The corresponding benzoyl-derivative is obtained by boiling tetramethoxydiamidodiphenyl with benzoic chloride; it melts at  $305^{\circ}$ .  
G. H. M.

**Isomeric Mono- and Di-benzoylphenylhydrazines.** By A. MICHAELIS and F. SCHMIDT (*Ber.*, 20, 43—48).—Sodium phenylhydrazine is suspended in benzene, the mixture well cooled with ice-water, and benzoic chloride diluted with benzene gradually added, the vessel being from time to time removed from the ice-water to prevent solidification of the benzene. When the reaction is completed and the contents of the vessel no longer smell of benzoic chloride, the benzene is distilled off, and the nearly colourless residue repeatedly extracted with ether, which dissolves the new unsymmetrical monobenzoylphenylhydrazine, and leaves a residue consisting of the sparingly soluble symmetrical mono- and di-benzoylphenylhydrazines. The ethereal extract, after distilling off the ether, yields a viscous red oil, which is poured into water, excess of concentrated hydrochloric acid added, and the separated hydrochloride washed with and repeatedly crystallised from water containing hydrochloric acid.

*Unsymmetrical benzoylphenylhydrazine*,  $NH_2 \cdot NPhBz$ , obtained by decomposing the hydrochloride with sodium carbonate, crystallises in thin, colourless needles, melts at  $70^{\circ}$ , and is very readily soluble in ether, alcohol, and chloroform, and sparingly in cold water. It is a feeble base, does not reduce Fehling's solution in the cold, but does so readily on heating, does not reduce ammoniacal silver solution even when heated, and is without action on yellow mercuric oxide. When heated with concentrated hydrochloric acid at  $150^{\circ}$ , it is decomposed into benzoic acid and phenylhydrazine. The *hydrochloride*,  $NH_2 \cdot NPhBz \cdot HCl$ , forms colourless needles, melts at  $202^{\circ}$ , and is soon decomposed by water. When an aqueous solution of the hydrochloride is treated with aqueous soda, a sodium-derivative,  $C_{13}H_{11}NaN_2O$ , separates as a thick, white precipitate. The formation of this compound is peculiar, and suggests a doubt as to whether an amido-group is present in the base, or if it should not rather be represented by the formula  $\langle \begin{smallmatrix} NH- \\ NPh \end{smallmatrix} \rangle CPh \cdot OH$ .

The *dibenzoylphenylhydrazine* obtained in this reaction has the same melting point ( $178^{\circ}$ ) as that obtained by Fischer (*Abstr.*, 1878, 309), but differs from it in not reducing ammoniacal silver nitrate. It is also obtained by the action of benzoic chloride on the unsymmetrical benzoylphenylhydrazine. It probably should be represented by the formula  $\langle \begin{smallmatrix} NBz \\ NPh \end{smallmatrix} \rangle CPh \cdot OH$ , Fischer's compound being the true dibenzoyl-derivative,  $NPhBz \cdot NHBz$ .

*Diacetylphenylhydrazine*,  $\text{N}_2\text{HPhAc}_2$ , is obtained by the action of acetic chloride on sodium or potassium phenylhydrazine; it crystallises in nodular groups of needles, melts at  $106^\circ$ , is readily soluble in water, alcohol, and chloroform, very sparingly in ether, and reduces Fehling's solution, but is not affected by yellow mercuric oxide.

*Potassium phenylhydrazine* is prepared in a manner similar to and resembles the sodium compound (Abstr., 1886, 1025). A. J. G.

**A Physical Peculiarity of  $\alpha$ -Triphenylguanidine.** By H. GIRAUD (*Bull. Soc. Chim.*, **46**, 505—506).—This substance, prepared from diphenylthiocarbamide and aniline, melts at  $143^\circ$ , and readily remains in a state of superfusion. When cooled quickly, its viscosity increases, and it passes insensibly into the solid state without showing any indication of crystalline form. It is then transparent, very fragile, is powdered by a blow, crumbles under pressure, and adheres to the fingers like resin. When cooled to  $60^\circ$ , it contracts and cracks, but does not crystallise. When slowly heated, it softens gradually until it becomes fluid (but no distinct melting point can be observed), and it then changes to the crystalline state with evolution of heat; this change is instantaneous at  $60^\circ$ . In contact with a liquid, the amorphous form becomes opaque and then crystalline before dissolving, the change being more rapid the greater the solvent action of the liquid. In this case also there is a rise of temperature of  $7^\circ$  to  $8^\circ$ . L. T. T.

**Thiocarbimides of Bibasic Aromatic Radicles.** By O. BILLETER and A. STEINER (*Ber.*, **20**, 228—232).—When an aqueous solution of the hydrochloride of an aromatic diamine is shaken with a solution of thiocarbonyl chloride dissolved in chloroform, a good yield of the corresponding thiocarbimide is obtained with meta- and para-bases, but falls to 10 per cent. of the theoretical quantity in the case of ortho-bases, the chief product being the corresponding monothiocarbamide.

*Orthophenylene thiocarbimide*,  $\text{C}_6\text{H}_4(\text{NCS})_2$ , forms colourless needles or scales, melts at  $59^\circ$  (corr.), is very readily soluble, and combines with alcohol and ammonia to form compounds analogous to those obtained from the meta-derivative.

*Metaphenylene thiocarbimide* crystallises in colourless needles, melts at  $53^\circ$  (corr.), boils with partial decomposition above  $250^\circ$ , and is readily soluble in all ordinary solvents. Alcoholic ammonia converts it into metaphenylene dithiocarbamide (Abstr., 1883, 324); and metaphenylenedithiourethane,  $\text{C}_6\text{H}_4[\text{NC}(\text{OEt})\cdot\text{SH}]_2$ , melting at  $116^\circ$ , is obtained by heating it with alcohol. When heated at  $250^\circ$  with finely divided copper, a small yield of the nitrile of isophthalic acid is obtained.

*Paraphenylene thiocarbimide* crystallises in long, lustrous needles, melts at  $130^\circ$  (corr.), and is less soluble than its isomerides. Under similar conditions, it yields paraphenylene dithiocarbamide, and paraphenylenedithiourethane melting at  $197^\circ$ .

*Orthotolylene thiocarbimide*,  $[\text{Me} : \text{NCS} : \text{NCS} = 1 : 3 : 4]$ , crys-

tallises in white scales, melts at  $42^{\circ}$  (corr.), and is extremely soluble. When heated with hydrochloric acid at  $200^{\circ}$ , it is mainly converted into the *monothiocarbamide*,  $C_7H_6(NH)_2CS$ , which forms scales melting at  $285^{\circ}$ ; whilst by the action of alcoholic ammonia it yields the monothiocarbamide and ammonium thiocyanate.

*Metatoluylene thiocarbimide* crystallises in long, colourless needles, melts at  $56^{\circ}$  (corr.) and boils at about  $300^{\circ}$  with partial decomposition. By the action of ammonia and aniline, it yields metatoluylene dithiocarbamide and diphenyltoluylene dithiocarbamide respectively. *Metatoluylenedithiourethane* crystallises in small, white scales, and melts at  $119-120^{\circ}$ . When metatoluylene thiocarbimide is heated at  $250^{\circ}$  with finely divided copper, a compound melting at  $140-141^{\circ}$ , and probably the nitrile of  $\beta$ -xylic acid, is obtained. W. P. W.

**Trianisylarsine and its Derivatives.** By A. MICHAELIS and L. WEITZ (*Ber.*, 20, 48-52).—*Trianisylarsine*,  $As(C_6H_4 \cdot OMe)_3$ , is prepared by adding sodium (20 grams) to a mixture of bromanisole (50 grams) with arsenic chloride (30 grams), diluted with four times the volume of ether and a small quantity of ethyl acetate. It forms hard, transparent, colourless crystals, which, although cubic in form, do not belong to the regular system. It melts at  $156^{\circ}$ , and is readily soluble in benzene, sparingly in alcohol and ether. It unites less readily than triphenylarsine with chlorine and bromine, and the oxide  $AsO(C_6H_4 \cdot OMe)_3$  is only obtained in a pure state with difficulty.

*Dianisylarsine chloride*,  $As(C_6H_4 \cdot OMe)_2Cl$ .—When trianisylarsine is heated with hydriodic acid (sp. gr. 1.56) and the oil formed is treated with aqueous soda, the crystalline dianisylarsine oxide,  $O(C_6H_4 \cdot OMe)_2$ , is obtained, melting at  $130^{\circ}$ , which, when treated with hydrochloric acid, is converted into the chloride. The latter crystallises in long, thin, pale yellow needles, melts at  $79-80^{\circ}$ , and is very readily soluble in ether, less so in alcohol.

*Anisylarsine dichloride*,  $AsCl_2 \cdot C_6H_4 \cdot OMe$ , prepared by heating trianisylarsine with a large excess of arsenic chloride for 24 hours at  $200^{\circ}$ , is a colourless liquid, which can be distilled at  $230^{\circ}$  under 117 mm. pressure, but suffers partial decomposition when distilled at the ordinary pressure. Sodium hydroxide or carbonate converts it into *anisylarsine oxide*,  $AsO \cdot C_6H_4 \cdot OMe$ , a colourless, crystalline mass. When the dichloride is cooled with ice-water and treated with chlorine, *anisylarsine tetrachloride*,  $OMe \cdot C_6H_4 \cdot AsCl_4$ , is obtained as a viscous, yellow liquid, which dissolves in water with considerable development of heat, and is soon converted into *anisylarsenic acid*,  $OMe \cdot C_6H_4 \cdot AsO(OH)_2$ . This forms hard, colourless crystals, sparingly soluble in cold water, readily soluble in alcohol. If quickly heated, it melts at  $159-160^{\circ}$ , but if slowly heated it loses water and is converted into an infusible *anhydride*,  $OMe \cdot C_6H_4 \cdot AsO_2$ , which is reconverted into the acid by boiling with water. The silver salt is described.

*Triphenetylarsine*,  $As(C_6H_4 \cdot OEt)_3$ , is prepared from bromophenetoil, arsenic chloride, and sodium; it melts at  $88-89^{\circ}$ , and is readily soluble in ether.

Similar trianisyl compounds were prepared from phosphorus and

antimony trichlorides, but have not yet been obtained in quantity sufficient for investigation. A. J. G.

**Organo-bismuth Compounds: Valency of Bismuth.** By A. MICHAELIS (*Ber.*, 20, 52—54).—The author has entered on a general investigation of the organo-bismuth compounds to ascertain if any undoubtedly pentavalent bismuth compounds can be obtained. The alkyl compounds are being investigated by Marquardt, whilst the author and Polis are working on the aromatic compounds. The results obtained so far, are that whilst trimethyl- or triethyl-bismuthine do not form additive compounds with bromine nor with ethyl iodide, substitution of halogen for methyl, &c., occurring, triphenylbismuthine unites with chlorine or bromine, to form stable and well characterised compounds, in which 1 atom of bismuth is united with 5 monovalent groups or atoms. The pentavalent nature of bismuth is thus rendered as certain as that of antimony.

A. J. G.

**Triphenylbismuthine and its Derivatives.** By A. MICHAELIS and A. POLIS (*Ber.*, 20, 54—57).—*Triphenylbismuthine*,  $\text{BiPh}_3$ , is prepared by boiling an alloy of bismuth and sodium (10 per cent.) with bromobenzene and a little ethyl acetate for 50 hours in a reflux apparatus. The product is filtered, the residue repeatedly extracted with benzene, and from the united liquids the benzene first distilled off, and then, under reduced pressure, the bromobenzene. The fused triphenylbismuthine left solidifies when cooled and stirred, and is purified by repeated crystallisation from hot alcohol. It forms colourless needles or tables which resemble the crystals of triphenylarsine and -stibine, and seem to be triclinic. It has a sp. gr. = 1.5851 at 20°, melts at 82°, is readily soluble in ether and light petroleum, sparingly in cold alcohol, and closely resembles triphenylstibine in its chemical properties, save that it is less stable. When gently heated with hydrochloric acid, it is completely decomposed into benzene and bismuth chloride. When treated with bismuth bromide in ethereal solution, a yellow precipitate, probably *phenylbismuthine dibromide*,  $\text{BiPhBr}_2$ , is obtained.

*Triphenylbismuthine dichloride*,  $\text{BiPh}_3\text{Cl}_2$ , is prepared by passing chlorine gas on to the surface of a solution of triphenylbismuthine in light petroleum cooled with ice, as long as a white precipitate forms. It crystallises in thick prisms, melts at 140°, is readily soluble in benzene, sparingly in ether and cold alcohol, and is not decomposed by concentrated hydrochloric acid.

*Triphenylbismuthine dibromide*,  $\text{BiPh}_3\text{Br}_2$ , is prepared by mixing solutions of its components in light petroleum; it forms long, pale-yellow prisms, melts at 119°, and is readily soluble in benzene, sparingly in ether and alcohol. Both the bromide and chloride are decomposed by hydrogen sulphide, triphenylbismuthine being regenerated with separation of sulphur.

A. J. G.

**Synthesis of Phenaceturic Acid.** By E. HOTTER (*Ber.*, 20, 81—85).—When glycocine, dissolved in as little water as possible, is

treated with sodium hydroxide and phenylacetic chloride and then with hydrochloric acid, a compound separates which, after drying and extraction with ether, dissolves in alcohol or water, and crystallises in the groups of white laminæ characteristic of phenaceturic acid. The yield is small. *Ethyl phenaceturate*,  $C_{10}H_{10}NO_3Et$ , crystallises in long broad prisms, melts at  $79^\circ$ , and is readily soluble in hot alcohol, less soluble in warm ether and benzene, insoluble in carbon bisulphide.

*Copper phenylacetate*,  $(C_8H_7O_2)_2Cu$ , is soluble in hot alcohol, and crystallises in small nodular masses consisting of radiating deep-green needles. W. P. W.

**Phenylamidopropionic Acid obtained from the Decomposition of Proteïds.** By E. SCHULZE and E. NÄGELI (*Zeit. physiol. Chem.*, 11, 201—206).—One of the authors has previously shown (Abstr., 1883, 1122) that one of the products of the decomposition of proteïds by means of hydrochloric acid is a substance with the properties and composition of phenylamidopropionic acid, and that the same substance, probably again the result of the decomposition of proteïds, can be obtained from the germinating seeds of certain plants (Abstr., 1882, 189).

This substance is very similar to the amido-acid prepared synthetically by Erlenmeyer and Lipp (Abstr., 1882, 971), and called by them phenyl- $\alpha$ -amidopropionic acid or phenylalanine. This opinion is held because by dry distillation both acids yield the same decomposition products, namely, carbonic anhydride, phenyllactimide, and phenylethylamine. Still there are certain differences between them. The acid obtained from proteïds and plants crystallises from warm concentrated aqueous solutions in shining plates, from dilute solutions in slender, white needles, containing water of crystallisation; whilst phenylalanine crystallises from hot water in prisms free from water, and from aqueous alcohol in shining plates. The melting point of the former acid is  $275\text{--}280^\circ$ , of the latter  $263\text{--}265^\circ$ . The copper salt of the latter contains 2 mols.  $H_2O$ , that of the former is free from water. Some of these differences might be explained on the supposition that the acid obtained from proteïds and plants is not so pure as that prepared synthetically. This would not, however, account for the difference of melting point. The optical examination of these substances led to the elucidation of this point. Phenylalanine prepared synthetically is optically inactive, whilst that obtained from proteïds and plants is active. In many pairs of isomerides, one of which is optically active, the other inactive, it is found that other differences, for instance, of solubilities and melting points, occur (see Abstr., 1886, 373). It is therefore concluded that the acid obtained from proteïds and plants is an optically active modification of phenyl- $\alpha$ -amidopropionic acid or phenylalanine. This conclusion is supported by the fact that tyrosin giving its typical microscopic appearances, and Piria's and Hoffmann's reactions, can be obtained from both acids by the two methods described by Erlenmeyer and Lipp. W. D. H.

**Reduction of the Phthalic Acids. Constitution of Benzene.** By A. BAEYER (*Ber.*, 19, 1797—1810).—An account of the theoretical portion of this paper will be found in the March number of the Transactions (A. K. Miller, *Trans.*, 1887, 208—215).

When tere- and iso-phthalic acids are reduced with sodium amalgam with the aid of heat, they both yield tetrahydro-acids, no intermediate dihydro-acid being formed; no reduction takes place in the cold. Phthalic acid, on the other hand, is reduced by sodium amalgam, slowly in the cold, more readily when warmed, to dihydrophthalic acid. The author explains this difference of behaviour on the assumption that only those double affinities (taking Kekulé's formula) can be reduced which belong to carbon-atoms in combination with carboxyl.

It is remarkable that the partly reduced acids behave towards bromine like unsaturated compounds; dihydrophthalic and tetrahydroisophthalic acids each take up two atoms of bromine. The dibromide of tetrahydroterephthalic acid yields a hydroxy-acid, from which by the action of bromine, a compound identical with tetrabromocatechol was obtained. Tetrahydroterephthalic acid has therefore the constitution—

Tetrahydroterephthalic acid is prepared by boiling for 20 hours 5 grams of terephthalic acid, dissolved in the smallest amount of aqueous soda, and gradually adding 4 per cent. sodium amalgam (500 grams). It dissolves in 120 parts of boiling water, and separates on cooling in small prisms. It melts above 300° and sublimes. The silver salt is amorphous. The methyl salt is obtained as an oil which has the odour of fennel, and solidifies to very large prisms melting at 39°; its solutions have a blue fluorescence. When the ethereal solution of the salt is treated with sodium ethoxide, a rose-coloured transient precipitate is formed, similar to that obtained from ethyl succinosuccinate. When tetrahydroterephthalic acid is heated with hydriodic acid (b. p. 127°) for six hours at 240°, it is converted into *hexahydroterephthalic acid*,  $\text{C}_8\text{H}_{12}\text{O}_4$ . This is less soluble than the tetrahydro-acid, from which it is also distinguished by its stability towards potassium permanganate. It melts at about 295°, and sublimes. The *methyl salt* melts at 58°; its solution has no fluorescence.

Tetrahydroisophthalic acid is prepared by boiling 2 grams of isophthalic acid for two to three days with sodium amalgam. It dissolves readily in hot water, from which it crystallises in needles melting at 199°. The *silver salt* is amorphous; the *methyl salt* is an oil.

The author confirms the statement of Graebe and Born (*Annalen*, 142, 345), that dihydrophthalic acid cannot be further reduced by sodium amalgam. It is best prepared by boiling phthalic acid with sodium amalgam; the yield is quantitative.

*Dibromohexahydroterephthalic acid*,  $\text{C}_8\text{H}_{10}\text{Br}_2\text{O}_4 + \text{H}_2\text{O}$ , is formed when 10 grams of tetrahydroterephthalic acid is shaken with 100 grams of a 5 per cent. ethereal solution of bromine, left for some time, and the ether poured off. This is repeated with fresh bromine solution until almost all the acid has dissolved. The united solutions

are decolorised with sulphurous acid and extracted with soda. The *methyl salt* crystallises from ether in large prisms, melting at  $73^{\circ}$ . The acid has about the same solubility in water as tetrahydroterephthalic acid; it is not decomposed when the solution is boiled for a short time. Warm soda solution decomposes it with formation of a *dihydroterephthalic acid*,  $C_8H_8O_4$ . When the dibromo-acid is treated with silver oxide, an acid is obtained, probably a dihydroxyhexahydroterephthalic acid.

According to Kekulé's formula, the two bromine-atoms and hence also the hydroxyl-groups, would both have the ortho-position:—

This position of the hydroxyl was proved by treating the dihydroxy-acid with bromine; tetrabromocatechol was obtained, which gave an intense blue coloration with ferric chloride.

Dry hydrophthalic acid combines readily with bromine (1 mol.), yielding dibromotetrahydrophthalic acid. The acid is subjected in small portions to the action of bromine-vapour, the product freed from excess of bromine, dissolved in soda, filtered, and acidified. The oil is exhausted with ether, and distilled in a vacuum; it solidifies to well-formed rhombohedra (compare Graebe and Born, *loc. cit.*).

N. H. M.

**Action of Potassium Hydroxide on Mixed Alkyl Bisulphides.** By R. OTTO and A. RÖSSING (*Ber.*, 20, 189—191).—When an alcoholic solution of ethyl phenyl bisulphide is warmed with small quantities of alcoholic potash until the reaction is complete, the following compounds are obtained:—Ethylsulphinic and benzenesulphinic acids, ethyl mercaptan and phenyl bisulphide; the latter is formed by the oxidation of the potassium phenylmercaptide first formed.

W. P. W.

**Action of Sulphurous Anhydride on Benzene.** By C. E. COLBY and C. S. McLOUGHLIN (*Ber.*, 20, 195—198).—When 100 grams of benzene and 35 grams of aluminium chloride, placed in a reflux apparatus, are treated with sulphurous anhydride until absorption of the gas is complete, then heated until hydrogen chloride ceases to be evolved, and the product, after cooling, poured into water, *diphenylsulphoxide*,  $Ph_2SO$ , is obtained, which crystallises from xylene in small, transparent crystals, which seem to be triclinic. It melts at  $70$ — $71^{\circ}$ , and is readily soluble in alcohol, ether, acetic acid, and benzene, sparingly soluble in cold light petroleum. When oxidised with potassium permanganate, it yields diphenylsulphone, and when reduced with sodium, diphenyl sulphide is obtained. The same compound can be prepared by the action of thionyl chloride on benzene. For this purpose, 50 grams of benzene and 16 grams of thionyl chloride, placed in a reflux apparatus, are treated in the cold with successive quantities of aluminium chloride until hydrogen chloride ceases to be evolved; the product, after heating for half an hour, is poured into water, and the diphenylsulphoxide purified by crystallisation.

When equivalent quantities of diphenylsulphoxide and sodium nitrate are dissolved in sulphuric acid, and the two solutions mixed and heated at  $100^{\circ}$ , three nitro-compounds appear to be formed:— (1) Gericke's dinitrosulphobenzide, melting at  $163^{\circ}$  (*Annalen*, **100**, 211); (2) an oil not yet further examined; and (3) *dinitrodiphenylsulphoxide*,  $(C_6H_4NO_2)_2SO$ , which forms yellow, indistinct, microscopic crystals, melts at  $116^{\circ}$ , and is soluble in alcohol, readily soluble in ether, benzene, acetic acid, and carbon bisulphide. W. P. W.

**Action of Potassium Hydroxide on Phenylenemetadiphenylsulphone.** By R. OTTO and A. RÖSSING (*Ber.*, **20**, 185—189).— Since ethylenedithiethylsulphone and ethylenediphenylsulphone are not attacked by alcoholic potash at  $140^{\circ}$  (*Ber.*, **19**, 2814), whilst ethylenediphenylsulphone readily yields benzenesulphinic acid and phenylsulphonethyl alcohol (*Abstr.*, 1885, 261), the authors have examined the behaviour under like conditions of a disulphone of a third class, phenylenemetadiphenylsulphone, and find that the products of the action are benzenesulphinic acid and diphenylsulphonophenyl ether,  $2C_6H_4(SO_2Ph)_2 + 2KOH = 2PhSO_2K + (C_6H_4SO_2Ph)_2O + H_2O$ .

*Diphenylsulphonophenyl ether*, obtained by heating phenylenemetadiphenylsulphone with alcoholic potash at  $160$ — $170^{\circ}$ , crystallises in small white feebly lustrous needles, melts at  $69$ — $70^{\circ}$ , and is readily soluble in alcohol, ether, and benzene, insoluble in water. It can be volatilised unchanged only when carefully heated in small quantities, and distils above  $200^{\circ}$ . When heated with concentrated aqueous ammonia, no change occurs. Sodium amalgam in alkaline solution reduces it to benzene, benzenesulphinic acid, and a crystalline compound, which yields a bromo-derivative crystallising in large rhombic tables melting at  $54$ — $55^{\circ}$ .

Ethylenediphenylsulphone when treated with an excess of concentrated aqueous potash, yields benzenesulphinic acid, and a small quantity of a compound possibly polymeric with diphenylsulphonethyl ether are obtained. W. P. W.

**Synthesis of Carbazole.** By A. GOSKE (*Ber.*, **20**, 532—534).— The author has succeeded in effecting the synthesis of carbazole from thiodiphenylamine. When this base is heated with an excess of metallic copper for two hours in an atmosphere of coal-gas, and the product afterwards distilled, a distillate is obtained which consists of carbazole; the yield amounted to 60 per cent. of the weight of the thiodiphenylamine employed. The synthetical carbazole melts at  $238^{\circ}$ , and gives the characteristic compound with trinitrophenol. Bearing in mind Bernthsen's synthesis of thiodiphenylamine from catechol and orthamidophenylmercaptan (this vol., p. 245), the constitution of carbazole must be represented by the formula—

W. P. W.

**Action of Hydroxylamine on Diketones.** By F. MÜNCHMEYER (*Ber.*, **20**, 228).—The compound  $\text{OH}\cdot\text{N}:\text{C}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2$  melts at  $233^\circ$ , and not at  $98-99^\circ$  as previously stated (*Abstr.*, 1886, 877).

W. P. W.

**Naphthoic Acids.** By Å. G. EKSTRAND (*Ber.*, **20**, 219—226).—The compound obtained by the reduction of dinitro- $\alpha$ -naphthoic acid (m. p.  $265^\circ$ ) with hydrogen sulphide in ammoniacal solution, to which the provisional formula  $\text{COOH}\cdot\text{C}_{10}\text{H}_5\cdot\text{N}_2\cdot\text{O}_2$  was ascribed (*Abstr.*, 1886, 948), contains sulphur either as an impurity or in combination. The purest specimen gave figures corresponding with the formula  $\text{C}_{33}\text{H}_{18}\text{N}_6\text{S}_6$ ; owing to its sparingly soluble and uncrystallisable nature it is impossible to decide whether the substance analysed was free from admixed sulphur, although none could be extracted by carbon bisulphide. If stannous chloride dissolved in aqueous potash is employed as the reducing agent, a compound is obtained resembling the preceding in its appearance, infusibility, and insolubility in alcohol.

*Dinitro- $\alpha$ -naphthoic acid*, probably  $[\text{NO}_2:\text{NO}_2:\text{COOH} = 1':4':1]$ , melting point  $218^\circ$ . When nitro- $\alpha$ -naphthoic acid (m. p.  $239^\circ$ ) is nitrated with red fuming nitric acid, three dinitro-acids are obtained, of which two, melting at  $205^\circ$  and  $265^\circ$ , have been previously described, whilst the third melts at  $218^\circ$  and is formed in very small quantity. It is very soluble in alcohol, from which it is obtained in hard, deep yellow, rhombic crystals,  $a:b:c = 0.9731:1:1.4424$ , whilst from water it crystallises in slender needles. The *ethyl* salt crystallises in long, hard, yellow needles melting at  $129^\circ$ ; the *calcium* salt, with 7 mols.  $\text{H}_2\text{O}$ , crystallises in thin, lustrous, broad, yellow needles, and is readily soluble in water. When reduced with tin and hydrochloric acid, the dinitro-acid is converted into the hydrochloride of an *amidonaphthostyryl*,  $\text{NH}_2\cdot\text{C}_{10}\text{H}_5\cdot\text{C}(\text{NH})\text{CO}$ ,  $\text{HCl}$ , which melts at a high temperature, and crystallises in long, bright yellow needles, sparingly soluble in cold water.

*$\alpha$ -Naphthamidoxime*, obtained together with  $\alpha$ -naphthamide by heating an alcoholic solution of  $\alpha$ -naphthonitrile and hydroxylamine in molecular proportions, crystallises in large laminae, melts at  $148-149^\circ$ , and is readily soluble in alcohol, acetic acid, and benzene, soluble in water and insoluble in light petroleum. The *hydrochloride* crystallises after a long time in stellate aggregates of needles, and melts at  $160^\circ$ ; the *platinochloride* forms long, prismatic, yellow needles. When heated at  $100^\circ$  with acetic anhydride, and the product treated with water,  $\alpha$ -naphthamidoxime is converted into  $\alpha$ -*naphthazoximethenyl*,  $\text{C}_{10}\text{H}_7\cdot\text{C}(\text{N}=\text{N})\text{CMe}$ ; this crystallises from alcohol in long, colourless needles and melts at  $36^\circ$ .  *$\alpha$ -Naphthoyl- $\alpha$ -naphthamidoxime*,  $\text{C}_{10}\text{H}_7\cdot\text{C}(\text{NH}\cdot\text{CO}\cdot\text{C}_{10}\text{H}_7):\text{N}\cdot\text{OH}$ , obtained by heating  $\alpha$ -naphthamidoxime and  $\alpha$ -naphthoic chloride in molecular proportions at  $100^\circ$ , crystallises in small, slender needles, and melts at  $228^\circ$ ; it is insoluble in alcohol and hydrochloric acid.

*$\beta$ -Naphthamidoxime*, prepared in manner similar to the  $\alpha$ -compound, forms lustrous scales, melts at  $150^\circ$ , is soluble in alcohol, and is

gradually decomposed by boiling water. The *hydrochloride* forms long needles, melts at  $178^{\circ}$ , and is very soluble in water.  *$\beta$ -Naphthazoximethenyl* crystallises in large scales, melts at  $87^{\circ}$ , and is soluble in alcohol.  *$\beta$ -Naphthazoximnaphthenyl*,

obtained by heating  *$\beta$ -naphthoic chloride* and  *$\beta$ -naphthamidoxime* in approximately molecular proportions, crystallises in broad needles or scales, melts at  $175^{\circ}$ , and is almost insoluble in alcohol.

W. P. W.

*$\alpha$ - and  $\beta$ -Naphthenylamidoxime*. By E. RICHTER (*Ber.*, **20**, 227).—The author has independently arrived at results which confirm those of Ekstrand (preceding Abstract); *acetyl- $\alpha$ -naphthenylamidoxime* melts at  $129^{\circ}$ . *Acetyl- $\beta$ -naphthenylamidoxime* melts at  $154^{\circ}$ ; the *benzoyl*-derivative melts at  $179^{\circ}$ ; the *ethyl* salt melts at  $74$ – $75^{\circ}$ . *Ethylidenenaphthenylamidoxime* melts at  $121$ – $122^{\circ}$ .

W. P. W.

**Chloronaphthalenesulphonic Acids.** By P. T. CLEVE (*Ber.*, **20**, 72–75).—*1:4' Chloronaphthalenesulphonic acid*,  $\text{C}_{10}\text{H}_6\text{Cl}\cdot\text{SO}_3\text{H} + 2\text{H}_2\text{O}$ , obtained by diazotising the amido-acid corresponding with  *$\alpha$ -nitronaphthalenesulphonic acid*, crystallises in colourless tables readily soluble in water. A chlorosulphosulphonic acid,

is also formed in this reaction, this yields an insoluble amorphous potassium salt. *Potassium chloronaphthalenesulphonate* crystallises in lustrous needles; the *sodium* salt forms thin scales; the *silver* salt forms thin tablets sparingly soluble in water; these salts are anhydrous. The *barium* salt with 2 mols.  $\text{H}_2\text{O}$  is a sparingly soluble, indistinctly crystalline powder. The *ethyl* salt melts at  $46^{\circ}$ , and crystallises in large, monoclinic prisms,  $a:b:c = 1.6785:1:?$ ;  $\beta = 68^{\circ} 58'$ , which show distinct pleochroism. The *chloride* forms triclinic crystals resembling hexahedra, melts at  $95^{\circ}$ , and is soluble in chloroform; the *amide* crystallises in lustrous scales, melts at  $226^{\circ}$ , and is sparingly soluble in alcohol.

*1:4 Chloronaphthalenesulphonic acid* (Abstr., 1883, 595) can be prepared by diazotising naphthionic acid. The *ethyl* salt melts at  $104^{\circ}$  and crystallises in large, thin, monoclinic tables,  $a:b:c = 1.32807:1:1.12623$ ;  $\beta = 80^{\circ} 59'$ . The *chloride* melts at  $95^{\circ}$ , and crystallises in triclinic forms; the *amide* melts at  $187^{\circ}$ .

*$\alpha$ -Chloronaphthalene- $\beta$ -sulphonic acid* (probably  $1':2$ ) is prepared by diazotising the amido-acid from the author's  *$\beta$ -nitronaphthalenesulphonic acid* (this Journal, 1877, i, 469); it crystallises in colourless rhombic tables and is readily soluble in water. The *potassium* salt forms very thin, glistening tables sparingly soluble in cold water; the *barium* salt, with 1 mol.  $\text{H}_2\text{O}$ , is a sparingly soluble, crystalline powder. The *ethyl* salt melts at  $111^{\circ}$ , is soluble in chloroform, readily soluble in hot alcohol, and crystallises in well characterised monoclinic forms;  $a:b:c = 0.43067:1:?$ ;  $\beta = 86^{\circ} 45'$ , the crystals being either long prisms almost quadratic in section, or thick tables. The *chloride*

forms small scales, melting at  $114-115^{\circ}$ ; the *amide* forms thin scales, melts at  $216^{\circ}$ , and is soluble in alcohol. W. P. W.

**Brönner's  $\beta$ -Naphthylaminesulphonic Acid.** By S. FORSLING (*Ber.*, 20, 76—81).—Brönner's  $\beta$ -naphthylaminesulphonic acid,  $\text{NH}_2\cdot\text{C}_{10}\text{H}_6\cdot\text{SO}_3\text{H} + \text{H}_2\text{O}$ , obtained by the action of ammonia on  $\beta$ -naphtholsulphonic acid at  $180^{\circ}$ , crystallises in colourless laminae of silky lustre, and is very sparingly soluble in water, the solution having a blue fluorescence. The *potassium* salt with 1 mol.  $\text{H}_2\text{O}$  forms long, white needles, and is soluble in cold water to the extent of 1 in  $40^{\circ}$  to  $45^{\circ}$ ; the *ammonium* salt with 1 mol.  $\text{H}_2\text{O}$  forms broad, white needles, and when heated at  $180^{\circ}$  gives off the whole of its ammonia; the *sodium* salt with 2 mols.  $\text{H}_2\text{O}$  forms white needles, and dissolves to the extent of 1 in 40 in cold water; the *silver* salt with 1 mol.  $\text{H}_2\text{O}$  is an indistinctly crystalline powder. The *barium* salt with 6 mols.  $\text{H}_2\text{O}$  crystallises in long, white needles, and requires 450 parts of cold water for its solution; the *calcium* salt with 6 mols.  $\text{H}_2\text{O}$  crystallises in laminae, and dissolves in 225 parts of cold water; the *magnesium* salt with 6 mols.  $\text{H}_2\text{O}$  crystallises in laminae or broad needles. The crystals of all these salts have a silky lustre, dissolve sparingly in water, and give solutions showing blue fluorescence. The *lead* salt with 2 mols.  $\text{H}_2\text{O}$  is very sparingly soluble in water; the *zinc* salt with 4 mols.  $\text{H}_2\text{O}$  forms well-characterised, microscopic crystals, and is sparingly soluble in water: the *copper* salt with 4 mols.  $\text{H}_2\text{O}$  forms microscopic needles, is very sparingly soluble in water, and has a mosaic gold colour which changes to red in the anhydrous salt. The corresponding diazonaphthalenesulphonic acid,  $\text{C}_{10}\text{H}_5\text{N}_2\text{SO}_3$ , a yellow microcrystalline powder, yields, by Sandmeyer's reaction and subsequent treatment with phosphoric chloride, the chloride of Arnell's  $\beta$ -chloronaphthalenesulphonic acid melting at  $110^{\circ}$  (*Abstr.*, 1886, 555), from which  $\epsilon$ -dichloronaphthalene, melting at  $136^{\circ}$ , is obtained by distillation with phosphoric chloride. The *amide*,  $\text{C}_{10}\text{H}_6\text{Cl}\cdot\text{SO}_2\text{NH}_2$ , crystallises in needles and melts at  $183-184^{\circ}$ .

W. P. W.

**Some Essential Oils.** By P. SOLTSIEN (*Chem. Centr.*, 1886, 936—937).—An examination of *Oleum citri*, *Oleum bergamotte*, and *Oleum cort. aurantiorum dulcium*. These oils were prepared specially and were therefore pure. The author has examined them with Hefpe's copper butyrate reaction and also various turpentine (Abstr., 1885, 1163); he finds that it is of little value, as the action depends on the age of the oil. He also re-examined the bromination of the oils, and confirms Wallach's statements in the main. G. H. M.

**Isomeric Camphols and Camphors.** By A. HALLER (*Compt. rend.*, 104, 66—68).—Camphol from madder, discovered by Jeanjean, crystallises from light petroleum in hexagonal plates similar to the crystals of the other camphols. Borneo camphol is similar to the others, but its rotatory power, though equal in amount, is opposite in direction. Its derivatives, however, correspond in rotatory power and other properties with the derivatives of other camphols. Cam-

phol from amber crystallises from light petroleum in the ordinary form, but differs from the other camphols in its rotatory power and its behaviour with bromine. When treated with bromine, it yields a buttery product, which contains a small quantity of a dextrogyrate monobromocamphor melting at  $75^{\circ}$ , but the greater part of the product melts below  $50^{\circ}$ . The corresponding camphoric acid also differs from that derived from other camphols, since it melts at  $202^{\circ}$  and is less soluble in water.

The author's investigations show that all camphols are chemically identical, and differ only in their action on polarised light. The camphols from madder, valerian, N'gai, and Bang-Phien have the same molecular lævorotatory power,  $[\alpha]_D = -37^{\circ}$ , and the corresponding camphors are identical with that from fever-few (*matricaire*). The camphor from *Dryabalanops camphora* has a rotatory power equal in amount but opposite in direction. Its derivatives are, however, identical with those from the other camphols. Camphol from amber is mainly a racemic camphol mixed with a dextrogyrate borneol.

C. H. B.

**Carveol, Borneol, and Menthol.** By R. LEUCKART (*Ber.*, **20**, 114—116).—The author gives the name *carveol* to an alcohol,  $C_{10}H_{15}\cdot OH$ , which he has obtained by reducing carvele with sodium and alcohol. It is a thick liquid, has a characteristic odour quite different from that of carvele, and boils at  $218-220^{\circ}$ . The acetate and benzoate are liquid. With phenyl cyanate, even in the cold, it yields *carvyl phenylamidoformate*,  $NHPh\cdot COO\cdot C_{10}H_{15}$ . This compound forms small needles, easily soluble in alcohol, sparingly so in ether, and melts at  $84^{\circ}$ . Borneol similarly forms *bornyl phenylamidoformate*,  $NHPh\cdot COO\cdot C_{10}H_{17}$ , crystallising in needles soluble in boiling alcohol and melting at  $133^{\circ}$ . Menthol, under similar circumstances, yields *menthyl phenylamidoformate*,  $NHPh\cdot COO\cdot C_{10}H_{19}$ , which crystallises in silky needles soluble in boiling alcohol and melting at  $111^{\circ}$ . No corresponding compounds are obtainable from carvele, camphor, or bromo-camphor, which seems to point to the absence of a hydroxyl-group in the latter substances. At higher temperatures, reaction takes place between carvele and phenyl isocyanate; carbonic anhydride is evolved, and diphenylcarbamide is among the products of the reaction.

L. T. T.

**Bornylamine.** By R. LEUCKART and E. BACH (*Ber.*, **20**, 104—114).—When small quantities of camphor (not more than 4 grams should be used in each operation) are digested with two and a half times their weight of ammonium formate in sealed tubes at  $220-240^{\circ}$ , carbonic anhydride, carbonic oxide, ammonium carbonate, and a syrupy mass are produced. The latter distils at  $290-300^{\circ}$ , and yields a compound of the formula  $C_{11}H_{19}NO$ , which crystallises in glistening scales, melts at  $60-61^{\circ}$ , and is easily soluble in alcohol and ether. When digested with aqueous hydrochloric acid, it yields a crystalline base, *bornylamine*,  $C_{10}H_{19}N$ , which melts at  $158-160^{\circ}$ , boils at  $199-200^{\circ}$ , and is easily volatile in steam. It resembles camphor in physical properties, smell, and volatility at ordinary temperatures, &c. It is very sparingly soluble in water, easily so in alcohol and ether, is a strong base, and forms easily soluble salts, the aqueous solutions of

which have an acid reaction. Its vapour-density is 5.5. It is lævoptatory, a 12.5 per cent. solution showing a rotation of  $[\alpha]_D = -18^\circ 35' 41''$ . The *hydrochloride*,  $C_{10}H_{19}N \cdot HCl$ , forms small, white needles melting with decomposition at  $280^\circ$ . An aqueous solution of the hydrochloride, on long-continued boiling, undergoes partial decomposition, depositing camphene. The *platinochloride* forms golden-yellow scales, the *acid sulphate*,  $C_{10}H_{19}N \cdot H_2SO_4$ , rhombic plates. *Formobornylamine*,  $C_{10}H_{18}N \cdot COH$ , is obtained by the action of anhydrous formic acid on the free base, or of sodium formate on the hydrochloride. It forms glistening scales melting at  $61^\circ$ . This substance is identical with the original substance formed by the action of ammonium formate on camphor, and described above. *Acetobornylamine*,  $C_{10}H_{18}N \cdot Ac$ , obtained by dissolving the base in acetic chloride, crystallises in colourless scales melting at  $141^\circ$ . *Benzobornylamine*, similarly prepared, crystallises in colourless scales which melt at  $131^\circ$ . *Bornylcarbamide*,  $NH_2 \cdot CO \cdot NH \cdot C_{10}H_{17}$ , is formed by boiling potassium isocyanate with bornylamine hydrochloride. It crystallises in colourless needles, which melt at  $164^\circ$ , and are easily soluble in alcohol and water. When an ethereal solution of bornylamine is allowed to act on methyl isocyanate, *methylbornylcarbamide*,  $NHMe \cdot CO \cdot NH \cdot C_{10}H_{17}$ , is formed; it crystallises in scales melting at  $200^\circ$ , and is soluble in water and alcohol. *Bornylphenylcarbamide*,  $NHPh \cdot CO \cdot NH \cdot C_{10}H_{17}$ , similarly obtained, forms silvery needles, easily soluble in hot alcohol, sparingly in cold alcohol and ether, insoluble in water. It melts with decomposition at  $248^\circ$ . *Bornylphenylthiocarbamide*,  $NHPh \cdot CS \cdot NH \cdot C_{10}H_{17}$ , formed from phenylthiocarbamide and the free base, crystallises in colourless needles melting at  $170^\circ$ .

The authors believe bornylamine to be isomeric and not identical with camphylamine, described by Goldschmidt (Abstr., 1886, 249 and 557).

The authors have also succeeded in obtaining bornylamine, although in very small quantities, by the reduction of camphoroxime by sodium amalgam. From this fact, and from its method of formation from camphor, they (accepting the ketone-formula of camphor as the most probable one) ascribe to bornylamine the formula  $C_8H_{14} \cdot \begin{matrix} CH_2 \\ \text{---} \\ CH(NH_2) \end{matrix}$ . They believe camphylamine to be very closely related to and probably only a position-isomeride of bornylamine.

The authors have also obtained from carvole a corresponding *caryylamine*, which is now being investigated.

L. T. T.

**Active Principles of *Asclepias Currassavica*, *A. Incarnata*, and *Vincetoxicum Officinale*.** By C. GRAM (*Chem. Centr.*, 1886, 735).—These three *Asclepiadæ* contain a glucoside which the author calls *Asclepiadin*. In the aerial parts of *Asclepias currassavica* the easily decomposed asclepiadin of Harnack was found; this appears to be identical with the asclepin of Feneulle. The asclepiadin isolated by the author is easily soluble in water, sparingly soluble in alcohol; it is easily converted into the less active asclepin. Only asclepidin, and no asclepin, could be obtained from the root of *Vincetoxicum officinale*. The asclepin which is prepared from *Asclepias tuberosa* by Keith and

Co. consists of a mixture of asclepiadin, asclepin, and asclepion; the latter has the composition  $C_{20}H_{34}O_3$ ; it melts at  $104^\circ$ , and is contained in *Asclepias syriaca* and in *Vincetoxicum*. The asclepiadin which is prepared by Parke, Davis, and Co., from *Asclepias tuberosa*, contains asclepin and a small quantity of a substance which has a tetanic action.

G. H. M.

**Conversion of Pyrroline into Pyridine-derivatives.** By G. CIAMICIAN and P. SILBER (*Ber.*, 20, 191—195).—Weidel has shown (Abstr., 1886, 56) that Hofmann's bromopyridine, which is identical with that prepared synthetically from pyrroline, is a  $\beta$ -derivative; with a view to confirm this result and to determine the position of the carbon-atom introduced into the molecule when pyrroline is converted into halogenated pyridine-derivatives by the action of chloroform (Abstr., 1881, 826), bromoform (Abstr., 1882, 1214), or methylene iodide (Abstr., 1886, 367), the authors examined the action of benzal chloride on pyrroline. When these substances are heated with sodium ethoxide in molecular proportions at  $160$ — $170^\circ$  for six hours, a non-basic substance, which has not been further examined, and phenylpyridine agreeing in all its properties with the  $\beta$ -compound prepared by Skraup (Abstr., 1883, 1013), are obtained. The introduced carbon-atom therefore takes up the  $\beta$ -position in the pyridine molecule, the relationship between the bases being best expressed by the formulæ

W. P. W.

**2 : 6 Dimethylpyridine Platinochloride.** By T. LIWEH (*Ber.*, 20, 66).—A reinvestigation of the crystalline form of this salt has entirely confirmed Groth's statement (Abstr., 1886, 558) as to its isomorphism with picoline platinochloride. The following faces were observed :  $\infty P\infty$ ,  $\infty P$ ,  $\infty R\infty$ ,  $OP$ ,  $P\infty$ ,  $-2P2$ ,  $+2P2$  (monoclinic).

**Oxidation of Symmetrical Trialkylpyridines.** By S. ALTAR (*Annalen*, 237, 182—201).—The formation of lutidinemonocarboxylic acid from  $\beta$ -collidine has been described by Voigt (Abstr., 1885, 812). The acid is most readily purified by precipitation from an alcoholic solution by platinum chloride. The *platinochloride*,

crystallises in thick prisms, which effloresce on exposure to the air, and change in colour from deep red to orange. At the ordinary temperature, the salt loses 2 mols. alcohol; at  $120^\circ$ , all the alcohol is expelled, and the anhydrous salt melts at  $221^\circ$ . By decomposing an aqueous solution of the platinochloride with sulphuretted hydrogen, the *hydrochloride*,  $C_8H_9NO_2 \cdot HCl + H_2O$ , is obtained in microscopic needles which are freely soluble in water. The free acid melts at  $153^\circ$ , and dissolves freely in water and alcohol; it crystallises with  $\frac{1}{2}$  mol.  $H_2O$ . All the salts of the acid are soluble. As lutidine monocarboxylic acid yields  $\alpha$ - $\gamma$ -lutidine on distillation with lime, this acid may be regarded as  $\alpha$ - $\gamma$ -dimethyl-picolinic acid.

Ethyl dihydroisopropylutidinedicarboxylate yields ethyl lutidinedicarboxylate on oxidation, and also when the ethereal solution is treated with dry hydrogen chloride.

When oxidised with potassium permanganate, parvoline,  $C_5NH_2EtMe_2$ , yields methylethylpyridinecarboxylic acid,  $C_5NH_2EtMe\cdot COOH$ . The platinochloride of this acid forms red crystals, which melt with decomposition at  $194-195^\circ$ .

The preparation of picolinedicarboxylic acid has been described by Voigt (*loc. cit.*). The crude product of the action of potassium permanganate on collidine is concentrated, and mixed with hydrochloric acid, when picolinedicarboxylic acid is slowly deposited. The precipitate is dissolved in ammonia and reprecipitated from the hot solution by hydrochloric acid. The pure acid melts at  $274^\circ$  with decomposition. It crystallises in slender needles, and is sparingly soluble in water. As picolinedicarboxylic acid is also formed by the oxidation of parvoline, the acid may be regarded as  $\alpha$ -methyllutidinic acid,  $COOH\cdot C_5NH_2Me\cdot COOH$ . It is identical with Böttinger's uvitonic acid.

W. C. W.

**Quinolinedisulphonic Acid and its Derivatives.** By W. LA COSTE and F. VALEUR (*Ber.*, 20, 95—104).—The best method of formation of the mixture of ortho- and meta-quinolinesulphonic acids is to heat 1 part of quinoline with  $3\frac{1}{2}$  parts of fuming sulphuric acid at  $170^\circ$ . The reaction is then complete in one hour. The acids are best separated by means of their mercury salts, that of the ortho-acid being easily soluble, that of the meta-acid insoluble, in cold water. The authors, differing from O. Fischer and Bedall (*Abstr.*, 1882, 869), find the ortho-acid to be sparingly, the meta-acid easily soluble in water.

The pure ortho-acid on sulphonation gives the same two disulphonic acids previously described by La Coste and Valeur (*Abstr.*, 1886, 628). It is thus clear that the meta-acid yields only one disulphonic acid, and that this is identical with one of the two obtainable from the ortho-acid. The authors have examined some of the derivatives of  $\alpha$ -quinolinedisulphonic acid. The *potassium salt*,  $C_9NH_5(SO_3K)_2 + 3\frac{1}{2}H_2O$ , crystallises in silky, white needles.  *$\alpha$ -Quinolinedicyanide*,  $C_9NH_5(CN)_2$ , was obtained by the dry distillation of a mixture of the above potassium salt and potassium cyanide. It crystallises in short, grey needles, insoluble in water, sparingly soluble in ether, benzene, and chloroform, readily so in acids and alkalis; it melts at  $220-222^\circ$ .  *$\alpha$ -Quinolinedicarboxylic acid*,  $C_9NH_5(COOH)_2 + H_2O$ , obtained by saponifying the dicyanide with soda, crystallises in needles which melt at  $268-270^\circ$ , and are soluble in alcohol, ether, chloroform, and boiling water.  *$\alpha$ -Hydroxyquinolinesulphonic acid* (*Abstr.*, 1884, 629) forms both normal salts and basic salts, in the latter, the phenolic hydrogen is also replaced. Both series of salts are crystalline, and mostly contain water of crystallisation; several of each series are described by the authors. Attempts to obtain oxidation products from this hydroxy-acid resulted almost uniformly in the total destruction of the compound, but in one case, with alkaline permanganate, a small quantity of a pyridinedicarboxylic acid was formed, which

seemed to be identical with the acid obtained by Hoogewerff and van Dorp by the oxidation of quinoline. L. T. T.

**Quinoline-red.** By A. W. HOFMANN (*Ber.*, 20, 4—20).—This substance was patented by Jacobsen (*Ber.*, 15, 2646), who obtained it by heating quinoline with benzotrichloride and zinc chloride at 120—130°; the zinc chloride may be omitted if a higher temperature is employed. The yield is only about 5 per cent. of the quinoline used. As the quinoline recovered from the manufacture gives scarcely any of the red dye when again treated in like manner, it seemed probable that some constituent of the crude quinoline was essential to the formation of the dye. Experiments were therefore made with quinaldine and with isoquinoline. With mixtures of quinaldine and quinoline (eq. mols.) a yield of only  $1\frac{1}{2}$  per cent. of the red was obtained, but when isoquinoline was substituted for quinoline the yield rose to 9 to 12 per cent. The dye thus obtained, although showing very great resemblance to quinoline-red, yet differs from it in several particulars; the two, therefore, are possibly isomeric.

*Isoquinoline-red*,  $C_{26}H_{19}N_2Cl$ , is obtained by heating quinaldine and isoquinoline (eq. mols.) with benzotrichloride and zinc chloride. The dye is formed far more readily than with quinoline. It crystallises in monosymmetric prisms, terminated by pyramids;  $a : b : c = 0.9783 : 1 : 1.3651$ ,  $\beta = 54^\circ 24'$ . By transmitted light, the crystals are deep crimson, in reflected light they appear reddish-brown with greenish-yellow, metallic lustre. It is soluble in water, alcohol, acetic acid, and phenol, insoluble in ether, carbon bisulphide, and benzene. The aqueous and alcoholic solutions are crimson with a strong yellowish-red fluorescence; the solutions dye wool and silk bright rose with some indication of yellow fluorescence; the colour is not fast. The dye prepared from quinoline crystallises invariably in slender needles, and in colour is pure red without metallic lustre; the solutions are crimson with a slight violet tint; the same violet tint is observable in wool or silk dyed with quinoline-red. The absorptive spectrum of both dyes in alcoholic solution consists of two bands in the green and bluish-green, but the bands of quinoline-red are narrower and more intense than those of isoquinoline-red. The platinochlorides,  $(C_{26}H_{19}N_2Cl)_2 \cdot PtCl_4$ , are obtained as scarcely crystalline precipitates, insoluble in water, alcohol, and hydrochloric acid; that from quinoline red is violet-red in colour, whilst the iso-compound is pure crimson.

As no difference has as yet been detected in the chemical behaviour of the two modifications, the term quinoline-red refers to both in the reactions and derivatives described. When treated with zinc and hydrochloric acid, quinoline-red is quickly decolorised with formation of a leuco-base, which has, however, not yet been further investigated. When the reduction is effected by heating with alcoholic ammonium sulphide in sealed tubes for 8 to 10 hours at 200°, benzyl mercaptan and a new base of the formula  $C_{19}H_{14}N_2$  are obtained. This base crystallises in plates of golden lustre, melts at 231°, and sublimes at a higher temperature without decomposition; it is insoluble in water, sparingly soluble in ether, benzene, and cold alcohol, more readily in

carbon bisulphide, and readily in phenol. It shows feeble basic properties; the hydrochloride crystallises in colourless needles.

When heated with hydrochloric acid or when oxidised, quinoline-red yields benzaldehyde; as in the reaction with ammonium sulphide, the group introduced in the form of benzotrichloride is again eliminated.

When quinoline-red is distilled with zinc, a mixture is obtained from which a base,  $C_{17}H_{15}N$ , was isolated. This is crystalline, melts at  $86-86.5^\circ$ , and yields a sparingly soluble crystalline platinumchloride.

Reviewing the evidence deducible from the formation and reactions of quinoline-red, the author considers that it must be represented either by  $C_9NH_6 \cdot CPhCl \cdot C_9NH_5Me$  or by  $C_9NH_6 \cdot CPhCl \cdot CH_2 \cdot C_9NH_6$ , but there is not yet sufficient grounds to decide which of the two formulæ is correct.

A. J. G.

**Combination of Quinaldine with Formamide.** By P. T. CLEVE (*Ber.*, 20, 76).—When equivalent quantities of quinaldine and formamide are mixed together, a white crystalline mass, readily soluble in alcohol, ether, and chloroform, is at once obtained. The compound  $C_9NH_6Me \cdot C(OH) \cdot NH_2$  forms radiating groups of needles, melts at  $76^\circ$ , and is decomposed by water; when heated in a sublimation apparatus, oily drops are obtained, which soon become crystalline.

W. P. W.

**1, 3 Dimethylquinaldine and its Derivatives.** By G. PANAJOTOW (*Ber.*, 20, 32—42).—1, 3 *Dimethylquinaldine*,  $C_9NH_4Me_3$  [ $Me_3 = 2' : 1 : 2$ ], is prepared by the condensation of metaxyldine with paraldehyde and concentrated hydrochloric acid. It crystallises in nearly colourless, monoclinic prisms or in small plates, melts at  $146^\circ$ , boils without decomposition at  $260^\circ$  under a pressure of 719 mm., and volatilises readily with steam. It has the characteristic odour of quinoline, is insoluble in water, readily soluble in alcohol, ether, and light petroleum. The *sulphate*,  $C_{12}NH_{13} \cdot H_2SO_4 + H_2O$ , forms small, white needles; the *hydrochloride*,  $C_{12}NH_{13} \cdot HCl$ , also crystallises in needles; the *nitrate* forms transparent, triclinic prisms; the *platinochloride*,  $(C_{12}NH_{13})_2 \cdot H_2PtCl_6$ , crystallises in orange-yellow needles; the *picrate* forms long, yellow needles, melting at  $185^\circ$ . The *methiodide*,  $C_{12}NH_{13} \cdot MeI + H_2O$ , crystallises in small, yellow needles.

*Tetrahydrodimethylquinaldine*,  $C_{12}NH_{17}$ , is formed by the reduction of the above base with tin and hydrochloric acid; it is an oil boiling between  $200^\circ$  and  $250^\circ$ , and, like tetrahydroquinaldine, gives the characteristic red colour when treated with dilute nitric acid; the *platinochloride*,  $(C_{12}NH_{17})_2 \cdot H_2PtCl_6$ , forms orange-coloured plates.

*Nitro-1, 3-dimethylquinaldine*,  $C_9NH_3Me_3 \cdot NO_2$ , is the only nitro-derivative obtained in the nitration of the base; it forms long, white needles, melts at  $92^\circ$ , and is readily soluble in ether and chloroform. The *platinochloride* has the formula  $(C_{12}H_{12}N_2O_2)_2 \cdot H_2PtCl_6 + 3H_2O$ . *Amidodimethylquinaldine*,  $C_{12}NH_{12} \cdot NH_2$ , obtained by reduction of the nitro-compound, crystallises in yellow plates.

*1, 3 Dimethylquinaldinesulphonic acid*,  $C_9NH_3Me_3 \cdot SO_3H$ , prepared by the action of pyrosulphuric acid on the base, crystallises in small, yellow needles, and does not melt up to  $260^\circ$ . The barium salt crys-

tallises with 3 mols.  $\text{H}_2\text{O}$  in silky needles, sparingly soluble in water. In order to ascertain the position of the sulphonic group in this substance, the author endeavoured to synthesise a corresponding or identical acid by condensation from Jacobsen and Ledderboge's metaxylidinesulphonic acid (Abstr., 1883, 593); he finds, however, that no condensation occurs with paraldehyde. This unexpected result would seem to indicate that the constitution of this metaxylidinesulphonic acid is not that given by its discoverers [ $\text{Me}_2 : \text{SO}_3\text{H} : \text{NH}_2 = 1 : 3 : 4 : 6$ ], but that it is the  $1 : 3 : 5 : 6$  acid, as this latter constitution not only agrees with the non-formation of a quinaldine, but also brings the formation of the acid into the general rule that the sulphonic group when introduced into an aromatic amide does not assume the meta-position relatively to amidogen.

*Dimethylquinolinecarboxylic acid*,  $\text{C}_9\text{NH}_4\text{Me}_2\cdot\text{COOH}$  [ $\text{Me}_2 : \text{COOH} = 1 : 2' : 3$ ], is obtained by oxidation of 1 : 3 dimethylquinaldine with chromic mixture. It crystallises in small, white needles, cannot be fused without decomposition, but can be sublimed in small quantity in long, lustrous needles; it is sparingly soluble in water and cold alcohol. The silver (with 1 mol.  $\text{H}_2\text{O}$ ) and barium salts are described. The *platinochloride*,  $(\text{C}_{11}\text{H}_{10}\text{N}\cdot\text{COOH})_2\cdot\text{H}_2\text{PtCl}_6 + 4\text{H}_2\text{O}$ , crystallises in orange-yellow needles; the *picrate* melts at  $221^\circ$ . When distilled with lime, it yields orthomethylquinaldine.

*Dimethylquinoline- $\alpha$ -acrylic acid*,  $\text{C}_9\text{NH}_4\text{Me}_2\cdot\text{CH} : \text{CH}\cdot\text{COOH} = [1 : 3 : 2']$ . When 1, 3 dimethylquinaldine is heated with dry chloral for eight hours on the water-bath, the condensation product  $\text{C}_{14}\text{H}_{12}\text{NCl}_3 + \text{H}_2\text{O}$  is obtained in small, yellow needles, melting at  $108^\circ$ , and readily soluble in ether, alcohol, benzene, and hot light petroleum. This is boiled with aqueous potassium carbonate in a reflux apparatus for 15 hours, and the potassium salt formed, is neutralised with hydrochloric acid, when dimethylquinoline- $\alpha$ -acrylic acid separates. The latter crystallises in small, yellow needles, which decompose at  $180^\circ$ ; the decomposition product melts at  $210^\circ$ . A. J. G.

**Nomenclature of the Quinoxaline Series.** By O. HINSBERG (*Ber.*, 20, 21—23).—The author suggests that whilst the whole group

of substances containing the typical ring  should be termed

quinoxaline bases, it will be convenient to divide them into two sub-groups. 1. The quinoxalines proper, in which only a single-ring group is combined with the nitrogen-ring, the names of the individual compounds being formed by adding the termination quinoxaline to the name of such ring group, for instance,—

Quinoxaline.

Toluquinoxaline.

Naphthaquinoxaline.

2. The azines, in which the nitrogen-ring is in union with two other rings, of these compounds, phenazine,  $C_6H_4 \begin{smallmatrix} \diagup N \diagdown \\ | \\ \diagdown N \diagup \end{smallmatrix} C_6H_4$ , is the first member, the higher members being named—

Naphthazine.

Tolunaphthazine.

Phenanthrazine.

&amp;c.

A. J. G.

**Nitrotolylglycine and Oxydihydrotoluquinoxaline.** By R. LEUCKART and A. HERRMANN (*Ber.*, **20**, 24—31. Compare Hinsberg, *Abstr.*, 1886, 82, Plöchl, and also the authors, *ibid.*, 351).—The barium, ammonium, and lead salts of orthonitrotolylglycine (nitrotoluidooacetic acid) are described. The *ethyl* salt crystallises in broad, yellow needles, melts at 65°, and is readily soluble in benzene, light petroleum, &c.

*Chlordihydrotoluquinoxaline*,  $C_7H_6 \begin{smallmatrix} \text{NH} \cdot \text{CH}_2 \\ \diagdown N : \text{CCl} \diagup \end{smallmatrix}$ , is prepared by heating oxydihydrotoluquinoxaline with phosphoric chloride at 140—150°; it forms colourless needles, melts at 77°, has a quinoline-like odour, and is insoluble in water, very readily soluble in alcohol, ether, benzene, and light petroleum. It has feeble basic properties. When heated with alcoholic potash, the chlorine-atom is displaced with formation of the *ethoxide*,  $C_7H_6 \begin{smallmatrix} \text{NH} \cdot \text{CH}_2 \\ \diagdown N : \text{C}(\text{OEt}) \diagup \end{smallmatrix}$ . This crystallises in brittle, silky needles, melts at 67°, and is readily soluble in hot water, alcohol, ether, benzene, or light petroleum. The corresponding *methoxide* melts at 71°. When the chloride is heated in acetic acid solution with hydriodic acid at 240°, amongst other products a few drops of an oil of quinoline-like odour was obtained; this probably is dihydrotoluquinoxaline, but the amount was too small for investigation.

A. J. G.

**Conyryne Platinochloride.** By T. LIWEH (*Ber.*, **20**, 67—68).—The author has submitted synthetical conyryne platinochloride (*Abstr.*, 1887, 160) to a crystallographic examination, and gives results which show that the crystals are precisely similar in form to those of the conyryne platinochloride obtained from natural conine.

W. P. W.

**Hydrastine.** By M. FREUND and W. WILL (*Ber.*, **20**, 88—95).—In this paper, the authors substitute the formula  $C_{21}H_{21}NO_6$  for that previously ascribed to hydrastine (this vol., p. 174). They have examined the base *hydrastinine*,  $C_{11}H_{11}NO_2 + H_2O$ , obtained together with opianic acid when hydrastine is treated with oxidising agents. Hydrastinine forms white crystals, melts at 116—117°, fusion, however, occurring if it be kept at 100° for some time, and is soluble in benzene, ethyl acetate (these solvents produce a partial decomposition), light

petroleum, ether, and water; the aqueous solution is strongly alkaline and intensely bitter. Like cotarnine, of which it is the next lower homologue, hydrastinine crystallises from all solvents with 1 mol.  $\text{H}_2\text{O}$ ; this, however, is not present in its salts. The *hydrochloride*,  $\text{C}_{11}\text{H}_{11}\text{NO}_2\cdot\text{HCl}$ , crystallises in feebly coloured needles, melts at about  $212^\circ$  with decomposition, and is readily soluble in alcohol and water; the aqueous solution shows a feeble fluorescence, and is optically inactive. The *sulphate*,  $\text{C}_{11}\text{H}_{11}\text{NO}_2\cdot\text{H}_2\text{SO}_4$ , forms yellow crystals showing a green fluorescence, and is soluble in alcohol. The *dichromate*,  $\text{C}_{11}\text{H}_{11}\text{NO}_2\cdot\text{H}_2\text{Cr}_2\text{O}_7$ , crystallises in slender, golden-yellow needles, and is soluble in water. The *methiodide*,  $\text{C}_{11}\text{H}_{11}\text{NO}_2\cdot\text{MeI}$ , crystallises in slender, yellow needles showing a vitreous lustre, and is soluble in alcohol and water. The *platinochloride*,  $\text{C}_{11}\text{H}_{11}\text{NO}_2\cdot\text{H}_2\text{PtCl}_6$ , and the *aurochloride* form yellow crystals, whilst with potassium ferri-cyanide a compound crystallising in reddish-brown needles is obtained.

*Hydrohydrastinine*,  $\text{C}_{11}\text{H}_{13}\text{NO}_2$ , is formed when hydrastinine is reduced with zinc and hydrochloric acid. This base forms white crystals, melts at  $66^\circ$ , and is readily soluble in ether, alcohol, benzene, carbon bisulphide, ethyl acetate, and acetone; the picrate crystallises in yellow needles. The *hydrobromide*,  $\text{C}_{11}\text{H}_{13}\text{NO}_2\cdot\text{HBr}$ , forms tufts of small, white needles, and, like the hydrochloride, is sparingly soluble in water.

*Hydrastinic acid*,  $\text{C}_8\text{H}_7\text{NO}_4$ , is obtained by boiling hydrastine with dilute nitric acid until potassium hydroxide no longer precipitates the product. The acid is crystalline, melts at  $232^\circ$  with decomposition, is soluble in alcohol and water, and resembles apophyllic acid (Abstr., 1881, 110) in its properties. The *silver salt*,  $\text{C}_8\text{H}_6\text{NO}_4\text{Ag}$ , crystallises in needles.

W. P. W.

**Action of Phosphorus Pentachloride on Substituted Formamides and on Piperidine-derivatives.** By O. WALLACH and F. LEHMANN (*Annalen*, 237, 236—260).—The hydrochloride of a base of the composition  $\text{C}_8\text{H}_{14}\text{N}_2$  is obtained by adding phosphoric chloride to a solution of diethylformamide in chloroform. The resulting phosphorus oxychloride is distilled off under reduced pressure, and the residue kept at a temperature of  $100^\circ$  for two hours. On the addition of platinum chloride to the alcoholic solution of the product, the platinochloride,  $(\text{C}_8\text{H}_{14}\text{N}_2)_2\cdot\text{H}_2\text{PtCl}_6$ , is precipitated. The intermediate product,  $\text{C}_{10}\text{H}_{19}\text{ClN}_2$ , previously described by Wallach (Abstr., 1881, 719) could not again be isolated.

Diethylformamide forms two platinochlorides of the composition  $(\text{NEt}_2\cdot\text{COH})_4\cdot\text{H}_2\text{PtCl}_6$  and  $(\text{NEt}_2\cdot\text{COH})_2\cdot\text{H}_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ .

Piperidine also forms two platinochlorides. When platinum chloride is added to a concentrated aqueous solution of piperidine hydrochloride, an anhydrous salt,  $(\text{C}_5\text{H}_{11}\text{N})_2\cdot\text{H}_2\text{PtCl}_6$ , is precipitated. But if this salt is recrystallised from boiling alcohol mixed with a small quantity of hydrochloric acid, orange, needle-shaped crystals containing 1 mol. of alcohol are obtained,  $(\text{C}_5\text{H}_{11}\text{N})_2\cdot\text{H}_2\text{PtCl}_6 + \text{C}_2\text{H}_5\text{O}$ . The anhydrous salt melts at  $198\text{--}200^\circ$ , the alcoholic salt at  $191^\circ$ , both with decomposition.

*Ethyl piperidylloxamate*,  $C_5NH_{10} \cdot CO \cdot COOEt$ , is obtained as a colourless, oily liquid, heavier than and insoluble in water, by boiling a mixture of piperidine and ethyl oxalate for several hours. The product boils at  $283-290^\circ$ . It is converted into the oxamide by ammonia. The *oxamide*,  $C_5NH_{10} \cdot CO \cdot CONH_2$ , is deposited from a hot aqueous solution in monoclinic prisms;  $a:b:c = 0.66182:1:0.53426$ ,  $\beta = 50^\circ 53.5'$ . It is soluble in alcohol and melts at  $126-127^\circ$ , and is converted into the nitrile of piperidylloxamic acid,  $NC \cdot CO \cdot C_5NH_{10}$ , by the action of phosphoric anhydride.

*Piperidylloxamic acid*,  $C_5NH_{10} \cdot CO \cdot COOH$ , is conveniently prepared by adding a concentrated alcoholic solution of sodium ethoxide to an alcoholic solution of ethyl piperidylloxamate. The free acid is deposited in needle-shaped crystals on the addition of hydrochloric acid to the solution of the sodium salt. It dissolves freely in alcohol and chloroform, and melts at  $128-129^\circ$  with evolution of carbonic anhydride. Piperidylloxamic chloride is decomposed by distillation, yielding carbonic oxide and piperidyl carbamic chloride. The carbamic chloride boils at  $237-238^\circ$ , and is decomposed by warm water. With aniline it yields *phenylpiperidylcarbamide*,

a white crystalline substance melting at  $171-172^\circ$ . *Dipiperidyl carbamide* melts at  $42-43^\circ$ , and boils at  $296-298^\circ$ . It is freely soluble in ether, alcohol, chloroform, and in acids.

*Formopiperidide*,  $HCO \cdot C_5NH_{10}$ , prepared by heating piperidylcarbamic acid in a flask with a reflux condenser, is a colourless liquid boiling at  $222^\circ$ . The aqueous solution reduces silver salts and Fehling's solution, and forms a crystalline double salt with mercuric chloride,  $HCO \cdot C_5NH_{10} \cdot HgCl_2$ .

The hydrochloride is precipitated in deliquescent needles when hydrogen chloride is passed into a solution of formopiperidide in absolute ether. If the hydrochloride is dissolved in a small quantity of water, and mixed with alcohol and platinum chloride, a crystalline platinochloride is deposited which has the composition

and is analogous to that obtained from diethylformamide. A complicated reaction ensues when phosphoric chloride acts on formopiperidide. The authors suggest that piperidine and the amidochloride,  $C_5NH_{10} \cdot CCl_2H$ , are formed in the first instance. These substances react on each other, yielding the compound  $CHCl(C_5NH_{10})_2$ , which unites directly with platinum chloride to form the salt  $(C_{11}H_{21}N_2Cl)_2, PtCl_4$ .  
W. C. W.

**Ptomaines.** By H. BECKURTS (*Arch. Pharm.* [3], 24, 1041—1065).—The detection of poisonous alkaloids in forensic and similar cases is greatly increased in difficulty owing to the formation of ptomaines from albuminoid substances of animal or vegetable origin, more especially as the ptomaines in their general chemical reactions bear great resemblance to the vegetable alkaloids. It has repeatedly occurred in criminal cases, that the two classes of compounds have

been confounded, even by experts. All the basic nitrogenous products which result from the action of bacteria, whether of disease or decomposition, must be considered as ptomaines; and perhaps also certain definite poisonous basic substances, the leucomaines, which according to Gautier are formed during life in man and the higher animals.

Until very recently, only ptomaines of unknown composition had been isolated, and in all cases by the methods of Stas-Otto and Dragendorff. It is mainly to Brieger's investigations during the past four years, that we are indebted for a more accurate knowledge of the composition of these compounds. (For Brieger's method see Abstr., 1885, 278.) From decomposing flesh, Brieger obtained neuridine,  $C_5H_{14}N_3$ , and neurine,  $C_5H_{13}NO$ . From decomposing fish he obtained a poisonous isomeride of ethylendiamine, possibly ethylenediamine,  $C_2H_4(NH_2)_2$ , muscarine,  $C_5H_{15}NO_3$ , and the physiologically inactive gadinine,  $C_6H_{17}NO_2$ . Fully decomposed cheese yielded neuridine. Decomposing glue gave neuridine, dimethylamine, and a muscarine-like base, whilst rotten yeast gave dimethylamine only. As these compounds result from the action of bacteria on animal tissues, so Brieger showed that the same or analogous compounds were similarly formed in the human subject. In the earlier stages of decomposition, only choline was found. After three days, neuridine appeared in increasing amounts, whilst choline gradually disappeared, being replaced by trimethylamine. After fourteen days, neuridine had also disappeared. Later, there most commonly appeared cadaverine,  $C_5H_{16}N_2$ , and putrescine,  $C_4H_{12}N_2$ . With cadaverine is also found a substance of the same composition, called *saprine*, but differing considerably in its reactions. The bases choline, neuridine, cadaverine, putrescine, and saprine are physiologically indifferent; but after fourteen days' decomposition a new poisonous base, *mydaleine*, was obtained which seems to be a diamine. In human remains (heart, lung, liver, &c.), maintained at  $-9$  to  $+5^\circ$  C. during four months, a new base, mydine,  $C_8H_{11}NO$ , was found, a strongly reducing agent, and a poisonous base, mydatoxine,  $C_6H_{13}NO_2$ , also the poisonous methyl-guanidine was isolated. O. Bocklisch, employing Brieger's method, obtained a large number of bases from decomposing fish. The bases so obtained were not poisonous, and attempts to separate the injurious compounds were unsuccessful. The fact that decomposition bacteria induce the formation of numerous basic substances from albuminoid compounds, makes it highly probable that pathogenic bacteria possess similar properties. Thus, Koch, Nicati, and Rietsch have found poisonous ptomaines in cholera. In cultivations of typhus bacilla, a strongly basic poison, typhotoxine,  $C_7H_{17}NO_2$ , was obtained; and from tetanus cultivations a strong base, tetanine,  $C_{13}H_{30}N_2O_4$ , was obtained. The bases obtained by Brieger are either liquids of definite boiling point, or solid crystalline substances. The salts show the so-called general alkaloïd reactions, so that as a group the ptomaines cannot be separated from the alkaloids. The non-poisonous ptomaines readily give rise to poisonous compounds; thus, cadaverine, which has been shown by Ladenburg to be pentamethylenediamine, is converted by rapid distillation of the hydrochloride into the poisonous

piperidine. Whilst the constitution of cadaverine has just been indicated, putrescine is either a dimethylethylendiamine or methyl-ethyl-methylendiamine; which of the two, further investigation must decide. The present methods of isolating the alkaloids do not yield absolutely certain results, and further extended investigation is required.

J. T.

**Origin of Ptomaines.** By C. GRAM (*Chem. Centr.*, 1886, 647).—Although it cannot be denied that a part of the basic products (so-called ptomaines) occurring in most putrefying substances is formed by the putrefactive process itself, for instance, the poisonous sepsine found in putrid yeast, it is nevertheless possible that some of these substances may arise simply by reason of the chemical processes involved in the separation of these basic products.

The simple action of heating organic compounds with ammonia salts may give rise to basic products.

The author has for a long time tried in vain to obtain poisonous bases from putrid meat by Maas's method. On treatment with amyl alcohol, an important quantity of these bases was obtained from meat in various conditions of putrefaction, but they were all perfectly inert.

The hydrochloric acid derivatives after heating on a water-bath were also inert, but the lactic acid compounds under similar treatment showed decidedly poisonous properties. Similar observations were made with other bases obtained from putrid yeast free from sepsine.

This transformation of a non-poisonous into a poisonous product by comparatively simple chemical action led the author to study the change of choline into the trimethylvinylammonium base. According to Brieger, the latter poisonous product is a frequent constituent of putrid matter, and arises from the action of putrefactive microphytes on choline.

This same change can be effected by purely chemical means. The lactate of choline when heated, gives rise to a poisonous substance with muscarine-like action. Inasmuch as many researches have shown that choline is widely distributed throughout animal and vegetable organisms, and as it is moreover capable of being converted into a poisonous substance by simple chemical action, the author considers it necessary to conduct researches on ptomaines with more caution, and perhaps to regard with mistrust ptomaines possessing a muscarine-like action.

J. P. L.

**Diastase.** By O. LOEW (*Ber.*, 20, 58).—A reply to Lintner (this vol., p. 166), in which the author reaffirms the utility of the method of purifying ferments with lead salts, provided due precautions are taken.

---

## Physiological Chemistry.

---

**Artificial Digestion.** By A. STUTZER (*Zeit. physiol. Chem.*, **11**, 207—232).—From a large number of artificial digestion experiments on the various forms of fodder used by cattle, it was found that after the gastric juice has digested all it can, a certain amount of the remaining proteid can be digested by means of an artificial pancreatic juice. The pancreatic extract was mixed with sodium carbonate solution, but equally good results were obtained whether the amount of sodium carbonate present was  $\frac{1}{4}$ ,  $\frac{1}{2}$ , or 1 per cent. It was also found that the best results were obtained when the digestive fluid consisted of 25 c.c. of pancreatic extract to 75 of sodium carbonate solution, or rather that when less pancreatic fluid was added than indicated by this proportion, there was a slight diminution in the amount of proteid digested; when more than a quarter of the digestive fluid consisted of the pancreatic fluid, there was no increase in the amount digested. In order to obtain trustworthy results, it was found that six hours was a sufficient length of time to expose (at a temperature of 37—40°) the fodder to the action of the digestive fluid: a longer exposure than this caused no further digestion. Tables are appended to the paper which give for 28 varieties of fodder, the total nitrogen, the amount of nitrogen combined as proteid, the amount of nitrogen not present in proteids, the amount of proteid digestible in gastric juice, the amount indigestible in gastric but digestible in pancreatic juice, and the amount not digestible by either. W. D. H.

**Place of Origin of Uric Acid in the Animal Organism.** By A. B. GARROD (*Proc. Roy. Soc.*, **40**, 484—485).—In continuation of previous experiments on the formation of uric acid in the animal economy (*Abstr.*, 1883, 876), it is here shown that uric acid is secreted by the kidney cell as ammonium urate, and that the traces of sodium urate ordinarily found in the blood result from the necessary absorption of the ammonium salt from the kidneys into the blood, in which it is subsequently converted into the sodium salt.

The daily quantity of uric acid secreted, expressed as a ratio of the body-weight, varies from 1 in 1,000,000 in some carnivorous mammalia to 1 in 85 in birds; in man it may be regarded as 1 in 120,000. The quantity contained in the blood has but little relation to that secreted by the kidneys. When the acid is absorbed from the alimentary canal, the blood becomes strongly impregnated with it, but if taken into the stomach, the secretion from the kidneys is not thereby increased. The proportion of acid found in different veins in the same bird is variable; but the quantity secreted daily by the kidneys is closely related to the quantity of nitrogenous food taken in the same time. V. H. V.

**Albuminoids of Human Milk and of Cows' Milk.** By BIEDERT (*Chem. Zeit.*, **10**, 1460—1461).—Remarking on the useless-

ness of the method of determining albuminoids in milk which depends on the precipitation with magnesium sulphate, it is shown that the filtrate from the magnesium sulphate precipitate (I) yields a precipitate (II) with acetic acid; the filtrate from this yields a precipitate (III) on boiling, and this filtrate gives a precipitate (IV) with tannin. With human milk, precipitate I = about 0.15—0.71 per cent.; II = 0.08—0.32; III, 0.02—0.08; IV, 0.05—0.32; with cow's milk I = 2.33—2.58; II, 0.04; III, none or an unweighable quantity; IV, 0.07—0.12. There is a decided difference between the two kinds of milk.

E. Pfeiffer remarks that no method can be considered trustworthy which professes to separate these different albuminoids in milks; and relies on methods such as Ritthausen's, in which all albuminoids present in the milk are precipitated at once. He, moreover, points out that not only human and cows' but also mares' and asses' milk have their characteristic albuminoids (caseins). D. A. L.

**Poisonous Ptomaine in Milk.** By R. H. FIRTH (*Lancet*, 1, 1887, 213—214).—An epidemic of attacks of violent purging and vomiting among the soldiers in the Punjab was traced to the use of certain milk. The residue of the suspected milk was found to be of sp. gr. 1.025; casein, 4.1; fat, 3.9; and sugar, 5.04 per cent. The dairy pans were found to be unwashed, and some emitted a repulsive odour; the weather at the same time was very hot. The milk was coagulated, filtered; the filtrate was neutralised and made feebly alkaline by potassium hydrate, and shaken with ether. On evaporating the ethereal extract, a crystalline residue of sickly odour and pungent taste was obtained. Given to men in small quantities, it produced nausea and headache. Given to dogs, in 15 minutes it produced violent purging and vomiting.

First, milk tested in a similar way gave negative results. Eight samples of milk were allowed to stand, and tested every 20 days. After two months, three of the samples yielded the same crystalline substance which produced the same symptoms when given to animals. This substance—which seems to be a ptomaine—is evidently the result of decomposition. No specific organisms on which to fasten it—beyond some common forms of oidium and penicillium—were found. The name proposed for it is *lactotoxine*. W. D. H.

**Nitrates in Animals and Plants.** By W. GOSSELS (*Chem. Centr.*, 1886, 805—806).—The source of nitric acid in urine is very uncertain; it remains undetermined whether the nitrates come from the food or originate in the animal body. Differences appear to prevail in the individual classes of animals; thus, whilst with a flesh diet the urine of dogs is free from nitrates, human urine under the same circumstances contains nitrates. In the human subject, a portion of the nitrates—which are either formed in the body or proceed from the food—are not altered. This is confirmed by the experiments of Weyl (*Abstr.*, 1885, 413).

The amount of nitric acid separated remains nearly constant, and undergoes no increase on adding potassium nitrate to the food.

Experiments on the action of uric acid showed that this changed the greater part of the potassium nitrate taken into other products, thus allowing only a small quantity to be secreted in the form of nitric acid. From this it may be concluded that a reduction process is going on in the body, the end-product of which is ammonia. G. H. M.

**Hüfner's Reaction in Bile.** By J. MARSHALL (*Zeit. physiol. Chem.*, 11, 233—238).—Observations were made on the contents of the gall-bladders of 543 American oxen who had lived on prairie grass in the West, and on dried hay during the three days' journey to Pennsylvania. Of these specimens 295 had a yellow, 248 a green colour. Hüfner's reaction was given by 15·4 per cent. of the yellow specimens, and by 6·8 per cent. of the green : 22 per cent. in all. The sp. gr. of the bile was on the average 1·024; the minimum being 1·016, the maximum 1·037. The mean volume of the contents of the gall-bladder was 322 c.c.; the maximum being 730, the minimum 90 c.c.

The proportion of glycocholic to taurocholic acid in those specimens which gave Hüfner's reaction was 1 : 0·77; in those which did not give the reaction it was 1 : 33; and, in some cases, glycocholic acid was absent altogether.

The bile was mixed with hydrochloric acid and ether; the proportion of bile, acid, and ether being 100 : 5 : 30. It was then allowed to remain 24 hours in a cool place. In some cases crystallisation began almost immediately, but after a long time there was but little increase in the amount of crystallisation which occurred. To hasten crystallisation, instead of the ethyl ether used by Hüfner, light petroleum was found better. Benzene was also employed, but it was found that the crystals obtained by that means were badly formed, and impregnated with the biliary pigment.

The best and quickest method of obtaining glycocholic acid in colourless crystals is as follows:—A drop of hydrochloric acid is added to fresh bile; the mixture shaken and filtered; ethyl ether and hydrochloric acid are then added to the filtrate in the proportion above noted; the mixture shaken and allowed to remain. The crystals formed are collected on a filter, washed with water holding hydrochloric acid and ether in solution, and dried in the air. By recrystallisation they are obtained perfectly colourless. W. D. H.

**Albumin in Normal Urine.** By C. POSNER (*Chem. Centr.*, 1886, 730—731).—When an excess of alcohol or tannin is added to a filtered urine in which the ordinary tests fail to detect albumin, a greater or less precipitate is thrown down under all conditions. In both cases, the precipitate must contain the whole of the albumin. The alcoholic precipitate, tested with the biuret reaction, with glacial acetic and concentrated sulphuric acids, and with gold chloride in formic acid solution, gives reactions which show that albumin is present in the urine. It is apparently serum albumin. G. H. M.

**Mucin in Urine.** By H. CITRON (*Chem. Centr.*, 1886, 775).—Filtered urine often gives a precipitate with acetic acid which is insoluble in an excess of the reagent, and gives the reactions for albumin.

This is especially the case with the decomposed and alkaline urine of patients suffering from catarrh of the bladder. This precipitate is probably a decomposition-product of cellular tissue. A similar substance also occurs in true albuminous urine, or in urine which does not contain ordinary albuminoids. This precipitate, when it does not consist of uric acid, must not be ascribed to mucin.

Mucin never occurs in undecomposed urine in cases of catarrh of the bladder, and only in the very slightest traces, if at all, when decomposition has occurred.

G. H. M.

**Physiological Action of Paraldehyde.** By A. BOCKAL (*Chem. Centr.*, 1886, 622).—In opposition to Cervello, the author has found that paraldehyde acts as a stimulant before it acts as a hypnotic; the magnitude and duration of this stimulating action being in inverse ratio to the dose. During the period of excitation, the reflexes are increased, but they gradually subside with larger doses until they are altogether completely lost.

With toxic doses, the power of reflex action is lost so rapidly that the stimulating action as well as the original increase of reflex action pass unobserved.

Applied locally, paraldehyde acts similarly to chloroform and ether. Death is caused by paralysis of respiration, which may to a certain extent be counteracted by artificial respiration. In consequence of its vasomotor action, paraldehyde causes an increased secretion of urine. It is a powerful antidote to strychnine, for 10 times the fatal dose of strychnine may be administered to dogs that have previously received paraldehyde without any toxic effect. Strychnine, on the other hand, is not an antidote to paraldehyde.

J. P. L.

**Physiological Action of Methylal.** By A. MAIRET and COMBE-MALE (*Compt. rend.*, 104, 248—250).—The experiments were made on guinea-pigs, cats, dogs, and monkeys. The results show that sleep is produced more rapidly by hypodermic injection or by inspiration of the vapour than by injection, but in the last case it is more persistent. The higher the animal in the scale, the more sensitive is it to the hypnotic action of the methylal. In large doses, methylal exerts a toxic action, and may cause death by producing inflammatory lesions of the different organs; but in doses of 0.25—0.5 gram per kilo. of body-weight the only symptom observed is deep sleep preceded by somewhat increased salivation; and if the slumber is very prolonged the temperature is slightly reduced. The methylal is rapidly eliminated from the system, and the heaviness which is apparent immediately on awakening rapidly passes away.

C. H. B.

**Butylchloral Hydrate and Chloral Hydrate as Antidotes for Strychnine and Picrotoxin.** By E. KOCH (*Chem. Centr.*, 1886, 811).—Butylchloral hydrate is useless as an antidote for strychnine poisoning; in picrotoxin poisoning, it behaves in the same way as chloral hydrate, both fail to overcome the treble minimum fatal dose of the poison. Picrotoxin is successfully used as an antidote against the narcosis of butylchloral hydrate and chloral hydrate. In spite of

many similarities, these two substances are very different in their mode of acting, not only quantitatively but also qualitatively.

G. H. M.

**Action of Gaseous Poisons.** By J. BELKY (*Chem. Centr.*, 1886, 887—889).—By applying a spectroscope to the ear of a rabbit, the author has been able to observe during life the changes produced in the spectrum of the blood by various gaseous poisons. On ligaturing the base of the ear, the blood thus cut off from the general circulation loses its oxygen, and the spectrum of reduced hæmoglobin is developed. In poisoning by *carbonic oxide*, the fact of the formation of carboxy-hæmoglobin during life was ascertained.

In poisoning by *hydrocyanic acid*, the oxyhæmoglobin bands were well seen up to the moment of death, but a few minutes afterwards they were replaced by a single band, which was proved to be that of hæmoglobin, and not of the hydrocyanic acid compound examined by Preyer, by the fact that the spectrum of oxyhæmoglobin returned when the ear was plunged for a time into cold aerated water.

*Nitrous oxide* appears to have no different action from that of other inert gases. With *nitric oxide*, reduction of the oxyhæmoglobin occurred in  $1\frac{1}{2}$  minutes, the hæmoglobin band being visible at the moment of death. By interrupting the experiment when reduction was nearly complete, or by immersing the ear after death in aerated water, the oxyhæmoglobin bands returned. There was therefore no evidence of the formation of a compound of nitric oxide and hæmoglobin incapable of absorbing oxygen. Moreover, the blood did not become purple, as was the case with blood treated with nitric oxide after removal from the body.

*Ammonia* gas reduces the oxyhæmoglobin, and may therefore cause death by asphyxia, even when so dilute as to be respirable. By discontinuing the ammonia in time, oxyhæmoglobin is again formed.

*Hydrogen sulphide* reduces oxyhæmoglobin vigorously, but oxidation returns when the blood is exposed to air.

M. J. S.

**Sausage Poisoning.** By A. EHRENBURG (*Zeit. physiol. Chem.*, 11, 239—256).—Sausages, the consumption of which had caused an epidemic of "sausage poisoning" in Würtemberg, were subjected to chemical investigation. Metallic poisons having been proved absent, Brieger's method (*Ptomaine*, Berlin, 1885—6) was used for the isolation of bases the result of putrefaction; the following bases were separated and identified by their reactions, and by the analysis of their auro- or platino-chlorides: choline, neuridine, dimethylamine, trimethylamine, and methylamine. The injection of these bases or their chlorides into animals subcutaneously, or their administration by the mouth, caused no symptoms of poisoning. It is supposed that in the later stages of putrefaction the poisonous bases become broken up into these simpler but non-poisonous compounds. This is supported by the fact that if poisonous sausages are kept over a certain time, they lose their toxic properties. Or again, in certain cases where poisonous products are not obtained, this may be due to the fact that the methods of investigation which involve repeated evaporation with hydrochloric acid, may decompose the bases in question. On

distilling the sausages with fuming nitric acid, a distillate containing indole and skatole was obtained. Ammonia was also present.

Bacteriological investigation showed the presence of two forms of micrococcus, and a bacillus which rapidly liquefied gelatin. This bacillus was alone investigated. Sterilised preparations of blood, liver, lung, heart, and intestine, the materials out of which the sausages are chiefly made, were subjected to its action, the usual precautions against infection from other bacteria being taken. From blood, skatole, indole, and leucine were obtained after it had acted for ten days; from the liver, lung, and heart similarly treated, indole, butyric acid, choline, neuridine, dimethylamine, and trimethylamine were obtained. From the intestine, ammonia, choline, methylamine, dimethylamine, trimethylamine, and diethylamine were obtained. In control experiments in which no special bacillus was employed, but simply putrefaction allowed to take place, the same substances were formed, with the exception of diethylamine. As a result of the action of the bacillus on a nutritive medium, consisting of meat infusion to which peptone was added, trimethylamine, diethylamine, neuridine, and triethylamine were formed. In all the preceding cases, the bases obtained were injected into animals (guinea-pigs and rabbits), and in all cases with a negative result. If this bacillus is the cause of the formation of a poisonous base, it is necessary to investigate its action at different stages, for in the later stages of its action it seems to act destructively on the bases formed, or it may be here again that the methods adopted to obtain the bases themselves bring about the decomposition of the poison into the simpler non-poisonous compounds above mentioned.

## Chemistry of Vegetable Physiology and Agriculture.

---

**Chemical Constituents of Bacteria.** By L. VINCENZI (*Zeit. physiol. Chem.*, 11, 181—183).—The experiments relate to *Bacillus subtilis*. A pure culture was obtained by Roberts' (*Phil. Trans.*, 164) method. The fluid containing them was filtered through asbestos, the bacteria remaining on the filter were washed with water and 0.5 per cent. sodium hydroxide solution, digested with artificial gastric juice for 24 hours, washed free from peptones; finally they were washed with alcohol and ether, and dried.

In the cell-wall, which was all that remained after this treatment, no cellulose was found; but it was nitrogenous, yielding from 5.3 to 11.15 per cent. of nitrogen in different specimens, the amount seeming to depend on the different stages of growth of the bacteria. No opinion is expressed as to the nature of this nitrogenous substance.

W. D. H.

**Behaviour of Micro-organisms in Artificial Mineral Waters.** By J. SOHNKE (*Chem. Centr.*, 1886, 699).—The author corroborates

previous observations as to the effect of carbonic anhydride on the micro-organisms present in water. Water thus impregnated suffers a constant diminution in the number of organisms possessing vitality. In spring water containing a number of organisms he found that from one-half to two-thirds were rendered inert, or incapable of reproduction, after the water had been impregnated with carbonic anhydride.

J. P. L.

**Source of Trimethylamine in Ergot of Rye.** By L. BRIEGER (*Zeit. physiol. Chem.*, **11**, 184—185).—The presence of choline bases in *Secale cornutum* suggested that it might be the source of the trimethylamine found by Walz. The base obtained is undoubtedly choline; crystals of its aurochloride were obtained; these were prismatic, the prisms often grouped in stars. They contained 44·57 per cent. of gold (theory 44·45). This salt is decomposed at 264° (uncorr.). With platinum chloride, the platinochloride was also obtained. After removing the choline from the alcoholic extract of *Secale cornutum* by precipitation with alcoholic mercuric chloride and filtering, not a trace of trimethylamine was obtained by distilling the filtrate, so showing that it is under ordinary circumstances a decomposition product of choline.

W. D. H.

**Amount of Caffeine in Various Kinds of Coffee.** By B. H. PAUL and A. J. COWNLEY (*Pharm. J. Trans.* [3], **17**, 565).—In estimating caffeine in coffee beans, the best results have been obtained by the following method. The finely powdered coffee is mixed with moist lime, and percolated with alcohol. The residue left on evaporating the percolate is treated with water and a few drops of dilute sulphuric acid, filtered, and the filtrate exhausted with chloroform, which on evaporation leaves the caffeine fit for weighing. By this method, the following results have been obtained with different kinds of unroasted coffee :—

| Kind of coffee.        | Percentage of caffeine. |
|------------------------|-------------------------|
| Coorg. . . . .         | 1·10                    |
| Guatemala . . . . .    | 1·18                    |
| Travancore . . . . .   | 1·16                    |
| Liberian { 1 . . . . . | 1·20                    |
| 2 . . . . .            | 1·28                    |

Roasted coffee contains about 1·3 per cent. of caffeine, but this amount varies slightly.

D. A. L.

**Ash of Cinchona Bark.** By D. HOOPER (*Pharm. J. Trans.* [3], **17**, 545—546).—The average obtained from 300 estimations shows that barks cultivated in India contain over 3 per cent. of ash. Renewed and old natural barks are poorer, but never fall below 2 per cent. of ash. Young bark and branch bark gives as much as 4 per cent., and the leaves as much as 5 and 6 per cent. Natural crown bark, which grows at an altitude of 7000—8000 feet, is richer in ash than natural bark which grows at 5000—6000 feet, and the red is

richer than the ledger growing at 3000—5000 feet. The following analyses are of ashes from the bark grown on the Nilgiris, *C. officinalis* in the Dodabetta plantation, *C. succirubra* at a lower level at Naduvatom. The figures agree on the whole with those of Carles for American barks, except that no copper has been detected.

D. A. L.

**Action of Mercurial Vapour on Leaves.** By V. JODIN (*Ann. Agronom.*, 12, 563—580).—The author has studied especially the influence of mercurialisation on respiration, and on the power of resistance to desiccation. Simple exposure of the leaf to an atmosphere which is in contact with a surface of mercury or of an amalgamated plate, is sufficient to excite the phenomena of mercurial poisoning. These are an increase at first in the respiratory power, due to a sort of stimulation, perhaps similar to that produced by electricity; after some time the respiratory power falls below that of a non-mercurialised leaf. As regards transpiration, the effect of mercurial vapour is to destroy in a very short time the resisting power of the leaf to desiccation, so that, for example, a leaf which normally takes 103 hours to lose half the total quantity of water which it is capable of losing by exposure to air, will, after mercurialisation, suffer the same amount of desiccation in 14 hours. A litre of air saturated with mercurial vapour at 20° contains at most 0.00071 gram of the metal, yet this quantity is sufficient to produce in a few hours the complete mercurialisation of 30 grams of fresh leaves. It is difficult to class this phenomenon amongst the chemical or mechanical phenomena hitherto recognised as physiological factors.

J. M. H. M.

**Direct Absorption of Nitrogen from the Atmosphere by Vegetable Soils.** By BERTHELOT (*Compt. rend.*, 104, 205—209).—The author has extended his researches (*Abstr.*, 1886, 175, 736) to the case of vegetable soils.

The soils were placed in vessels of glazed earthenware, and in some cases were protected, in others exposed to air and rain, the rain-water being collected and analysed, and the amount of ammonia and nitric acid in the air being also determined. The results show that vegetable soils continually absorb nitrogen from the air, even when they are not supporting vegetation. The amount absorbed is in all cases very much greater than the quantity of nitrogen existing as ammonia or nitrogen

oxides in the air or rain. In fact the rain removes from the soil in the form of soluble nitrates considerably more nitrogen than it brings in the form of ammonia. At the same time, the amount of nitrogen absorbed is far greater in the case of soil exposed to rain than where the soil is protected, probably owing to the greater activity possessed by the nitrogen-absorbing organisms under the former conditions. In the majority of cases, a notable proportion of the absorbed nitrogen is converted into nitrates. C. H. B.

---

## Analytical Chemistry.

---

**Determination of Sulphur in Albuminoid Substances.** By W. KOCHS (*Chem. Centr.*, 1886, 894).—Carius's method always gives low results, since even after heating for three hours at 200° the oxidation of the sulphur is not complete. Liebig's method, on the other hand, gives higher and concordant results. Since, however, albuminoid substances free from ash are liable to produce too violent an evolution of gas, it is convenient to heat the substance with 10 parts of nitric acid of sp. gr. 1.4, and evaporate to dryness on the water-bath before fusing with potash and nitre. M. J. S.

**Weil's Method for the Volumetric Estimation of Sulphides.** By C. FRIEDHEIM (*Ber.*, 20, 59—62).—The author states that this method is utterly untrustworthy, as copper sulphide when precipitated by hydrogen sulphide from ammoniacal copper solutions carries down copper oxide, and the copper sulphide has a great tendency to oxidise and redissolve. Under these circumstances, a correct result can only be obtained when the error in the one direction chances to equal that in the other. A. J. G.

**Volumetric Estimation of Nitrous Acid.** By A. G. GREEN and F. EVERSLED (*J. Soc. Chem. Ind.*, 5, 633—634).—In a previous communication (*Abstr.*, 1884, 870), Green and Rideal described a process for the volumetric estimation of nitrous acid by means of aniline. Although the results obtained by this process are very accurate, it is somewhat lengthy, and requires too much care in manipulation to be generally available for technical purposes. In the modification described in the present paper, the authors have greatly simplified and shortened the operation by substituting normal for decinormal solutions. The advantage of this process is that most oxidisable substances which may be simultaneously present are not affected. In fact it is possible to estimate nitrites by this means under conditions which would entirely preclude an oxidation method. D. B.

**Determination of Phosphorus in Steel and Iron.** By C. MEINEKE (*Chem. Centr.*, 1886, 682).—By precipitating with molybdate

solution at not too high a temperature, the percentage of phosphorus in the ignited precipitate may be taken as 1.754. At higher temperatures the percentage is smaller, but can never exceed the above. There is no necessity to remove silica when determining phosphorus by this method in siliciferous iron.

M. J. S.

**Determination of Phosphoric Acid.** By F. BENTE (*Chem. Centr.*, 1886, 948).—On the occasion of a phosphoric acid determination, in which the precipitates with molybdate and magnesia respectively were allowed only 3 or 4 hours to form instead of 12, as was formerly the practice, low results were obtained. As no other cause for the deficiency could be assigned, the author thinks that the modern practice requires reconsideration.

M. J. S.

**Detection of Arsenic.** By H. HAGER (*Chem. Centr.*, 1886, 680—681).—The liquid to be tested is brought in contact with a plate of brass, when the presence of arsenic will be indicated by a grey deposit. Heavy metals, even iron, must be absent. Pure hydrochloric acid should be added until the liquid contains 5—15 per cent. of hydrogen chloride. If much arsenic is present, it is sufficient to put a few drops of the liquid on the brass plate and warm gently. After a minute or two the plate may be rinsed with water and examined. For minute traces, it is better to leave the drops on the plate in the cold, and examine from time to time without rinsing off. One part of arsenic in 80,000 will give a grey film in half an hour, 1 in 250,000 in an hour. If  $1\frac{1}{4}$  hours elapse without any indication, arsenic may be considered to be absent.

If antimony is suspected, it is better to immerse a strip of brass in the liquid, and either warm (50—99°) or set aside for some hours at ordinary temperature. Arsenic gives a steel-grey to black film, antimony a light-grey. Held in a spirit lamp flame, an arsenic film becomes steel-blue and volatilises; antimony remains unchanged. If the deposit can be scraped off into a dry test-tube, add to it two drops of water, then 10 of nitric acid (30 per cent.). Arsenic will dissolve, antimony remain undissolved.

M. J. S.

**Use of Copper containing Arsenic for the Dearsenification of Hydrochloric Acid. Reinsch's Test for Arsenic.** By H. HAGER (*Chem. Centr.*, 1886, 772—773).—Copper foil used for the dearsenification of hydrochloric acid must be pure and its surface bright and free from dirt. Copper foil which has been already used for this purpose, may be scoured with sand to remove the film of arsenic, and again used. The fact that the copper usually contains traces of arsenic does not interfere with its use for the dearsenification of hydrochloric acid, since the arsenic exists in the form of an alloy which is not attacked by acid.

Before using copper foil for the qualitative detection of arsenic by Reinsch's method, it should be tested as follows:—A piece of perfectly bright foil is immersed in perfectly pure hydrochloric acid of 10 to 12.5 per cent., and allowed to remain for two hours; if at the end of that time it is still quite bright, it may be used for the detection of

arsenic; if the surface has become dimmed, the foil is of course rejected. The foil may contain traces of arsenic and still give no coloration with acid; in that case, it can be used both for the dearsenification of acid and for the qualitative detection of arsenic.

For the detection of arsenic in copper, Odling's method may be used. This consists in distilling the copper with hydrochloric acid and iron oxide or chloride; volatile arsenic chloride passes over and is found in the distillate.

A rapid and good test for arsenic in copper is to place a drop of ammonium hydroxide on a piece of bright metal, allow it to remain 30 minutes, wash off with water and dry with a cloth; then place a few drops of dilute acetic acid on the spot and allow to remain 10 minutes, again wash with water and dry with a cloth. If the copper contains traces of arsenic, a gray colour is seen where the ammonium has been. This is a very sure test. G. H. M.

**Apparatus for Estimating Carbonic Anhydride and all similar Gases.** By R. BAUER (*J. pr. Chem.* [2], 35, 86—87).—Improvements in the form previously described (Abstr., 1884, 1216) with the object of rendering it less fragile.

**Application of Allen's Nitrometer to the Estimation of Ammonium Carbonate in Spiritus Ammoniae Aromaticus. B.P.** By E. D. GRAVILL (*Pharm. J. Trans.* [3], 17, 445).—For the purpose suggested in the title, the nitrometer is filled with mercury, 5 c.c. of spiritus ammoniae aromaticus admitted, then gradually 5 c.c. of hydrochloric acid, and the volume of carbonic anhydride liberated is measured with the necessary precautions. D. A. L.

**Estimation of Zinc as Pyrophosphate.** By M. BRAGARD (*Chem. Zeit.*, 10, 1605—1606).—The process described by Lösekann and Meyer (Abstr., 1886, 836) is identical with that given by Tamm (this Journal, 1871, 1214). The author states that it is more convenient to treat the zinc solution with the necessary quantity of ammonium chloride, acidify with hydrochloric acid, heat to boiling and, whilst hot, add the disodium phosphate until the reaction is alkaline. The liquid must be stirred all the time, care being taken to avoid rubbing the sides of the vessel; it is then boiled for two or three minutes and left at rest for 24 hours. The precipitate (without the filter-paper) may be ignited to fusion without suffering loss of pyrophosphate; but it is more convenient not to carry the ignition so far. The presence of filter-paper during ignition occasions loss owing to reduction and volatilisation of zinc. Many ways were tried to get rid of the paper; the best way is to remove as much of the precipitate as possible, then treat the filter with a saturated solution of ammonium nitrate, evaporate, ignite, &c. The precipitate is practically insoluble in water at 16°. D. A. L.

**Determination of Cadmium and its Separation from Copper.** By A. KOHNER (*Chem. Centr.*, 1886, 813—815).—The author has examined the methods proposed for the estimation of cadmium and

its separation from copper. He concludes that the gravimetric determination of the sulphide is not accurate enough for anything but technical work; the volumetric method gives good results for amounts of cadmium sulphide between 0.07 and 0.6 gram. The determination as sulphate is fairly accurate for large quantities. The pyrophosphate method is quite untrustworthy, since the double phosphate is soluble in water (0.03 gram in 1000 c.c.) and very easily reduced during ignition. To obtain good results, the precipitate must be washed with the smallest possible quantity of water, dried at  $100^{\circ}$ , separated as completely as possible from the filter-paper, and what remains on the paper neglected. The precipitate, when washed with alcohol and ether and dried, has the composition  $\text{CdNH}_4\text{PO}_4$ .

The following is the best method for the separation of copper:—The solution of the two metals, freed as far as possible from free nitric and hydrochloric acids, is treated in an Erlenmeyer's flask in a water-bath with a concentrated solution of sulphurous anhydride. When the copper solution is nearly reduced, a little more sulphurous anhydride solution and a previously calculated amount of potassium iodide are introduced. If sufficient sulphurous anhydride is present, the slight yellow colour disappears on boiling. The excess of sulphurous anhydride is driven off and the copper iodide collected on a tared filter. The cadmium is precipitated from the filtrate by hydrogen sulphide and weighed as sulphate. This method requires the amount of copper present to be approximately known, since the presence of an excess of potassium iodide leads to errors. The separation of the two metals by sulphuric acid can under certain conditions give good results. The methods which require the addition of an organic substance to effect the separation are not to be depended on.

G. H. M.

**Estimation of Manganese.** By R. W. ATKINSON (*J. Soc. Chem. Ind.*, 5, 365—367, and 467—468).—A detailed criticism of the methods in general use for the estimation of manganese. The old gravimetric method depends for its accuracy on attention to details combined with the recognition of the fact that the manganese dioxide first precipitated is impure, retaining both lime and zinc oxide when these are present in the original sample. Owing to the length of time occupied in the gravimetric method of estimating manganese, the use of Pattinson's volumetric process is strongly recommended by the author, although it is said to give results which are slightly below the truth, the difference being attributed to the incomplete oxidation of the manganese. Where accuracy is required, the gravimetric method in which the manganese is twice precipitated by bromine and ammonia, however tedious, is the only practical process.

D. B.

**Volumetric Determination of Manganese.** By R. SCHÖFFEL and E. DONATH (*Monatsh. Chem.*, 7, 639—650).—When arsenious acid is added to a hot, neutral solution of potassium permanganate previously treated with a corresponding amount of zinc sulphate and some zinc oxide, the solution is quickly decolorised with formation of arsenic acid and manganese dioxide. The titration of the arsenious acid is carried out as follows:—300 c.c. of water is heated

to boiling and treated with 30 to 50 c.c. of a saturated solution of zinc sulphate together with some zinc oxide sludge; a known volume of permanganate solution is added, and then, drop by drop, the solution of arsenious acid until the permanganate is decolorised. The arsenious acid solution is prepared by dissolving 1.5 to 1.8 gram of the ordinary acid in 1 litre of water. The zinc oxide and sulphate must both be treated with permanganate before being used.

200 to 300 c.c. of water and 30 c.c. of a saturated zinc sulphate solution are heated to boiling; some zinc oxide sludge and a known volume of permanganate solution are added, and then gradually the manganese solution. The amount of permanganate must be such that the solution after addition of the manganese solution is still strongly coloured. It is again heated to boiling and titrated with the arsenious acid solution. Better results are obtained when zinc oxide is not added until before the titration with acid. When iron is present, as is often the case, it is necessary to add the zinc oxide as first described, otherwise the separation of the precipitate containing iron is not so quick.

The estimation of manganese in special cases is carried out as follows: 1 or 2 grams of the spiegeleisen or crude iron, &c., in the form of borings is dissolved by boiling with hydrochloric acid, diluted and filtered, and the solution boiled with an excess of potassium chlorate. The solution is made up to 200 or 300 c.c., and an aliquot part neutralised with sodium carbonate and treated with a slight excess of prepared zinc oxide. It is added to a mixture of 200 to 300 c.c. of water and 30 c.c. of saturated zinc sulphate solution previously boiled and then treated with a known amount of permanganate solution; it is boiled and the excess of permanganate titrated with arsenious acid.

In the case of manganese ores containing more than 40 per cent. of manganese, the amount taken is about  $\frac{1}{2}$  gram. N. H. M.

### **Volumetric Estimation of Antimony in the Presence of Tin.**

By H. GIRAUD (*Bull. Soc. Chim.*, **46**, 504—505).—It is well known that whilst in neutral solutions antimony trichloride is oxidised by iodine, in very acid solutions the reverse reaction takes place. Stannic chloride is not thus reduced by hydriodic acid. The author makes use of this difference as a means of estimating antimony.

The mixed salts are converted into chlorides, dissolved in hydrochloric acid, and potassium chlorate added to convert them into perchlorides. The excess of chlorine is driven off by heat, and an equal volume of hydrochloric acid and an excess of potassium iodide then added. The iodine liberated is extracted with carbon bisulphide, and titrated with sodium thiosulphate. L. T. T.

**Ferric Chloride as a Test for Organic Substances.** By W. H. INCE (*Pharm. J. Trans.* [3], **17**, 461—462).—The author prepares a neutral ferrous chloride from cupric chloride by means of iron wire, and in the course of testing he converts this into ferric salt by adding bromine. The following reactions are obtained: I, being with

ferrous chloride; II, with addition of bromine; III, with addition of excess of bromine.

|                      | I.                                 | II.                | III.              |

D. A. L.

**Precipitation of Dextrin by Iron.** By H. A. LANDWEHR (*Chem. Centr.*, 1886, 954).—In opposition to Nasse, the author maintains the possibility of separating gum and glycogen from dextrin, by precipitating ferric oxide in the liquid; the two former being thrown down, and the dextrin remaining in solution. The precipitation by iron of the achroodextrin, obtained by Nasse from glycogen, proves its distinctness from ordinary dextrin. The insolubility of the precipitate in hydrochloric acid, and the difficulty of removing all the iron, however, renders this method for the determination of glycogen less convenient than the older one of Brücke.

The precipitation of glycogen or gum by ferric hydroxide appears to be due to a mechanical adhesion, as there is too much iron in the precipitate for a compound in molecular proportions. M. J. S.

**Estimation of Fatty Acids in Soaps.** By R. BAUER (*J. pr. Chem.* [2], 35, 88—89).—The solution and decomposition is performed in the usual manner by warming 5 grams of the fresh soap covered with glycerol until the mixture is homogeneous; it is then treated with 100 c.c. of alcohol, and titrated with hydrochloric acid. An excess of acid is then added, and the layer of fat which separates transferred by means of a pipette to a clock-glass; the clock-glass is placed on a larger glass previously covered with a layer of fine glass pearls, and heated in an oven. The flask is washed out with a little light petroleum until free from fat. The glasses which had previously been weighed are then weighed with the fat. The percentage of free alkali is determined by estimating the carbonic anhydride before and after treatment with ammonium carbonate.

N. H. M.

**Quantitative Estimation of Oxalic Acid in Urine.** By O. NICKEL (*Zeit. physiol. Chem.*, 11, 186—200).—The methods of estimating oxalic acid in urine, proposed by Neubauer and Schultzen, were compared together, and found to give very varying results. The amount of variation was not constant, as the percentage of oxalic acid was sometimes higher by the one, sometimes by the other method.

Various modifications of both methods were also tried, but with equally unsatisfactory results. The variations seem to depend on the slight solubility of calcium oxalate in media in which it was formerly supposed to be insoluble, such as acetic acid, distilled water, and alcohol. There is also no certain method of separating calcium oxalate from the phosphate. No new method of analysis is, however, proposed.

W. D. H.

**Estimation of Fat.** By M. KRETZSCHMAR (*Chem. Zeit.*, 10, 1556).—To avoid the inconvenience attached to the removal of the dried mass when using gypsum as the absorbing material in the estimation of fat in milk, the following modification is suggested. By means of a suitable mould, a square piece of tin-foil is pressed firmly in to the porcelain dish which is intended for use, the foil is made fast by turning down the projecting corners. The gypsum and milk are put in this, and when dry are easily lifted out and pulverised; the foil is cut up and put in the extraction apparatus along with the powder.

D. A. L.

**Analysis of Oils.** By L. ARCHBUTT (*J. Soc. Chem. Ind.*, 5, 303—312).—*Maumené's Test.*—In employing this test for the examination of rape and olive oil, the author found that without great care very discordant results might easily be obtained. He describes in detail the method he uses. From the results of a series of experiments made with a view of showing the effect of employing sulphuric acid of different strengths, it is inferred that there is no advantage in using weak acid on the ground of greater concordance in the results, the use of an acid of 97 per cent. strength being preferred. It appears best to allow the acid to drop slowly from the pipette into the oil.

*The Elaidin Test.*—The author describes a method of preparing a reagent for this test, which gives perfectly concordant results, and which will keep for several days, whilst Poutet's solution rapidly undergoes change, and has always to be freshly prepared. From a series of trials made with a view to determine the best mode of applying this test so as to detect fraudulent admixtures, the author concludes (1) that the test must be made at a temperature not lower than 25°, and that the temperature must be uniform throughout the experiment; (2) that the length of time required for solidification is of far greater importance than the ultimate consistence of the elaidin formed.

*Iodine Absorption.*—The author has made some experiments with rape oil, the results of which on the whole confirm those of Hübl, which were made on olive oil. He finds that in order to obtain the maximum absorption, it is necessary to add about twice the quantity of iodine actually absorbed, and to allow the solution to remain at least from 3 to 6 but not more than 24 hours before titrating.

D. B.

**Distinction of Castor Oil from other Fatty Oils.** By FINKENER (*Chem. Zeit.*, 10, 1500).—Shaking with alcohol, sp. gr. 0·829, at ordinary temperature (about 17·5°) yields turbid solutions with olive, sesame, linseed, cotton-seed, or rape oil, or with castor oil

mixed with these oils, whereas pure castor oil gives a clear solution. For testing purposes, 10 c.c. of the castor oil is poured into a 100 c.c. cylinder marked at 10 c.c. and 60 c.c. from the bottom, 50 c.c. of alcohol is added, the whole well shaken, and examined after being at rest two or three minutes; turbidity indicates the presence of at least 10 per cent. of other oils. Castor oil yields with sulphuric acid a substance soluble to a clear solution in 40 volumes of water, but this is the case even when it is mixed with 20 per cent. of olive or sesame oil; although these oils and other fatty oils yield milky solutions when treated in a similar manner.

D. A. L.

**Preserving Standard Tartar Emetic Solutions.** By A. R. MILLER (*J. Soc. Chem. Ind.*, 5, 464).—It was found that by excluding the air from the solution it was possible to keep it for any length of time without decomposition taking place.

D. B.

**Opium Analysis.** By C. M. STILLWELL (*Amer. Chem. J.*, 8, 295—308).—The method differs from those of Flückiger and Squibb in a number of details. The sampling must be very carefully conducted and the whole made homogeneous by rolling with the hands on a slab of glass, in case the opium is soft; but by grinding with or without additional drying if it be hard. About 10 grams of the sample is broken up with 100 c.c. of water in a beaker, and when completely disintegrated allowed to remain some hours; a few drops of sulphuric acid may be added. The solution is filtered and the residue washed with about 20 c.c. of water, then returned to the beaker, digested for some minutes with 30 c.c. of water, again filtered, and this process repeated twice more. The washings are first concentrated at a gentle heat on a water-bath, then the stronger solution is added and the whole evaporated to about 25 c.c. When cold, 5 c.c. of alcohol (sp. gr. 0·82) is added, and the whole transferred to an Erlenmeyer's flask, using 5 to 10 c.c. of wash water; 5 c.c. of alcohol and finally 30 c.c. of ether are added with gentle shaking; any precipitate that may form is to be disregarded, as it is removed afterwards, 4 c.c. of ammonia solution (sp. gr. 0·960) is added, the flask closed with a cork moistened with ether, and at once shaken until the morphine separates, when it is allowed to remain 12 hours.

The ethereal layer is decanted on to a small filter, the flask rinsed several times with 10 c.c. of ether without shaking, and these rinsings also decanted on to the filter; the aqueous portion is then filtered, the crystals removed from the flask, and the whole washed with morphiated spirit (1 part of strong ammonia and 20 parts of alcohol, the whole saturated with morphine, namely, 0·33 per cent.); secondly, with morphiated water (containing 0·04 per cent.), again with morphiated spirit; and finally twice with 10 c.c. of ether to remove all narcotine. The paper is dried at 100°. The mother-liquor and the first washings of ether and morphiated spirit are treated with 3 c.c. of ammonia in a closed flask, and again allowed to remain to make sure of the precipitation being complete. The chief impurity in the morphine so obtained is calcium meconate, and some organic matters insoluble in water and alcohol; the purification is effected by treating

the dried and weighed precipitate with hot alcohol of 95 per cent.; after removing the bulk of it to a beaker, the paper and residue, after thorough extraction with hot alcohol, are dried and weighed, thus giving the weight of the pure morphine. H. B.

**Estimation of Quinine Sulphate.** By G. VULPIUS (*Arch. Pharm.* [3], 24, 1022—1023).—The method described is identical with that given in the next Abstract.

**Quinine Chromate in Analysis.** By J. E. DE VRIJ (*Arch. Pharm.* [3], 24, 1073).—4 grams of quinine sulphate is dissolved in 400 grams of boiling water; to this is added 1 gram of potassium chromate dissolved in a little water; after remaining some hours quinine chromate separates in anhydrous crystals of the composition  $(C_{20}H_{24}N_2O_2)_2, H_2CrO_4$ ; it is soluble at 14° in 2733 parts of water, and at 16° in 2000 parts.

For the estimation of cinchonidine in quinine sulphate, 5 grams of the sulphate is dissolved in 500 grams of boiling water, 1.2 grams of potassium chromate dissolved in a little water added, and the whole allowed to remain until next day, when the quinine chromate is collected on a filter and washed. The mother-liquor and washings are heated with soda on a water-bath for some time, whereby the cinchonidine separates out in the crystalline form, and is collected, dried at 160°, and weighed. The author found in 5 grams each of three commercial samples, 0.197, 0.205, and 0.244 gram of cinchonidine respectively.

To determine the amount of pure quinine in the sulphate, 2 grams of the sulphate was taken and treated as above with 0.5 gram potassium chromate. The precipitated chromate was weighed, and this weight was increased by 0.05 gram for each 100 c.c. of mother-liquor and wash-water. From the total thus obtained, the amount of quinine is easily calculated. J. T.

**Neutral Quinine Chromate.** By O. HESSE (*Pharm. J. Trans.* [3], 17, 585 and 665).—Recently De Vrij (preceding Abstract) recommended a process for estimating quinine in the sulphate, it was based on the formation of quinine chromate, which was washed, air-dried, and weighed as  $(C_{20}H_{24}N_2O_2)_2, H_2CrO_4$ . The author of the present communication now points out that the air-dried sample contains, in addition to the above, 2 mols.  $H_2O$ . It becomes anhydrous at 80°, at higher temperatures decomposes. In a note, the Editor of the above Journal points out that the dry salt rapidly absorbs moisture from the air, and attains the same weight it had before drying. For this and another reason, the large correction required for solubility, the method is not recommended.

In the second paper, it is shown that hydroquinine and cinchonidine, when present in quinine sulphate, cannot be correctly determined by De Vrij's chromate method, for although the neutral chromates of these two substances are more readily soluble than quinine chromate, yet they cannot be separated from the latter by crystallisation, as they crystallise out with the quinine chromate. In fact, where quinine

sulphate contains 8 per cent. or less of hydroquinine, the latter behaves exactly like quinine; whilst in the presence of 0·3 per cent. of cinchonidine, the mother-liquor from the quinine chromate yields a precipitate consisting not wholly of cinchonidine, as is supposed by De Vrij, but for the most part of a compound of seven molecules of cinchonidine with one molecule of quinine; also when the percentage of cinchonidine exceeds 0·3, the mother-liquor not only behaves in the same way, but a varying quantity of cinchonidine chromate crystallises with the quinine chromate. The mixture of chromates obtained on treatment with ammonia and ether yields the compound  $C_{20}H_{24}N_2O_2, 2C_{19}H_{22}N_2O$ , which by crystallisation from hot dilute alcohol can be converted into large, brilliant, rhombohedrons of the formula  $C_{20}H_{24}N_2O_2, 7C_{19}H_{22}N_2O$ .  
D. A. L.

**Quinine Sulphate.** By E. JUNGLEISCH (*J. Pharm.* [5], 15, 5—18).—A criticism of methods of assaying quinine sulphate, showing that the methods given in the Codex of 1884, after Kerner and others cited, are more or less unsatisfactory.  
J. T.

**Detection of Rosaniline Salts and Sulphonated Rosaniline.** By A. LIEBMANN and STUDER (*J. Soc. Chem. Ind.*, 5, 287).—Schiff's researches (*Compt. rend.*, 64, 487) have shown that aldehydes give an intense violet coloration with a solution prepared by treating rosaniline salts with sulphurous anhydride. Schmidt (*Abstr.*, 1882, 179) confirmed the general application of this reaction, and showed that acetone produced the same violet tint. The authors have successfully applied this reaction to the detection of aldehydes or acetone in the urine of persons suffering from diabetes. They have found that this property of the aldehydes and of acetone can be applied inversely for the detection of rosaniline salts and sulphonated rosanilines in dyes, wines, and lozenges. This test is exceedingly delicate, a distinct reaction with acetone being obtained, for instance, when cudbear is adulterated with only one-fortieth per cent. of rosaniline.  
D. B.

**Detection of Acid Coal-tar Colours in Wine.** By J. H. DE REGO (*Chem. Centr.*, 1886, 842—843).—Girard's process in its original form fails to detect acid coal-tar dyes, but it can be used by filtering whilst the mixture is still acid.

The following method is very serviceable for red dyes, but not for others:—10 c.c. of the wine is nearly neutralised with a 5 per cent. potash solution; a saturated acid solution of mercuric acetate is added until the mixture is greenish, and it is then filtered. If the wine contains an acid dye, the filtrate will be coloured, and the colour will become more intense on adding hydrochloric acid; if otherwise, the filtrate will be yellowish, and will become paler with acid. A deep yellow filtrate, becoming red with hydrochloric acid, may be obtained from a pure wine if the process be varied.

A much more sensitive test is the following:—To 5 drops of the wine, if a strongly coloured Portuguese wine, or about 1 c.c. of any other wine, add a solution of manganous sulphate in strong hydrogen peroxide, then 2—3 drops of 10 per cent. ammonia, heat to boiling,

and filter. A colourless filtrate is obtained, which, if acid dyes be present, assumes a red colour on addition of hydrochloric acid. Basic coal-tar colours give at once a coloured filtrate. If too much wine is employed the filtrate will not be quite colourless.

The author, however, prefers the following process:—To 15 c.c. of the wine add sufficient barium peroxide, then pass carbonic anhydride until the mixture assumes a chocolate colour, but not longer. It will then give a perfectly colourless filtrate, which, on addition of hydrochloric acid, will exhibit characteristic colours if acid dyes are present.

M. J. S.

**Reactions for Discriminating between Chrysophanic Acid and the Santonin Colouring Matter in Urine.** By G. HOPPE-SEYLER (*Chem. Centr.*, 1886, 746).—Aqueous soda produces a red colour in urine containing both the santonin colouring matter and chrysophanic acid. In the former case, the red colouring matter is easily soluble in amyl alcohol, and gradually changes to yellow in contact with atmospheric oxygen, whilst in the latter case the red colouring matter is insoluble or almost insoluble in amyl alcohol, and persists for a very long time. These colours differ also in spectroscopic properties.

J. P. L.

**Quantitative Reactions for the Separation of Some Resins.** By M. v. SCHMIDT and F. ERBAN (*Monatsh. Chem.*, 7, 655—672).—The authors have applied the methods of Köttstorfer (*Zeit. anal. Chem.*, 18, 199) and of v. Hübl (*Dingl. polyt. J.*, 253, 281) for the detection of fats, to the examination of resins, and are enabled to determine the relative amounts of the various resins in a mixture without actual separation. The resins are identified by (1) the amount of potash required to saturate 1 gram of the resin dissolved in alcohol; (2) the amount of caustic potash which combines with 1 gram of the resin when the latter is boiled with an excess of alcoholic potash solution; (3) the percentage of iodine which the resin is capable of taking up. The methods for determining these data are given, and also a table in which are the numbers already determined for the various resins.

In the examination of solutions of resins in alcohol or in turpentine, the liquid is first steam distilled until the distillate shows no acid reaction. The residue is dried at 110°. A systematic method of fractional separation of the resins by means of solvents is described in detail. Tables are also given showing the solubility of resins.

N. H. M.

**Test for Tannin.** By J. E. SAUL (*Pharm. J. Trans.* [3], 17, 387).—The substance is mixed with water, a few drops of an alcoholic solution of thymol are added, and then concentrated sulphuric acid. Commercial tannin yields a rose-coloured turbid solution, pyrogallol a dull-violet solution, whilst gallic acid remains colourless, or nearly so.

D. A. L.

**Separation of Globulin from Albumin in Urine.** By A. OTT (*Chem. Centr.*, 1886, 540).—The author points out that the separation of globulin from albumin in urine by saturation with magnesium sul-

phate, is only complete in those cases where at least one-half of the phosphoric acid is in the form of neutral phosphate, otherwise the urine should be brought to this condition by the addition of alkali. 60 grams of magnesium sulphate is added to 50 c.c. of urine, and the solution allowed to remain 24 hours at 30—35°, being shaken occasionally. When these precautions are observed, the results are trustworthy. C. F. C.

**Detection of Traces of Albumin.** By R. PALM (*Zeit. anal. Chem.*, **26**, 35—38).—The sensitiveness of the test for albumin depending on its precipitation by an acid, can be much increased by dissolving the acid in alcohol, or, better, alcohol containing 10 per cent. of ether; an excess of the reagent will not then redissolve the precipitate.

Sodium sulphantimonate added to an albumin solution made alkaline with ammonia, gives a yellow precipitate. Sodium nitroprusside acidified with acetic acid, and also potassium antimonate, are sensitive reagents, but all three give precipitates with the alkaloids. The following are free from that defect:—(1.) An alcoholic solution of ferric acetate, previously rendered basic by heating with excess of recently precipitated ferric hydroxide. (2.) An alcoholic solution of basic cupric acetate. The precipitate dissolved in acetic acid and boiled with excess of soda, shows reduction in presence of albumin. (3.) An alcoholic solution of lead acetate or chloride; or (4) a solution of freshly precipitated lead hydroxide in water. This last will detect 1 part of albumin in 500,000 of water. The colourless precipitates from (3) and (4) are adapted for confirmation by Adamkiewicz's test (violet colour on mixing with glacial acetic and sulphuric acids). M. J. S.

**Presence of Albumin in Vegetable Tissue: Microchemical Test for Albuminoids.** By F. KRASSER (*Monatsh. Chem.*, **7**, 673—697).—The various colour tests for albumin are discussed and shown to be insufficient, as they are also produced by substances other than albuminoids. When albuminoids are treated with alloxan an intense purple coloration is produced; the colour is also produced by tyrosine, aspartic acid, and asparagine. The reaction must take place in the cold and the mixture be kept free from ammonia. In testing for albumin, the substance is first washed with hot water to remove other compounds present which give the reaction with alloxan. Millon's reagent (*Compt. rend.*, **28**, 40) is the only one which shows a definite structure in albumin; namely, the presence of a monohydroxylated aromatic nucleus. The reaction has the drawback that it will not take place in the case of a tissue containing much water, owing to the formation of basic mercury salts. In testing for albumin by this method in cellular tissue, the absence of vanillin (the only other substance containing a monohydroxylated aromatic ring which has as yet been found to be present) is determined by Wiesner's phloroglucinol reaction; it is still better to wash the section to be tested with warm water.

The author's methods for detecting albumin consist (1) in showing

the presence of the monohydroxylated aromatic nucleus by Millon's reaction; (2) in showing the presence by means of alloxan of the group  $-\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$  formed by the decomposition of albumin after exclusion of aspartic acid and other non-albuminoid substances.

N. H. M.

**Detection of Blood Stains in Presence of Iron Rust.** By E. DANNENBERG (*Chem. Centr.*, 1886, 840—842).—The test for blood based on the formation of hæmin crystals fails when the stain is on rusty iron, in consequence of the insolubility of the compound of hæmin with ferric oxide. The following treatment, however, yields crystals which it would appear are absolutely characteristic of blood. A few drops of strong potash solution is placed on the stain, and the object is—when possible—warmed by a spirit-lamp flame. Meanwhile the stain is loosened by scraping, and the turbid liquid is transferred to a porcelain basin. There it is washed by decantation, pouring away the pale-red ferric oxide, but retaining any heavy, dark-brown, granular substance. This, after draining off the water, is treated with a drop or two of ammonium sulphide and triturated while gently warming. The solution is filtered from the ferrous sulphide, and is examined by Erdmann's method (Otto, *Ausmittlung der Gifte*, 6th Ed., p. 228). The dry residue on the microscope slide is treated with acetic acid—not adding so much as to escape beyond the cover-glass; the acid is then slowly heated just to incipient boiling. On examining with a magnifying power of 300—800 the presence of blood will be indicated by the appearance of elongated, rhombic plates of brown colour, but with a colourless stripe in the direction of the longer diameter. They are found usually at the edges of the drop or of the cover-glass. It appears to be difficult to produce them at will from blood alone, but in 30 experiments with the iron compound no failure occurred. The name *hæmidin* is proposed for these crystals.

M. J. S.

**Dannenberg's Hæmidin Crystals.** By C. AMTHOR (*Chem. Zeit.*, 10, 1479).—These crystals, obtained by Dannenberg (preceding Abstract) by treating blood mixed with ferric oxide with ammonium sulphide and water, are now shown to be simply sulphur crystals.

D. A. L.

**Analysis of Hoofs and Horns.** By J. HUGHES (*Chem. News*, 54, 314—315).—The author draws attention to the importance of taking moisture into consideration when analysing hoofs and horns, as, when powdered for analysis, these substances become very hygroscopic. When determining nitrogen in such highly nitrogenous substances by the soda-lime method, the quantity of soda-lime should exceed that generally used in nitrogen combustions; it is doubtful even then if all the nitrogen is obtained as ammonia.

D. A. L.

## General and Physical Chemistry.

---

**Red Fluorescence of Alumina.** By L. DE BOISBAUDRAN (*Compt. rend.*, 104, 330—334).—The author has obtained the red fluorescence with pure alumina after it has been strongly heated.

Alumina which has been heated at a temperature between the melting points of copper and silver gives only a trace of the red fluorescence in a vacuum, but after addition of 0.01 per cent. of chromic oxide, the fluorescence becomes much more intense. The fluorescence increases in intensity with an increase in the proportion of chromic oxide, and is very brilliant when the amount of the latter reaches 0.33 per cent. The spectrum of the fluorescence shows a nebulous band in the region of the line C.

Alumina containing about 6 per cent. of potassium oxide, after it has been moderately heated and mixed with 0.00021 per cent. of manganous oxide, shows no red fluorescence, but a feeble green fluorescence is visible, and this increases in intensity with the proportion of manganese, and becomes very brilliant when the amount of manganous oxide is 1.0, 0.1, or 0.033 per cent. If the mixture is very strongly heated, the green fluorescence becomes much more intense and is very brilliant—even when the proportion of manganous oxide is only 0.001 per cent.

Magnesium oxide, prepared from magnesium sulphate, when mixed with 0.1 per cent. of chromic oxide, shows a brilliant red fluorescence; this is still distinct, although not so intense, with somewhat less than 0.01 per cent. of chromic oxide. The spectrum shows a nebulous band in the region of the line C. If the magnesium oxide is very strongly heated, the fluorescence becomes more intense.

Gallium oxide, prepared from the nitrate and strongly heated, shows a violet-blue fluorescence which changes to a magnificent red when 0.67 per cent. of chromic oxide is added. The red fluorescence is obtained with 0.1 per cent. of chromic oxide, and if the amount of the latter is only 0.01 per cent., the fluorescence is at first blue, but soon changes to red.

C. H. B.

**Phosphorescence of Alumina.** By E. BECQUEREL (*Compt. rend.*, 104, 334—335).—Some strongly ignited alumina, obtained from Boisbaudran, showed only a faint, greenish fluorescence in a vacuum, but it showed a bright red phosphorescence in the phosphoroscope when subjected to the influence of the electric arc. The rays in sunlight, &c., which excite the phosphorescence of alumina are between D and F, and from half-way between F and G to H. In a vacuum, the exciting rays are chiefly of much higher refrangibility. The results obtained by different methods of excitation are evidently very different.

If the vacuum in a tube containing rubies is imperfect, the rubies show scarcely any trace of luminosity under the influence of the elec-

tric discharge, but when the exhaustion becomes great, a brilliant red phosphorescence is observed.

It is possible that chromic oxide confers on alumina the power of absorbing different exciting rays, and thus increases its power of phosphorescence. This action would be similar to that exerted by certain dyes on photographic plates.

C. H. B.

**Phosphorescence.** By E. LOMMEL (*Ann. Chem. Phys.* [2], 30, 473—487).—By a method already described (*ibid.*, 20, 847) the author has examined the light emitted by a series of 16 phosphorescent substances prepared by Dr. Schuchardt, and by Balmain's paint. The substances were placed in small mica cells, and sunlight or the electric light, filtered through two blue and two violet glasses and a solution of ammonio-cupric sulphate, concentrated on them by means of a lens. The exciting light thus contained only rays from midway between F and G to the ultra-violet. The phosphorescent light was examined spectroscopically both during illumination and subsequently. The calibration of the spectroscope is very fully described.

None of the specimens were chemically examined. Twelve of them were styled calcium sulphide, one strontium sulphide, and the remaining three double sulphides of strontium and antimony. The calcium preparations emitted light of all colours—from red to violet. The spectra obtained from them were sometimes continuous, sometimes not; but *collectively* they agreed in showing three well-marked and fixed maxima of luminous intensity; namely, I, for  $\lambda = 0.584$  in the yellow; II, for  $\lambda = 0.517$  in the green; and III, for  $\lambda = 0.462$  in the blue. In individual specimens, however, sometimes one, sometimes two of these maxima were either faint or wanting; this giving rise to the various colours emitted by them. The 12 specimens may be divided into five groups according to the maxima present.

Azure-blue and bluish-violet (two specimens), three maxima present.

Blue (2 and Balmain's paint), II and III present.

Violet to rose-red (5), I and III present.

Greenish-blue (1), only II present.

Orange (1), only I present.

After illumination has ceased, some of these maxima may fade more rapidly than others, and hence the tint of the phosphorescence may change.

The spectra of the strontium sulphide (green) and of the strontium antimony sulphides (yellow) were continuous from red to violet; but each showed only one maximum of intensity. During illumination, this maximum was not only differently placed in each case ( $\lambda = 0.542$  in the green for strontium sulphide:  $\lambda = 0.556$  in the yellow-green, and  $0.578$  in the yellow for strontium antimony sulphide), but on withdrawal of the light it appeared to move slightly towards the violet, while the spectrum rapidly faded from the two ends towards the centre.

By inserting a little screen coated with the phosphorescent substance into the eye-piece of the spectroscope, the author has also been able to examine the effect of the various rays of the spectrum on the above substances after they had been excited by a short exposure to daylight.

In every case there was a period of intensified phosphorescence in the parts exposed to the red and ultra-red rays, followed by more or less rapid extinction. As a rule, the first period was very short; but in those specimens in which the green maximum, II, was well developed, the intensifying effect lasted for a long time—sometimes for hours, and even after the red illumination was withdrawn. All calcium preparations showed, in the intensified parts, the luminous bands already described (*loc. cit.*) during illumination; and after the intensifying rays were cut off a dark image of the less refrangible spectrum on a bright background appeared on the screen sooner or later.

By means of the phosphorescent eye-piece, the author has also traced the rays which are most effective in exciting phosphorescence in each case. The general result arrived at is, that the least refrangible rays of the light emitted by the calcium preparations are produced by the most refrangible rays of the exciting light. The same rule holds, though less generally, for the strontium antimony preparations.

CH. B.

**Comparative Actions of Heat and Solar Radiation.** By E. DUCLAUX (*Compt. rend.*, 104, 294—297).—A large number of organic compounds containing carbon, hydrogen, and oxygen were subjected to the action of heat or solar radiation in presence of air, silver nitrate, potassium permanganate, platinic chloride, auric chloride, and other oxidising agents.

The results show that all reactions of the nature of combustion which can be produced by the action of heat can also be produced by solar radiation; but several decompositions which are effected by sunlight cannot be brought about by the influence of heat alone. All the decompositions consist in the splitting up of the original molecule into simpler molecules, amongst which may be mentioned formic, acetic, and butyric acids, methyl and ethyl alcohols, and ether—compounds which are relatively stable in the conditions under which they are formed. As a rule, the same substance yields the same products, whatever the nature of the oxidising agent with which it is in contact; but to this law there are a few exceptions. Lactic acid, for example, yields acetic acid when oxidised by the action of air, but butyric acid when oxidised by mercury salts. The stable products of combustion do not exist ready formed in the original molecules, but are the result of a rearrangement of the atoms. This is shown by the fact that the same products are obtained from different substances, and also by the fact that one and the same substance may yield different products under different conditions. As a rule, the products contain a smaller number of hydrogen and carbon-atoms than the original substances, the exceptions being formic acid, which is obtained from oxalic acid, and butyric acid which is obtained from lactic acid. Potassium permanganate, which in many cases will act in the dark, yields the same products as the action of sunlight, and the compounds, which it attacks most readily, are those which are also least stable in contact with other oxidising agents. It constitutes the most convenient reagent for determining the influence of alkalinity, acidity, &c., on the rate and limit of the oxidising action.

C. H. B.

**Simple Form of Water Battery.** By H. A. ROWLAND (*Amer. J. Sci.*, **33**, 147).—Strips of zinc and copper, each 2 inches wide, are soldered together so as to make a combined strip rather less than 4 inches wide. This is then cut into pieces about a quarter of an inch wide, each composed of half zinc and half copper. A thick plate of glass, a foot square, is heated and coated with shellac, and to this are stuck the strips of copper and zinc which have been bent into the shape of the letter **U**, with the branches a quarter of an inch apart. The soldered portion is fixed in the shellac, and the two branches stand up in the air, so that the zinc of one piece comes within one-sixteenth of an inch of the copper of the next one. A row 10 inches long will thus contain 30 elements. The rows being placed one-eighth of an inch apart, a space 10 inches square will contain 800 elements. The plate is carefully warmed, and a mixture of beeswax and resin is poured on to a depth of half an inch. The back of the plate is fitted into a wooden frame with a ring screwed in the centre, so that the whole can be suspended with the elements below. When required for use, the tips of the elements are dipped into a pan of water, and the battery again hung up. The space between the elements will hold a drop of water that will not evaporate for an hour. The battery is thus in operation in a minute, and is perfectly insulated by the glass and cement.

B. H. B.

**Sodium Dichromate Cell.** By S. L. HARDING (*Amer. J. Sci.*, **33**, 61—66).—The author has made a series of comparative tests of sodium dichromate and potassium dichromate with reference to the relative constancy or powers of endurance, the electromotive force, and the resistance of the two batteries. The cells, in every case, were set up like the Bunsen battery; the proportions used being those given by the chemical reactions which take place within the cells.

*Resistance.*—Lodge's method was used for determining the resistance of the cells. For the sodium dichromate cell the resistance was found to be 0.4967 ohm, and for the potassium salt cell it was 0.468 ohm. The resistances of both cells could undoubtedly be reduced if occasion should demand it.

*Electromotive Force.*—The electromotive force of the sodium salt cell, obtained by the open circuit method of comparison, was 1.893 volts. That of the potassium salt cell was found to be 1.852 volts. The electromotive force of the ordinary Daniell cell was 1.059 volts.

*Constancy.*—The author obtained a series of photographic records of cells set up with the two dichromates, by substituting a sheet of sensitive paper for the ground glass scale of the reflecting galvanometer (see *Amer. J. Sci.*, **29**, 374). The sodium salt cells, it was found, ran on an average fully 20 hours, or more than one-third longer, than the potassium salt cells. The greater power of sodium dichromate is due to the fact that, of the two dichromates, the sodium salt can provide the greater amount of oxygen to unite with the hydrogen set free at the negative electrode. The chemical reactions for the two salts are exactly similar; the oxygen coming from the chromic

acid in both cases. The salt which, for a given weight of the solution, can furnish the most chromic acid is the superior. The solubilities of the two salts are as follows:—At 15°, 100 parts of water dissolve 12·5 parts of potassium dichromate and 83·16 parts of anhydrous sodium dichromate. The available oxygen, therefore, in a saturated solution is 0·0852 per cent. for the sodium salt, as compared with 0·0180 per cent. for the potassium salt.

B. H. B.

### Ferric Chloride as an Exciting Agent for Voltaic Batteries.

By H. N. WARREN (*Chem. News*, 55, 49).—The power of a current from an ordinary dichromate cell may be very greatly increased by employing a slightly acidified, strong solution of ferric chloride mixed with bromine, in place of the potassium dichromate. The bromine serves to reoxidise the ferrous chloride formed, and when consumed may be again set free by the addition of bleaching powder.

D. A. L.

**Specific Inductive Power of Liquids.** By NEGREANO (*Compt. rend.*, 104, 423—425).—The author has determined the dielectric constants  $K$  and the refractive indices of benzene (both pure and mixed with thiophen), toluene, xylene (mixture of isomerides), meta-xylene, pseudocumene, cymene, and terebenthene. The square roots of the dielectric constants differ from the refractive indices in the second decimal place only. The dielectric constant seems to decrease with a rise of temperature within certain limits. In the series examined, the value of the dielectric constant increases as the molecule becomes more complicated. The ratios  $\frac{\sqrt{K} - 1}{d}$  and

$\frac{K - 1}{d}$  increase irregularly with an increase in molecular weight.

The ratio  $\frac{K - 1}{(K + 2)d}$ , however, is practically constant, and for the same liquid is the relation which connects the dielectric constant with the density. In this particular series, the value of this constant is about 0·34.

|                        | T.  | K.     | $\sqrt{K}$ . | Refractive index, $n_D$ . | Density. | $\frac{K - 1}{(K + 2)d}$ . |

C. H. B.

**Electromotive Force of some Thermo-elements consisting of Metals and Solutions of their Salts.** By A. EBELING (*Ann. Phys. Chem.*, [2], **30**, 530—543).—According to Gore (*Proc. Roy. Soc.* **36**, 50, and **37**, 251), the electromotive force of a thermo-couple formed of a metal and a salt solution changes with the concentration of the solution; according to Bouty (*Abstr.*, 1881, 336), who employed the same metal in the electrodes and the solution, it is independent of the concentration. The author has, therefore, reinvestigated the question, using pure copper in contact with copper sulphate or nitrate, and amalgamated zinc free from arsenic in contact with zinc sulphate, nitrate, or chloride. An element consisted of two glass cylinders containing the air-free solution, and communicating through a narrow glass syphon tube. In each mass of liquid was immersed an accurately graduated thermometer, round the bulb of which the metal was wound in the form of wire. One cylinder was surrounded by melting ice, and the other heated to various temperatures. The electromotive force was measured by Du Bois Raymond's modification of Poggendorff's compensation method, using two Daniell cells which were from time to time compared with Helmholtz's constant calomel cell.

It was impossible to find two wires of the same metal so perfectly homogeneous as to give no current in the above cell, even with both contacts at the same temperature. The strength of this chemical current was therefore measured at constant temperature before and after each set of experiments, the rate of its change with time calculated, and a correction thus made. Since observations with different elements could not all be made at precisely the same temperature, this source of error was allowed for on the assumption that the electromotive force is proportional to the difference in temperature of the contacts. The temperature intervals were 20°, 35°, and 47°. Tabular statements of the results in each case are given. The author's conclusions are:—

The electromotive force is not proportional to the difference of temperature of the contacts, but increases with it in some greater ratio.

With any constant temperature difference, the electromotive force diminishes slightly with the time, probably as the result of chemical actions.

The electromotive force does not increase continuously with the concentration, but exhibits maxima and minima.

For the same acid, these maxima correspond with the same state of concentration.

Some idea of the results may be gathered from the following table of electromotive forces due to a difference of temperature = 20°. P signifies the percentage of anhydrous salt in solution.

The results are expressed in terms of a calomel cell as unit. To reduce them to electromagnetic units the figures must be multiplied by  $10542 \cdot 10^4 \text{ cm.}^3 \text{g.}^{\frac{1}{2}} \text{sec.}^{-2}$ . The maxima for strong solutions are indicated by brackets, for weak solutions by asterisks.

Certain other conclusions are also stated, but with some reserve. According to Neumann's law, substances of similar constitution and

properties have equal atomic heats; but according to the fourth statement above the maximum electromotive force for different metals, but the same acid, occurs for solutions of different concentration. Also, the strength of solution for which the electrical conductivity is a maximum is also that for which the electromotive force is a maximum. This is shown by a table of electrical conductivities taken from Wiedemann's *Electricity*. Finally it appears that here, as in the case of ordinary thermo-couples, the worst conductors make the most effective combinations.

CH. B.

**Galvanic Polarisation of Aluminium.** By F. STREINZ (*Phil. Mag.*, [5], 23, 304).—The author finds that if aluminium plates be polarised, the difference of potential between the oxygen plate and the zinc of the polarising cell increases within very wide limits with the electromotive force of the cell, whilst the hydrogen plate shows very little polarisation for small electromotive forces, but with large electromotive forces acquires a difference of potential opposite in direction to that usually obtained. The small amount of gases usually obtained from aluminium electrodes can be explained by the great opposing force of oxygen polarisation.

H. K. T.

**Conductivity of Mixtures of Aqueous Solutions of Acids.** By S. ARRHENIUS (*Ann. Phys. Chem.* [2], 30, 51—76).—Previous observations by Bouchotte, Paalzow, Bender, and Klein, have led to no general conclusions. In the following experiments, the author has used Kohlrausch's method, employing a telephone as indicator.

The fact that the molecular conductivity of a solution is not proportional to the amount of dissolved electrolyte, proves that the solvent liquid is not always uniformly distributed amongst the dissolved molecules, even when the electrolyte is a single substance. Ostwald, however, by some experiments, which are here described for the first time, has shown that the molecular conductivity of a mixture of butyric and acetic acid solutions in any proportions, is always the sum of the molecular conductivities of the constituent solutions.

Each electrolyte behaves as if the other were absent. Such solutions are termed by the author "isohydric."

In the foregoing case, the two acids are very similar; but when they are of different character, their solutions can be isohydric only under special conditions. Now, the specific conductivity of any solution is directly proportional to the contained mass of electrolyte, and inversely proportional to the frictional resistance to the transference of the ions. For dilute solutions, the latter may be regarded as not changing with dilution. Hence, when two weak solutions are mixed, and the distribution of the water is not thereby altered, the conductivity is the arithmetical mean of the separate conductivities; or if  $l_1v_1$  and  $l_2v_2$  are the specific conductivities and volumes of the original solutions, and  $L$  and  $(v_1 + v_2)$  those of the mixture—

$$(Lv_1 + v_2) = l_1v_1 + l_2v_2 = N_1\mu_1 + N_2\mu_2,$$

where  $N_1$  and  $N_2$  are the numbers of dissolved gram-molecules, and  $\mu_1$ ,  $\mu_2$  the molecular conductivities of the electrolytes.

When the distribution of the water is altered by mixture, let  $v_1$  and  $v_2$  become  $v_1 + dV$  and  $v_2 - dV$ ; then  $L_1$ ,  $\mu_1$ , and  $\mu_2$  will increase by  $dL_1$ ,  $d\mu_1$ , and  $d\mu_2$ . Therefore—

$$(v_1 + v_2)dL = \left( N_1\mu_1 \frac{d\mu_1}{\mu_1 dV} - N_2\mu_2 \frac{d\mu_2}{\mu_2 dV} \right) dV.$$

The ratios  $d\mu_1/\mu_1 dV$  and  $d\mu_2/\mu_2 dV$  can be calculated from Ostwald's data (*J. pr. Chem.* [2], 32, 300). For a small increase of  $v_1$ ,  $d\mu/\mu dV = \sigma$ , where the values of  $\sigma$  are different for different acids, and also diminish gradually with dilution. Finally,  $(v_1 + v_2)dL = (l_1\sigma_1 - l_2\sigma_2)dV$ .

The author has calculated  $\sigma$  for solutions of equal conductivity of six different acids, and finds that its value is greater the more feeble the acid (strength = molecular conductivity). When, therefore, two solutions of different acids, of not very different conductivity, are mixed, and when the specific conductivity of the mixture is found to be greater than the arithmetical mean of the specific conductivities of the original solutions, then the more feeble acid has taken part of the solvent water from the stronger; and *vice versa*. When the conductivity of the mixture is equal to the above arithmetical mean, the solutions are isohydric.

In practice, it is desirable to compare feeble acids with a stronger acid, rather than with each other, so that  $\sigma_1$  and  $\sigma_2$  may be as different as possible; and to use equal volumes, since  $dV$  is then a maximum. The solutions should also be dilute, and of such strengths that their specific conductivities do not greatly differ. From two observations, then, in which one solution is varied, the isohydric strengths can be found by linear interpolation.

The following propositions are experimentally proved. If two solutions are isohydric when mixed in equal volumes, they are also isohydric when mixed in any other ratio. If a solution A is isohydric with solutions B and C, B and C are also mutually isohydric.

*Mutually Isohydric Acid Solutions.*

In this table, isohydric solutions are arranged in *horizontal* series. The upper of each pair of numbers gives the corresponding strength of the solution in gram-molecules per litre; the lower gives the conductivity in mercury-units  $\times 10^8$ . The latter is uncertain, sometimes to the extent of 5 per cent.

From the table, it may be seen that the conductivities of isohydric solutions are usually about equal. It is also shown that solutions of equal conductivity are approximately isohydric. The difference in the latter case is usually a slight *increase* of conductivity.

By a method of approximations, the conductivity of any mixture of these acids may be calculated from Ostwald's data. No simple relation exists between the molecular strengths of isohydric solutions, such as Bender (*Ann. Phys. Chem.* [2], 22, 197) claims to have proved.

**Theory of Voltaic Action.** By J. BROWN (*Proc. Roy. Soc.*, 41, 294—315).—A number of experiments are described in this paper to establish the two following propositions: (1) that the difference of potential near two metals in contact, as observed by Volta's bimetallic condenser method or Thomson's quadrant method, is due to the chemical action of a film of condensed vapour or gas on the surfaces of the metals; (2) that these two metals, with their liquid film, form a cell similar to one composed of the same metals as elements, and a liquid of the same kind as electrolyte, which in contact experiments is divided by the intervening insulating diaphragm of air or other gas. From this it follows that in these experiments it is the difference of potential at the outer surfaces of the two metals which is measured. Thus, in the case of a single metal covered by its chemically active electrolytic film, at the surface of the film and metal there is an electromotive force corresponding with the chemical action between

them. In the case of two metals joined metallically, the potentials of the metals will be equalised, a portion of the negative charge going through the connection between the two metals, and thence to the film.

In the experiments, a pair of metals were taken, each of which was carefully cleaned, and the difference of their potential determined immediately; into the apparatus, a gas which acts chemically on the metals was then introduced, and the difference of potential determined after various intervals of time. The gas causes an immediate reversal of the potential; this is compared with a similar reversal which occurs when a solution of the same gas is added to water in which the same pair of metals is immersed. Experiments were made with copper-iron in ammonia and hydrogen sulphide, silver-iron in hydrogen sulphide, and copper-nickel in ammonia and hydrochloric acid gases, and the results compared with those obtained by adding solution of ammonia, hydrochloric acid, and potassium sulphide to water, in which these several pairs of metals were immersed. It would appear from these results that no contact experiment with clean metals has as yet been made, since they are cleaned whilst exposed to the atmosphere, and are thereby covered with a film of condensed water containing dissolved gases. Experiments are quoted to show that the difference of potential of a copper-zinc pair in air is reduced by the introduction of dehydrating agents, such as sodium and phosphoric anhydride. It was further found possible to join the films only on the two metals, without bringing the metals themselves in contact, and thus to produce an electromotive force from metals apparently dry; the thickness of the environing film was determined by means of a micrometer screw.

From the above experiments, it follows that difference of potential in a pair of metals is not an intrinsic property of the metals in themselves, but results from a chemical action induced by their exposure to the atmosphere; this action proceeds until terminated by its own effects.

Thus, in the case of a copper-zinc pair in air, the oxygen of the moisture combines with the zinc, and thus is produced a configuration of oppositely electrified atoms, forming a double layer. This idea has been put forward by Helmholtz in illustration of the phenomena of electrolysis, and successfully applied to explain polarisation.

**Electric Accumulators.** By D. DRAKE and J. M. GRAHAM (*Dingl. polyt. J.*, 262, 382).—From the results of a series of experiments on the permanency of accumulators, the authors draw the following conclusions:—(1.) The duration of lead plates or conductors and the retention of their structure is not dependent on the amount of current condensed in and discharged from the cells. (2.) New cells or cells which have been out of use for some time should be charged to the maximum extent. (3.) The cells should not be completely exhausted; moreover, it is proposed not to discharge them beyond the point at which the E.M.F. begins to be sensibly reduced. (4.) The film of dioxide formed during the condensation of the current is said to protect the plate from the injurious effects of overcharging and

local action. (5.) A certain (small) amount of sulphate is necessary to hold the active material together; an excess, however, causes the oxide to separate from the conductor. D. B.

**Determination of Atomic Weight from Specific Heat.** By G. JANEČEK (*Chem. Centr.*, 1887, 3—4).—The author denies, on theoretical and experimental grounds, the correctness of the law of Dulong and Petit. Of the 70 known elements, there are only 16 whose atomic heats can be shown to undoubtedly lie between 6.028 and 6.849, whilst there are two (S and P) much below 6, one (Si) between 4 and 5, one (Be) about 3.8, one (B) about 2.5, one (C) about 2, and five (Al, Cr, Cu, Fe, and Ga) between 10.4 and 12.6. For all the remaining elements, the atomic weight has simply been adjusted to the law of Dulong and Petit. The atomic heats of the gaseous elements in their solid condition have been deduced almost exclusively from such arbitrary values. Of the values so obtained, only those of two elements (Cl and N) correspond in some degree with the law of Dulong and Petit, whilst those of the others (F, O, and H) do not at all agree. Weber's researches on the influence of temperature on the specific heat of the solid elements afford no support to the law. Weber's numbers for carbon, boron, and silicon do not refer to the absolute specific heat, but rather show the entire absorption of heat under different conditions. It is possible to calculate the atomic heats from the differences in the observed values, and the numbers obtained have been used to confirm the law of Dulong and Petit. The conclusions, however, which are applicable to these three elements may also be applied to all the other elements, the atomic heats of which have been calculated from specific heat determinations made at an arbitrarily selected temperature. When this temperature is departed from for the specific heat determinations, the agreement of the atomic heat with the law of Dulong and Petit entirely disappears.

G. H. M.

**Specific Heats of Liquids.** By M. LANGLOIS (*Compt. rend.*, 104, 420—422).—The author has defined the terms *enveloping molecule* and *secondary molecule* in a previous communication. His experiments on the heat of vaporisation show that the enveloping molecule, considered by itself, behaves as a true liquid molecule. The secondary molecules, on the other hand, behave like gaseous molecules, and consequently in calculating the specific heat of a liquid, it is merely necessary to calculate the heat which they would absorb in the gaseous state when expanding under constant pressure. The variations in the attraction on the molecular surface are so small within a comparatively narrow range of temperature, that they may be neglected. When the temperature of an enveloping molecule is raised, it experiences an alteration in the force of atomic translation, and this results in an oscillating motion with absorption of a quantity of heat, which the author defines as the *heat of oscillation*. From these considerations, the author has calculated the specific heats of water, carbon bisulphide, chloroform, carbon tetrachloride, ether, ethyl alcohol, and acetone, and has obtained numbers which agree closely with the actual determinations of Regnault.

C. H. B.

**Isomerism of Position.** By A. COLSON (*Compt. rend.*, **104**, 428—430).—The author has determined the specific heats and the heats of fusion of the dibromo-, dichloro-, and tetrachloro-xylenes:—

|                             | Sp. heat. |         | D.    | C × D. |      |
|-----------------------------|-----------|---------|-------|--------|------|
|                             | 15—40°.   | 15—60°. |       |        |      |
| Dibromoparaxylene.....      | 0·180     | 0·188   | 2·012 | 0·362  | 15·3 |
| Dibromortho-xylene.....     | 0·183     | 0·190   | 1·988 | 0·363  | 15·4 |
| Dibromometaxylene.....      | 0·184     | 0·191   | 1·959 | 0·361  | 15·2 |
| Dichloroparaxylene.....     | 0·282     | —       | 1·417 | 0·414  | —    |
| Dichlorortho-xylene.....    | 0·283     | —       | 1·393 | 0·394  | 17·0 |
| Dichlorometaxylene.....     | 0·295     | —       | 1·370 | 0·404  | 16·2 |
| Tetrachloroparaxylene.....  | —         | 0·242   | 1·606 | 0·290  | 14·7 |
| Tetrachlorortho-xylene..... | —         | 0·24    | 1·601 | 0·288  | 14·3 |
| Paraxylene.....             | —         | —       | —     | —      | 14·4 |

The last column contains the values obtained by multiplying the molecular weight into the number obtained by dividing the latent heat by the absolute temperature of fusion. The higher values obtained for the bromine-derivatives may be due to their greater instability, or to the fact that the mean specific heat (0·199) used in calculating the numbers is too high. If the results can be generalised, it follows that at the melting points the difference between the entropy of the liquid and solid is constant for all isomerides of position. When the results are calculated to the molecular weights, it is found that this difference will not be sensibly altered by the substitution of chlorine for hydrogen. The heat of fusion  $L$  is connected with the temperature  $t$ , pressure  $p$ , and contraction  $v' - v$  by the equation of Clausius and Clapeyron:—

$$\frac{L}{273 + t} = \frac{1}{425} (v' - v) \frac{dp}{dt}.$$

From the author's results, it follows that for isomerides of this kind the first term in this equation is constant, and hence

$$t = K(v' - v)(p - p_0),$$

or the temperature of fusion increases proportionally with the pressure.

C. H. B.

**Determination of the Constitution of Carbon-compounds from Thermochemical Data.** By H. E. ARMSTRONG (*Phil. Mag.* [5], **23**, 73—109).—The author quotes the chief results obtained by Thomsen (*Thermochem. Unters.*, Bd. iv) in the determination of the heats of combustion of a large number of carbon-compounds, and criticises the views there put forward with reference to their constitution. In Thomsen's work, all the heats of combustion are based

on the assumption that the substance burned is in the state of gas at  $18^\circ$ , and that the products are gaseous carbonic anhydride and liquid water at that temperature; before, however, these data can be applied to the determination of the constitution of the compounds themselves, it is necessary to deduce the heat of combustion of gaseous atomic carbon, a value denoted by the symbol  $f(C_1)$ . The argument by which this value,  $f(C_1)$ , is estimated by Thomsen is as follows:—The heat of combustion of carbon in its compounds is greater than that of amorphous carbon, and the average value obtained by the comparison of the heats of combustion of compounds differing in constitution by one or more atoms of carbon is 121090 units; these comparisons are instituted between a saturated and an unsaturated compound, the latter being formed from the former by the addition of a carbon-atom, which, it is usually said, becomes doubly linked with another carbon-atom. Now, if carbonic anhydride were capable of combining with an atom of carbon, it is to be supposed that it would form an unsaturated compound  $CO:CO$ , bearing the same relation to it that ethylene bears to methane, and that the heat of combustion of this compound would exceed that of carbon dioxide by 121090 units; whence it follows that the heat of combustion of carbonic anhydride being *nil*, the heat of combustion of the product in question should be 121090 units. But in point of fact, 2 mols. of carbonic oxide are produced by assimilating an atom of carbon with a molecule of carbonic anhydride, the double linkage being annulled whilst the volume is doubled. In the act of expansion 580 units are absorbed; hence the heat of combustion of the product of the union of an atom of carbon with a molecule of carbonic anhydride exceeds 121090 units by the amount absorbed in the separation of doubly-linked carbon-atoms ( $v_2$ ), plus 580 units, or  $f(C_1) = 121090 + v_2 = 135920 - 580 = 135340$  units; whence also  $v_2 = 14250$  units.

Very important conclusions are drawn by Thomsen with reference to the heat developed in the combination of carbon-atoms by *one, two, or three* affinities of each, that is, in the way in which they are assumed to be associated in the paraffins, in ethylene, and in acetylene respectively—these values are severally denoted by  $v_1$ ,  $v_2$ , and  $v_3$ . These values can be deduced from the heat of formation of compounds containing carbon-atoms united by one, two, or three affinities, as the case may be, by employing as a constant the heat developed by the union of 1 gram-molecule of hydrogen with gaseous atomic carbon. This constant ( $2r$ ) is evaluated thus: the heat of formation of methane,  $CH_4$ , at constant volume, calculated on the assumption that it results from the combination of *ordinary* hydrogen with gaseous atomic carbon—of 2 hydrogen *molecules* with 1 carbon-*atom*—is 59550 units; halving this number,  $2r$  is found to be 29775 units. With regard to the value of  $v_1$ , the heat developed in the formation of ethane,  $C_2H_6$  (104160 units), results from the combination of 3 hydrogen molecules with 2 carbon-atoms, and of these carbon-atoms with each other by single affinities; hence,  $(2C, 3H_2) = 3.2r + v_1 = 104160$  units  $\therefore v_1 = 14835$  units. The value of  $v_2$  has already been determined to be 14250 units, whilst that of  $v_3$  can be obtained from the heats of

formation of acetylene (28990 units), allylene (74610 units), and dipropargyl (133080 units), and is found to be  $-81$  units, a value so small that it can be neglected. From these values, it follows that the same amount of heat is developed in the combination of carbon-atoms, whether they become singly or doubly linked—in other words, there is no difference between these modes of union—whilst the so-called treble linking of carbon-atoms is unattended with the development of heat.

In addition to his already published views on the constitution of benzene (Abstr., 1881, 89), pyridine, and thiophen (Abstr., 1885, 1126), the following are among the more curious conclusions having reference to the constitution of carbon-compounds arrived at by Thomsen by the use of these values of  $v_1$ ,  $v_2$ , and  $v_3$ : phenol is ranked with primary alcohols; ethylene oxide is in reality methylene oxide,  $\text{CH}_2 \cdot \text{O} \cdot \text{CH}_2$ ; aldehydes are unsaturated substances of the general formula  $\text{R} \cdot \text{C}(\text{OH})$ ; methylal and methyl orthoformate contain hydroxyl and are analogous to alcohols in constitution; cyanogen has the formula  $\text{N} : \text{C} : \text{C} : \text{N}$ , and the amines are compounds of pentad nitrogen; methylamine, for example, is  $\text{H}_2\text{C} : \text{NH}_3$ , dimethylamine,  $\text{H}_2\text{C} : \text{NH}_2\text{Me}$ , and trimethylamine,  $\text{H}_2\text{C} : \text{NHMe}_3$ , although aniline is found to be  $\text{Ph} \cdot \text{NH}_2$ ; the nitro-paraffins are nitroso-alcohols, nitro-methane being formulated  $\text{CH}_2 \cdot (\text{NO}) \cdot \text{OH}$ ; and finally pyridine is not analogous in constitution to benzene.

The author recalling some of these results, and noting the conclusion that  $v_1 = v_2$ —in other words that there are no such things as double bonds—and that  $v_3 = 0$ , namely, that in acetylene there is not even a single bond between the carbon-atoms, adds that it cannot be admitted by chemists that ethylene oxide is methylene oxide, whilst Thomsen's formulæ for the amines are altogether improbable. The method of proof that the carbon-atoms are united in ethylene oxide and that the amines have the constitution usually assigned to them, is the method by which the constitution of compounds generally is arrived at, and results obtained by this method would have to be retained in some instances but rejected in others were Thomsen's views adopted. The explanation of these anomalous results is most probably to be found in the view that the true heat of combustion of gaseous atomic carbon is greater than 135340 units. Thomsen's determination of this value involves the assumption that the addition of the first and second atom of oxygen to a carbon-atom involves the development of the same amount of heat, but consideration of the properties of carbonic oxide (such as its tendency to combine with but a limited number of other substances, and, as a rule, only under special conditions) appears to favour the contrary view that, of the total heat developed in the formation of carbonic anhydride, the larger proportion is evolved in the combination of the carbon-atom with a single oxygen-atom—in other words,  $f(\text{C}_1) = 135340 + x$ , where  $x$  has probably a high value.

Among the results independent of the value of  $f(\text{C}_1)$ , Thomsen finds that in the formation of haloïd derivatives of hydrocarbons, the addition of a *single* atom of chlorine to methane, for example, is attended with a heat-evolution of only 13500 units; that of *two*,

2.16500 units; that of *three*,  $13500 + 2.16500$  units; and that of *four*,  $2.13500 + 2.16500$  units. Again, among the alcohols, the primary are found to have the highest, and the isomeric tertiary the lowest heats of combustion, the secondary occupying an intermediate position. These results are attributed by the author to the effect of the local accumulation of negative elements in the molecule.

W. P. W.

**Note on the Foregoing Communication.** By S. U. PICKERING (*Phil. Mag.* [5], 23, 109—112).—The author points out that if Thomsen's value of  $f(C_1)$  be erroneous, the only meaning then attaching to his values of  $v_1$ ,  $v_2$ , and  $v_3$  will be that they are the *differences* between their actual values. Adopting Armstrong's view that  $f(C_1) = 135340 + x$ , it is shown that the value for  $r$  will become  $r + \frac{x}{4}$ ,

while those of  $v_1$ ,  $v_2$ , and  $v_3$  will be converted into  $v_1 + \frac{x}{2}$ ,  $v_2 + x$ , and

$v_3 + \frac{3x}{2}$ , respectively. If, as is most probable,  $x$  represents some number considerably larger than 14000 units, the heat developed in the union of two carbon-atoms will be very nearly, though not quite, proportional to the number of bonds by which they are united.

Thomsen's argument that the aldehydic radicle consists of hydroxyl rests on the fact that the heat of formation of  $H \cdot C : O$  in the aldehydes, together with that of  $C : O$  in the ketones, was found to be equal to that of  $O : C \cdot OH$  in the acids; the introduction of  $x$ , however, destroys this equality, for the sum of the heat of formation of the aldehydic and ketonic radicles will exceed that of carboxyl by  $\frac{x}{2}$ , and this excess renders the results entirely in accordance with

the generally accepted views concerning the constitution of these substances.

W. P. W.

**Criticism of Thomsen's Theory of the Heat of Formation of Organic Compounds.** By J. W. BRÜHL (*J. pr. Chem.*, 35, 181—204, and 209—236).—Starting with the premise that conclusions drawn from experiments undertaken with the object of ascertaining the molecular structure of compounds from physical considerations require, for the present at least, a general confirmation from chemical data, since this question has been studied for a longer time and to a greater degree by chemical than by physical methods, the author submits that such conclusions must be received with caution when they lead to constitutional formulæ which are inexplicable, having regard to the methods of formation and the chemical properties of the compounds concerned. The views on the constitution of carbon-compounds put forward by Thomsen (*Thermochem. Unters.*, Bd. iv) are of this nature (compare preceding Abstracts), and the author criticises these views with the object of demonstrating that they are untrustworthy and based on fallacious arguments.

With regard to the calculation of the fundamental constant  $v_2$

(*loc. cit.*), it is noted that Thomsen assumes without any experimental proof that the union of gaseous atomic carbon with two atoms of oxygen is attended with the development of twice as much heat as when combination ensues with one atom; and further that the value of  $v_2 = 14250 \pm 5000$ , if the extreme values be substituted for the mean deduced from 14 comparisons of the heats of combustion of saturated and unsaturated compounds. Moreover, the values of the fundamental constants,  $v_1$  and  $r$ , and the conclusion  $v_1 = v_2$ , deduced in the first instance from the heat of formation of hydrocarbons, are assumed by Thomsen to hold for all classes of compounds, and on these values he bases his theories of the constitution of carbon-compounds, although the author shows that assuming  $v_1$  and  $r$  constant,  $v_2$  has among others the values 7500 units, 9590 units, and 11110 units (deduced from the heats of formation of allyl and ethyl alcohols, the ethers, and formates respectively).

The method adopted by the author in his criticism is well illustrated in the section of the paper devoted to the consideration of Thomsen's views of the constitution of aldehydes, ketones, acids, and ethereal salts. Thomsen deduces the heat of formation of COH (65400 units), CO (54250 units), and CO·OH (119960 units), by subtracting from the heat of formation of the aldehyde, ketone, or acid the amount of heat assumed to be developed in the formation of the contained hydrocarbon radicle, it being assumed that in these compounds  $v_1 = 14200$ , and  $r = 15000$  units; and since  $65400 + 54250 = 119650$ , he argues that the aldehyde radicle contains hydroxyl, thus C(OH). No evidence is offered of so surprising a conclusion, and with the same right that Thomsen argues that the group CO in formic, acetic and propionic acids has the same value as CO in acetone, the author submits that the residue, C(OH), of the acids should be supposed to have the same value as it has in methyl, ethyl and propyl alcohols, that is, 44600 units, whence  $119650 = 44600 + 75050$ , and CO = 75050 units. But even if Thomsen's unproved assertion that the heat of formation of the CO-group in the ketones and acids has a constant value = 54250 units be accepted, it does not follow that because in this case the heat of formation of the COH residue must be 65400, a similar value to that already deduced for the aldehyde residue from independent considerations, that the aldehyde radicle must have an analogous constitution any more than a similar sp. gr., boiling point, or other physical property establishes the identity of two compounds. Adopting Thomsen's value that the heat of formation of the aldehyde radicle = 65400 units, and that  $r = 15000$ , the constitution H·C : O would lead to a value for CO = 50400 units, a value not very different from that of CO in acetone; that the value should be exactly the same even in one and the same series is scarcely to be expected: for example, in the alcohols the heat of formation of C(OH) varies between 41800 and 61600, and in the acids = 65400 units, so that Thomsen's view that the aldehyde radicle contains hydroxyl must be regarded as arbitrary.

Passing on to acetic anhydride, Thomsen calculates for the heat of formation of the group O : C·O·C : O, the value 165940 units, and, inasmuch as  $165940 = 3.55310$ , assumes that the heats of

formation of the groups  $\text{C}\cdot\text{O}\cdot\text{C}$  and  $\text{C}:\text{O}$  are identical. But as, in the case of the ethers, Thomsen has deduced for the heat of formation of  $\text{C}\cdot\text{O}\cdot\text{C}$  the value 31500 units, and since  $165940 = 31500 + 2 \cdot 67220$ , the heat of formation of  $\text{C}:\text{O}$  must be 67220 units instead of 55310; hence the author urges that the fundamental hypothesis of the thermal constancy of the affinity between carbon and oxygen is disproved, inasmuch as the heat of formation of the group  $\text{C}:\text{O}$  or  $\text{C}\cdot\text{O}\cdot\text{C}$  is shown to be variable. Moreover, comparing Thomsen's value of the heat of formation of the group  $\text{C}:\text{O}$  in ketones and acids, 54250 units, with the value of this group in carbonic oxide and carbonic anhydride which, according to Thomsen's fundamental assumption, must be 67670 units, the difference between these values, 25 per cent., is irreconcilable with the hypothesis on which the whole theory is based.

With regard to ethereal salts, the author severely criticises the argument by which Thomsen is led to deduce the value 105000 units for the heat of formation of the group  $\text{O}:\text{C}\cdot\text{O}\cdot\text{C}$ , and to alter the formulæ of those salts in which there is a marked deviation from this average value; moreover, it is pointed out that the formula proposed for ethyl acetate,  $\text{OH}\cdot\text{CHMe}\cdot\text{CMe}:\text{O}$ , and calculated from the equation  $7r + 3v_1 + 54250 + 65400 = 267250$  (the actual value being 265910), is based on an entirely wrong conception, inasmuch as Thomsen's proposed formula for the aldehyde radicle is  $\text{R}\cdot\text{C}(\text{OH})$ .

||

This radicle is not present in the proposed formula for ethyl acetate, and as a compound of the formula given would most probably resemble a secondary alcohol, the value of the heat of formation of  $\text{C}(\text{OH})$  in isopropyl alcohol, namely, 50710 units, ought to be substituted for 65400, giving a total 252560, which in no wise agrees with the experimental results. Criticising in a similar manner Thomsen's views with regard to the molecular structure of the other classes of carbon-compounds, for details of which the paper must be consulted, the author concludes that they cannot be maintained, and finally calls attention to the controversy which has arisen as to the correctness of Thomsen's value for the heat of combustion of benzene.

W. P. W.

**Thomsen's Investigations.** By F. STOHMANN (*J. pr. Chem.* [2], **35**, 136—141; compare Abstr., 1886, 842).—In determining the heat of combustion of liquid ethyl ether the mean 8805 cal. per gram or 651570 per gram-mol. was obtained. Thomsen obtained the number 660200 cal. as the mean of the series of experiments in which the ether was burnt partly as vapour mixed with air, partly in a universal burner as vapour at  $22^\circ$ . Thomsen's number when corrected gives 652830 cal.

A second series of experiments is described in which the ether is burnt as gas at  $17^\circ$  in a current of oxygen by the method employed for burning benzene vapour (*J. pr. Chem.* [2], **33**, 256). The mean number 8921 cal. per gram, equal to 660175 cal. per gram-mol., was obtained. Thomsen found the heat of combustion of ether at  $18^\circ$  to be 659600 cal. These experiments show that the author and Thomsen obtain concordant results when working under the same conditions.

The author still maintains that the higher numbers obtained by

Thomsen are due to heat carried over from the burner to the calorimeter (Abstr., 1886, 409), and suggests that the error in the case of benzene being 11,400 cal., the errors in the case of substances which have to be heated at 116° and higher must be still greater.

**Alcoholates of Sodium Glyceroxide.** By DE FORCRAND (*Compt. rend.*, 104, 291—294).—If a concentrated solution of sodium methoxide in absolute methyl alcohol is mixed with an equivalent quantity of glycerol, the mixture deposits an alcoholate of sodium glyceroxide,  $C_3H_5(OH)_2 \cdot ONa + MeOH$ , in very deliquescent, white needles, which lose the whole of their methyl alcohol when heated at 120° in a current of dry hydrogen. It dissolves in methyl alcohol to the extent of 120 grams per litre at 15°. Heat of dissolution in water at 16° = -2.00 cal.

It is evident that as in the case of the ethyl alcoholate the formation of the alcoholate is exothermic whilst that of the glyceroxide alone would be endothermic. The thermal disturbances which accompany the four corresponding reactions in the case of the ethyl alcoholate are respectively,

$$+16.60 \qquad +4.58 \qquad +3.92 \qquad -0.63.$$

The ethyl alcoholate of sodium glyceroxide dissolves in ethyl alcohol to the extent of 13 grams per litre at 15°.

The propyl alcoholate,  $C_3H_5(OH)_2 \cdot ONa, PrOH$ , is obtained in a similar manner; one litre of propyl alcohol dissolves 7 grams at 15°. Heat of dissolution in water = -0.57 cal. The thermal disturbances corresponding with the four reactions already given are respectively,

$$+16.69 \qquad +4.67 \qquad +6.10 \qquad 1.65 \text{ cal.}$$

The isobutyl alcoholate is obtained in the same way; one litre of isobutyl alcohol dissolves 4.6 grams at 15°. Heat of dissolution in water = +1.23 cal. The thermal disturbances corresponding with the four reactions are respectively,

$$+14.73 \qquad +2.71 \qquad +14.89 - x \qquad +12.41 - x,$$

where  $x$  is the heat of dissolution of sodium isobutyl oxide in excess of isobutyl alcohol, which has not been determined, but is in all probability between +10 and +12 cal.

The amyl alcoholate dissolves in amyl alcohol to the extent of 28 grams per litre at 15°. Heat of dissolution in water +0.99 cal. The thermal disturbances corresponding with the four reactions are

$$+14.82 \quad +2.80 \quad +15.02 - x \quad +12.41 - x,$$

where  $x$  has the same signification as in the case of the isobutyl compound.

**Alcoholates of Potassium Glyceroxide.** By DE FORCRAND (*Compt. rend.*, **104**, 361—364).—These alcoholates are compounds of potassium glyceroxide,  $C_3H_7O_3K$ , with one molecule of an alcohol of the paraffin series. They are obtained by adding one molecule of glycerol to a solution of one molecule of the potassium alkyl oxide in the corresponding alcohol. The following table gives the heats of dissolution of the alcoholates in water, the thermal disturbances corresponding respectively with the following reactions:—

and the amount of the alcoholate dissolved by one litre of the corresponding alcohol.

|                      | Heat of<br>dissolution. | 1.     | 2.    | 3.    | 4.    | Solu-<br>bility. |
|----------------------|-------------------------|--------|-------|-------|-------|------------------|
|                      | cal.                    |        |       |       |       | grams.           |
| Methyl alcoholate .. | -1.48                   | +19.49 | +3.65 | +2.54 | -1.22 | 400              |
| Ethyl       "    ..  | —                       | +18.53 | +2.69 | +3.17 | +0.46 | 187              |
| Propyl     "    ..   | -0.67                   | +19.60 | +3.76 | +5.79 | +1.89 | 158              |
| Amyl       "    ..   | +1.05                   | +17.62 | +1.78 | +6.28 | +4.47 | 40               |

Isobutyl alcohol forms no alcoholate with potassium glyceroxide; with this exception, all the monhydric alcohols behave in the same way. The formation of the alcoholate is exothermic, but the quantity of heat developed, with the same metallic derivative, decreases as the molecular weight of the alcohol increases. For the same alcoholate, the heat developed diminishes as the atomic weight of the metal in the glyceroxide increases. The solubility of the alcoholates in the corresponding alcohol also diminishes as the molecular weight increases.

**Heat Equivalents of the Homologues of Benzene.** By F. STOHMANN, P. RODATZ, and W. HERZBERG (*J. pr. Chem.* [2], **35**, 40—42).—These investigations presented considerable difficulties

which made it desirable to check the results of observations, the difficulties being principally due to the impurity of the substances employed although subjected to repeated fractional distillation. Benzene constitutes an exception, as it may be purified by fractional solidification. The results of combustion of the successive homologues show such inconstancy of difference that it can only be accounted for by impurity of the hydrocarbon employed. The results are, however, capable of being checked by comparing them with those obtained by calculation from three distinct methods, namely:—(1) Starting from benzene and employing the formula  $x = -H + CH_3 + 156000 \text{ cal.}$ ; (2) from the mean values obtained for the liquid phenols from the formula  $C_6H_6 = C_6H_5 \cdot OH + 53600 \text{ cal.}$ ; and (3) from the mean value of the phenol ethers according to the formula  $C_6H_6 = C_6H_5 \cdot O \cdot CH - 121700 \text{ cal.}$  The mean results obtained from these calculations agree within 0.6 per cent. with those obtained by experiment.

|               | Calculated. | Found.     |
|---------------|-------------|------------|
| Benzene ..... | 779.5 cal.  | 779.5 cal. |
| Toluene ..... | 935.6 "     | 933.8 "    |

A. H. F.

**Heat Equivalent of Ethers of the Phenol Series.** By F. STOHMANN, P. RODATZ, and W. HERZBERG (*J. pr. Chem.* [2], **35**, 22—39).—1. Phenol Ethers.—*a. Anisöl*, OPhMe. This was rectified by a distillation between 152° and 153°, the pressure being about 755 mm. Five determinations were made of the heat of combustion, giving mean values of 8345 cal. per gram, or 901282 cal. per molecular equivalent. *b. Phenetöl*, OPhEt, rectified between 166.5° and 167.5°. A mean of nine determinations gave the heat of combustion as 8666 cal. per gram, or 1057225 per molecular equivalent. *c. Phenyl propyl ether*, OPhPr<sub>z</sub>. This was made by distilling together normal propyl bromide with alcoholic solution of potassium phenoxide, separating the product subsequently from water, washing with aqueous potash, drying, and redistilling. The boiling point was then constant at 185.2° under normal pressure, and the ether so obtained gave 8922 cal. per gram, or 1213426 per molecular equivalent. Experiments were made on higher members of the series, but not with sufficiently concordant results for figures to be given.

2. *Cresol Ethers*.—Two of these were examined, namely, meta-cresyl methyl ether, C<sub>7</sub>H<sub>7</sub>·OMe, and paracresyl ethyl ether, C<sub>7</sub>H<sub>7</sub>·OEt, and were found to have heat-equivalents almost identical with their isomerides of the previous group, namely, 8666 and 8920 cal. respectively.

3. *Xylenol Ethers*.—Two of these were examined, namely, xylyl methyl ether (1 : 3) and xylyl ethyl ether (1 : 4).

4. Two thymyl ethers were experimented on, and finally two ethers obtained by substitution of methyl for hydrogen in resorcinol and quinol.

Comparison of the results for this series of ethers shows that the

introduction of a methyl-group corresponds with an increase of 155900 cal., whether the methyl-group enters the phenyl- or the methyl-group. Also the heat of formation is found to rise uniformly by 7100 cal. for each successive homologue.

These results agree closely with those obtained from examination of allied groups, namely, the alcohols and the phenols; the former giving 156163 cal. the latter 156356 cal. as the equivalent of the methyl-group.

From these experiments, calculations were made on the heat value of the methoxyl-group in these ethers ( $x = -H + OCH_3$ ); thus, for liquid benzene 779530 cal., for phenyl methyl ether 901282, and for dimethylresorcinol 1022966 cal., these corresponding with successive additions of  $CH_2 \cdot O$ , of which the equivalent is 121718 cal.

The latter part of the paper is concerned with deductions from the foregoing experimental results. First it is observed that similarly constituted isomeric substances have practically the same heat-equivalent, for instance, resorcinol, catechol, and quinol; or the ortho-, meta-, and para-cresols. Secondly, it is seen that isomerides if belonging to different chemical groups have markedly different heat-equivalents; thus the heat-equivalent of phenyl methyl ether is 901282 cal., whilst that of any one of the metameric cresols is 882288 cal. Similar results were obtained for other metameric bodies.

Finally the heat of formation of the phenyl ethers was calculated by subtracting the sum of the heat-equivalent of one molecule of phenol and of alkyl alcohol from that of the ether. Calculated in this way, the values for the different homologous and isomeric ethers were found to be practically constant, and equal to -6720 cal. Slight differences for two of these ethers are accounted for by the difference falling well within the limits of experimental error, considering the nature of the calorimetric method employed.

The ethers of dihydroxybenzenes give similar results, the calculation, however, being somewhat complicated by the difference of physical condition of the reacting substance and the product. Dimethylresorcinol gives -6824, and dimethylquinol -3412 cal. for their heat of formation.

A. H. F.

**Relation between the Critical Temperatures of Substances and their Thermal Expansions as Liquids.** By T. E. THORPE and A. W. RÜCKER (*Phil. Mag.* [5], 21, 431-434), and by A. BARTOLI and E. STRACCIATI (*ibid.*, 533-534).—Controversial papers in relation to Mendéleff's formula (compare Thorpe and Rücker, *Trans.*, 1884, 135).

**Specific Heats of the Vapours of Acetic Acid and Nitrogen Tetroxide.** By R. THRELFALL (*Phil. Mag.* [5], 23, 223-224).—The author contends that the values obtained by Berthelot and Ogier for the specific heats of vapours of acetic acid and nitrogen tetroxide (*Abstr.*, 1883, 6) support the theory of the dissociation of these gases. He further compares the specific heats of these vapours where the temperature coefficient is large with those of nitrous oxide and carbonic anhydride where the temperature coefficient is small, and argues that the usual formulæ for these gases only expresses the con-

stitution of the large majority of the molecules, whilst others of greater and less complexity also exist. With rise of temperature, dissociation proceeds, and an increased absorption of heat takes place.

H. K. T.

**Influence of Change of Condition from the Liquid to the Solid State on Vapour-pressure.** By W. RAMSAY and S. YOUNG (*Phil. Mag.*, **23**, 61—68).—Fischer (*Ann. Chim. Phys.* [2], **28**, 400) has stated that although he found the pressure of vapour in presence of water and in presence of ice identical at the melting-point of the latter, yet this was not the case with benzene. The authors have found that Fischer's statement, which is opposed to the second law of thermodynamics, is based on a wrong interpretation of his own results; for Fischer applied a formula of the form  $p = a + bt + ct^2$ , which is not adapted to express the relations of the temperatures and pressures of saturated vapours, instead of the formula devised by Biot and employed by Regnault,  $p = a + b\alpha^t + c\beta^t$ , and, moreover, did not make use of his own results at low temperatures. On recalculating from Fischer's results by means of the latter formula the vapour-pressure of liquid and solid benzene at the melting point of the latter, it is evident that the values are identical. The authors have also redetermined these constants for benzene, and confirm Fischer's results as regards the liquid; but their results do not quite agree with Fischer's as regards the solid. By making use of Regnault and Schiff's determinations of the heat of volatilisation of benzene, Petersen and Widmann's and Fischer's number for the heat of fusion of solid benzene, Schiff's formula to express the specific heat of liquid benzene, and Fischer's determination of the specific heat of solid benzene, it is possible to bring a check to bear on the value of Fischer's and the authors' experiments. The result proves that the balance of evidence is in favour of the authors' determinations of the pressures of benzene vapour in contact with the solid.

W. R.

**Nature of Liquids, as shown by a Study of the Thermal Properties of Stable and Dissociable Substances.** By W. RAMSAY and S. YOUNG (*Phil. Mag.*, **23**, 129—138).—The authors refer to previous memoirs (*Phil. Trans.*, i, 1884 and 1886, and *Chem. Soc. Trans.*, 1886, 790), in which they have shown that whilst the density of the saturated vapours of stable substances, such as ethyl alcohol and ethyl ether, becomes normal at low temperatures and correspondingly low pressures, those of acetic acid, and, as is shown by results lately published by the Messrs. Natanson, also those of nitric peroxide, increase with fall of temperature. It is held by many chemists that gaseous molecules, in changing to liquid, form molecular groups of definite complexity, exercising cohesive attraction on each other; on the other hand, it is conceivable that the liquid condition is a purely physical one, and that a liquid consists of molecules similar in every respect to those of a gas, but, owing to their closer proximity, exhibiting only that form of attraction known as cohesion. The arguments which have led the authors to adopt the latter view as correct are, that it is difficult to conceive that the rise of density of the saturated vapour of acetic acid, both at high and at low temperatures, can be

due to the same cause, for at high temperatures the conditions are unfavourable to chemical combination, but owing to the necessarily high pressure, the molecules are in close proximity, and the substance exhibits a high vapour-density; whereas at low temperatures the conditions are favourable to chemical combination, whilst the molecules, owing to the corresponding low pressures, are very far apart; so that cohesive attraction is out of the question. With alcohol and ether, a rise of density does not accompany fall of temperature; but at high temperatures they exhibit that rise of density common to all substances, stable or dissociable. Hence it is argued that there is no combination of the nature termed "chemical," that is elective, in the case of stable liquids; each molecule exerts cohesive attraction on all within its influence, but does not single out any small number of other molecules with which to combine. The authors also call attention to the fact observed by them that while the vapour and liquid of a stable substance exist in a closed space in presence of each other, pressure remains absolutely constant through the widest possible changes of volume; but with dissociable substances the pressure rises somewhat as volume is decreased, thereby revealing the partial formation of more complex molecules during the act of condensation. It is shown that the thermodynamical formula suggested by Willard Gibbs to represent the dependence of dissociation on pressure and temperature, does not represent facts at high temperatures in the case of acetic acid. The conclusion at which the authors arrive is that the difference between liquids and gases is one of degree, not of kind; is quantitative, and not qualitative.

W. R.

**Apparatus for Determining Vapour-densities.** By G. DYSON (*Chem. News*, 55, 88).—The apparatus described is a modification of Victor Meyer's apparatus, and is arranged, by means of a manometer attached to it, to read the pressure produced by the volatilisation of a known weight of substance in a space of known capacity.

D. A. L.

**Thermodynamics and Chemistry.** By H. LE CHATELIER (*Bull. Soc. Chim.*, 46, 737—746).—The writer considers the conditions of equilibrium of a gaseous mixture, such as a mixture of hydrogen, oxygen, and water at temperatures and pressures such that the water is partially dissociated. If we denote by  $N$  the number of molecular weights of the various substances existing in the mixture, this number will be a measure of the degree of dissociation, and will depend on two other quantities only, namely, the pressure  $P$  and the temperature  $T$ . Between these three quantities, there must exist a relation of the form  $F(N, P, T) = 0$ , which is the law of equilibrium of the system under consideration. The form of this function cannot be directly determined, but if we suppose a surface to be described representing the nature of the function for any particular system, then the sections of this surface made by three planes perpendicular to each of the coordinate axes respectively, will give us three distinct curves. The one in which the temperature remains constant is an *isothermal*, that in which the pressure is constant is an *isobar*, and the third is a *curve of equal dissociation*. By applying the second law of thermodynamics

and assuming the correctness of Boyle's and Gay-Lussac's laws, the author obtains the differential equation to the curves of equal dissociation, and points out that the equation contains no coefficient depending on the proportions of the substances initially present in the mixture.

It also appears that the sign of the change of pressure consequent on elevation of temperature depends on the sign of the latent heat of reaction of the system.

In general, it is easy to calculate or study experimentally the equations to the isothermals and isobars; and when these are known, the form of the function can be determined. The author applies this method to several cases, including saturated vapours, liquids in presence of soluble gases, and the dissociation of gaseous mixtures. In many cases (for instance, the vapour-tension of mixed liquids), the forms of the isothermals are not known with sufficient accuracy to admit of calculation. The author criticises severely the manner in which the principles of thermodynamics have been applied by some writers to the study of chemical phenomena, and points out the uncertainty of the assumption made in W. Gibbs's mathematical theory, namely, that the entropy of a mixture of gases is equal to the sum of the entropies of its constituents.

L. T. T.

**Representation of the Connection between the Gaseous and Liquid States of Matter by Isopyknics.** By S. v. WROBLEWSKI (*Ann. Phys. Chem.* [2], 29, 428—451).—All former researches on this subject were based on investigations of the isothermal, a curve which gives the relation between pressure and volume at different temperatures. Jamin (*Abstr.*, 1884, 5) has recently substituted for volume its reciprocal density. The author proposes the following:—Suppose a mass of gas or liquid of any definite density; when the temperature is changed, the pressure must also be changed in order to keep the density constant. The curves which represent the relation between pressure and temperature for different densities are named *isopyknics* (from *ἴσος πυκνός*). If a system, of such curves be drawn for any homogeneous isotropic substance, these curves can nowhere intersect each other.

Such a system has been constructed by the author for carbonic acid by means of Sarrau's formula (*Abstr.*, 1886, 203), which is taken as most nearly representing the experimental results. The curve corresponding to density  $d$ , of which the values of  $T$  (absolute temperature) are abscissæ, and of  $p$  (pressure in atmospheres) ordinates, is called for brevity the isopyknic  $d$ . A diagram is given showing the course of the isopyknics from  $d = 0.025$  to  $d = 1.2$  for temperatures up to  $T = 370^\circ$  and  $p = 400$  atmospheres; and on the same diagram is drawn the curve of minimum values of  $pv$ . For temperatures below  $30^\circ$ , this is of course identical with the curve of liquefaction. This portion has been calculated from the data of Regnault and of Pictet (*Ann. Chim. Phys.* [5], 13, 213); it is slightly *convex* towards the axis of temperature. The upper part of the curve, which is slightly *concave* towards the axis of  $T$ , has been calculated from the experiments of Amagat (*ibid.* [5], 22, 374) from  $35^\circ$  to  $100^\circ$ .

There is thus a gap in the middle of this curve (named by the author "principal curve") for which observations are either wanting or untrustworthy; and here the point of inflection would evidently occur. The general aspect of this curve is that of a slightly wavy line, from various points along which the isopyknics radiate; those proceeding from the lowest points being nearly parallel to the axes, and those from the critical point onwards being nearly parallel to the principal curve. Inspection of the diagram leads to some new conclusions.

Sarrau's equation gives good results for the higher pressures, but is unusable in the neighbourhood of the curve of liquefaction, since here it allows the isopyknics to pass through and intersect each other. The true course of an isopyknic would probably be that it would bend slightly on approaching the curve of liquefaction and thenceforward run downwards close beside it. Thus all isopyknics should collect into a bundle in this region. Such a course, however, is not indicated by Sarrau's equation. In the neighbourhood of the critical point, the densities of liquid carbonic acid measured by Andreew (*Annalen*, 110, 1) are much higher than those calculated by Sarrau. Although Andreew's observations are untrustworthy, it is probable that here Sarrau's values are too low. In other cases, too, Sarrau's equation leads to impossible results.

By moving along an ordinate in the diagram, we change from one isopyknic to another by simple change of pressure; but by moving along an abscissa the same thing is effected by change of temperature. Thus the passage from one isopyknic to another in a vertical or a horizontal direction gives a conception of the compressibility of the substance, or of its expansion by heat.

Now, according to Andrews' conception, everything on the diagram above the curve of liquefaction, and within the ordinate of so-called "critical temperature," indicates *liquid*; everything outside these limits, *gas*. The author believes, however, that the two states are separated, not by the ordinate in question, but by the principal curve, or the curve  $pv = \text{minimum}$ . Everything below this indicates *gas*; everything above it, *liquid*. His reasons are as follows.

In the first place, the rate of change of density with pressure  $(d_1 - d)/(p_1 - p)$  when  $dp$  and  $d_1p_1$  refer to neighbouring isopyknics, changes uniformly from below upwards, whether to right or left of the ordinate of critical temperature. The values of this quotient for different absolute temperatures are given in a table, and in each case they first increase, then reach a maximum, and then begin to decrease. If the curves of equal values of  $(d_1 - d)/(p_1 - p)$  are drawn, they are, like the principal curve, convex below and concave above, towards the axis of temperature. So also over the whole diagram this quotient slowly diminishes with increase of temperature.

Again, the coefficient of compressibility,  $K = \frac{1}{v} \cdot \frac{v_1 - v_2}{p_2 - p_1}$ , has constantly diminishing values for increase of temperature, when always calculated between neighbouring isopyknics; but constantly increasing values for increasing temperature when the pressure is kept constant. Carbonic anhydride is thus more compressible at high than at low temperatures. And, finally, the coefficient of expansion

by heat  $(d - d_1)/d_1(t_1 - t)$  under different pressures points to no specific difference between the regions on each side of the critical ordinate. In no case, therefore, is any *discontinuity* observed at this ordinate. It has then no special significance, and the conception of critical temperature as that above which liquefaction of a gas is impossible is erroneous and only an obstacle to progress. The same is true of Mendeléeff's conception (O. E. Meyer, *Kinetische Theorie der Gase*, p. 64).

Andrews' conception was based on the absence of a meniscus at any temperature above  $30.92^\circ$  and the forms of the isothermals. But, as Jamin has pointed out, the absence of the meniscus is simply due to the approximately equal densities of the gas and liquid at the critical point; hence the formation of liquid cannot be *seen*.\* These conditions are well seen in the diagram. At the critical point, the isopyknics 0.4 and 0.5 approach opposite sides of the curve of liquefaction. At higher points, the densities on opposite sides of the principal curve differ still less.

The forms of the isothermals also prove nothing. For since the difference between the densities of the liquid and of the saturated vapour above it is exceedingly small above the critical temperature, there is here no cause for the *bending* which in the lower isothermals denotes liquefaction. This bending is, in fact, due to difference of density.

It is commonly asserted that from the critical point upwards there is no latent heat; and it might be objected to the author's view, that if there is no difference of density no heat can be necessary to produce a change of state; there can then be no liquid state above the critical temperature. The author meets this objection by quoting some of his own experiments on the liquefaction of nitrogen (*Ann. Phys. Chem.* [2], **25**, 398), in which the passage of the liquid to the state of gas at the critical point was certainly attended by absorption of heat. Such a change could not be brought about without either absorption of heat or diminution of pressure.

It is to be noted that the isopyknic 0.05, which corresponds nearly with the density of liquid carbonic anhydride at the critical point, comes very close to the upper branch of the principal curve; and when our knowledge of carbonic anhydride is more accurate, it may be found to coincide with it. Every point on this isopyknic from  $30.92^\circ$  upwards, might be regarded as "the critical point." For Andrews' conception, "critical temperature," it would be better to substitute the conception "critical density," or the least density which the substance can have as a liquid. The corresponding isopyknic would then be named "critical isopyknic."

The author dwells on the great difficulty in determining the precise conditions under which the meniscus really disappears. Disregard of this has led Cailletet (*Abstr.*, 1880, 604) and Van der Waals to assert that by increased pressure the liquid could be made to dissolve in the gas above it.

\* This view was first advanced by Ramsay, *Proc. Roy. Soc.*, **30**, 323.—  
CH. B.

Stefan has lately shown that when a liquid exists under the pressure of its saturated vapour, and whilst a meniscus is distinctly visible, there must nevertheless be a gradual transition between the gas and the liquid at the boundary. The diagram represents this perfectly. For although the gas and liquid are both under the same pressure, and the points on the diagram corresponding with the two states are immeasurably close together, these points are still on opposite sides of the principal curve, and between them all the isopycnics for intermediate densities must pass down. A particle of liquid, then, to reach the other side of the curve must pass through all these intermediate states. A meniscus is, however, visible because the transition layer is exceedingly thin.

CH. B.

**Specific Gravities of Mixtures of Ethylic Alcohol and Carbonic Anhydride.** By A. BLÜMCKE (*Ann. Phys. Chem.* [2], **30**, 243—250).—The author has determined the specific gravities of mixtures of alcohol and carbonic anhydride at different temperatures and pressures, by a slightly modified form of the method already described (*Abstr.*, 1885, 215). The following are the results, the figures in column *p* denoting the percentages of carbonic anhydride in the mixtures:—

|            | 0·4°.<br>P = 35 atmos. | 17°.<br>P = 55 atmos. | 25°.<br>P = 66 atmos. |
|------------|------------------------|-----------------------|-----------------------|
| <i>p</i> . | Specific gravities.    |                       |                       |
| 0          | 0·810                  | 0·795                 | 0·790                 |
| 10         | 0·826                  | 0·808                 | 0·799                 |
| 20         | 0·841                  | 0·822                 | 0·808                 |
| 30         | 0·858                  | 0·835                 | 0·818                 |
| 40         | 0·874                  | 0·848                 | 0·827                 |
| 50         | 0·890                  | 0·859                 | 0·836                 |
| 60         | 0·899                  | 0·870                 | 0·845                 |
| 70         | 0·916                  | 0·876                 | 0·852                 |
| 80         | 0·925                  | 0·877                 | 0·844                 |
| 90         | 0·931                  | 0·871                 | 0·830                 |
| 100        | 0·934                  | 0·841                 | 0·728                 |

The specific gravity thus reaches a maximum for 80 per cent. of carbonic anhydride under 55 atmospheres pressure, and for 70 per cent. under 66 atmospheres. No relation between the specific gravities of the constituents and that of the mixture has been discovered.

A table is also given showing the increase of volume produced in alcohol by addition of carbonic anhydride. If the new volume of 1 c.c. of alcohol,  $V = 1 + na$ , where *n* equals the number of c.c. of gaseous carbonic anhydride at 0° and 760 mm., the value of *a* is approximately constant for mixtures containing less than 50 per cent. of carbonic anhydride; and for a mixture of this strength = 0·00199 at 0·4°,

0.00210 at 11°, and 0.00221 at 25°. For greater proportions of carbonic anhydride,  $a$  increases, especially at the higher temperatures.

The author's values for the specific gravity of liquid carbonic anhydride ( $p = 100$  in the table) at the liquefying pressure are different from those observed by Andreew (*Annalen*, **110**, 1) and those calculated by Clausius' and Sarrau's equations. Andreew found 0.947 at 0°, 0.849 at 17°, 0.783 at 25°.

These measurements were however made by compressing carbonic anhydride in glass tubes and calculating the uncondensed gas on the basis of Boyle and Mariott's law, which does not hold near the critical temperature. The author's results are also different from those recently obtained by Cailletet and Matthias (*Abstr.*, 1886, 758), namely, 0.908 at 0°, 0.842 at 10°, 0.748 at 20°.

The carbonic anhydride used by the author may have been slightly impure.  
CH. B.

**Dissociation of Sodium Phosphate and the Measure derived from the Vapour-tension of the Chemical Attraction of the Water of Crystallisation.** By W. MÜLLER-ERZBACH (*Ber.*, **20**, 137—141).—The results of two series of experiments made with disodium hydrogen phosphate show that within the limits of temperature of 13° and 62° the chemical attraction between sodium phosphate and its water of crystallisation has a constant or nearly constant value. With a considerable rise of temperature, the attraction must become slighter, owing to the increased distance of the components, so that the greater dissociability of strongly heated salts is readily explained. The behaviour of water absorbed by alumina (*Ann. Chim. Phys.* [2], **28**, 695) makes it probable that greatly diminished chemical affinity will be found only at a temperature considerably above 62°.  
N. H. M.

**Solubility of Solid Substances, and the Changes in Volume and Energy accompanying Solution.** By F. BRAUN (*Ann. Phys. Chem.* [2], **30**, 250—274).—Let  $p$  be the pressure,  $t$  temperature,  $V$  volume, and  $E$  total internal energy, all in absolute units, of the mixture of a solid salt with its saturated solution; and let  $dQ$  be the quantity of heat added for an infinitesimal change of  $p$  and  $t$ ; then

$$JdQ = pdV + dE = \left( p \frac{V}{\partial p} + \frac{\partial E}{\partial p} \right) dp + \left( p \frac{\partial V}{\partial t} + \frac{\partial E}{\partial t} \right) dt,$$

where  $J$  = mechanical equivalent of heat. Let  $r$  be the mass,  $v$  specific volume,  $m$  coefficient of compression,  $\alpha$  coefficient of expansion by heat, and  $u$  internal energy per unit mass, of the solution; and let  $\rho$ ,  $\phi$ ,  $\mu$ ,  $\alpha$ , and  $\omega$  be the similar magnitudes for the solid salt. Then  $v$  is directly changed by the pressure, and indirectly by the further solution (or deposition) of salt. Hence  $dv/dp = \partial v/\partial p + \partial v/\partial \gamma \cdot \partial \gamma/\partial p$ , when  $\gamma$  is a magnitude depending on the amount of salt initially in solution, and the partial differential coefficients refer only to the first part of the change; so also for  $\partial r/\partial t$ ,  $\partial u/\partial p$ , and  $\partial u/\partial t$ . The total change of  $V$  due to pressure alone will then be

$$\frac{\delta V}{\delta p} = r \frac{\delta v}{\delta p} + \rho \frac{\delta \phi}{\delta p} + \nu \cdot \epsilon \phi r,$$

where  $\epsilon$  = the mass of salt which dissolves in 1 gram of solution when the pressure is increased by unity, and  $\nu$  = coefficient of contraction of this salt in dissolving. In a similar way,

$$\frac{\delta V}{\delta t} = r \frac{\delta u}{\delta t} + \rho \frac{\delta \phi}{\delta t} + \nu \cdot \eta \phi r,$$

where  $\eta$  = mass of salt which dissolves in 1 gram of solution saturated at  $t^\circ$ , when the temperature is raised  $1^\circ$ .

Again since at pressure  $p$ ,  $E = ur + wp$ , at  $p + dp$ , the total internal energy =  $E + \delta E / \delta p \cdot dp$ , by partial differentiation with respect to  $p$  and to  $t$ , and putting  $\delta \eta / \delta p = x\epsilon$  and  $\delta \eta / \delta t = x\eta$ , we find,

$$\begin{aligned} \frac{\delta E}{\delta p} &= r \frac{\delta u}{\delta p} + \rho \frac{\delta w}{\delta p} + \left( u - w + x \frac{\delta u}{\delta \gamma} \right) \frac{\delta r}{\delta p}. \\ \frac{\delta E}{\delta t} &= r \frac{\delta u}{\delta t} + \rho \frac{\delta w}{\delta t} + \left( u - w + x \frac{\delta u}{\delta \gamma} \right) \frac{\delta r}{\delta t}. \end{aligned}$$

Here we may write  $u - w + x \delta u / \delta \gamma = -J\lambda$ , where  $\lambda$  = the heat absorbed when 1 gram of salt dissolves in its nearly saturated solution, neglecting external work. Then by substitution in the first equation, and putting  $p \delta v / \delta p + \delta u / \delta p + T \delta v / \delta t = 0$ , and  $p \delta \phi / \delta p + \delta w / \delta p + T \delta \phi / \delta t = 0$ , since  $dQ/T$  must be an exact differential, we get finally

$$\epsilon(J\lambda - p\nu\phi) = T\nu\eta\phi.$$

In this expression  $\lambda - p\nu\phi/J = L$ , the latent heat of solution at pressure  $p$ , including external work.

This equation shows that—first, substances which dissolve in their nearly saturated solutions with development of heat and diminished volume, must have their solubility increased by pressure; second, substances which dissolve either with absorption of heat or with increased volume, must be partly precipitated by pressure. Other interesting relations follow from it.

Sorby (*Proc. Roy. Soc.*, 12, 538), reasoning from the change of melting point by pressure, has already been led to experiment in this direction, and found for sal ammoniac, which dissolves with increased volume, diminished solubility at high pressures; but for sodium chloride, copper sulphate, potassium sulphate, and potassium ferri-cyanide, which dissolves with contraction, increased solubility at high pressures. Möller also (*Ann. Phys. Chem.* [1], 117, 386), has made similar experiments; his results partly contradict those of Sorby.

In the experimental part of his work, the author has used a cast-iron block pierced lengthwise by two narrow communicating channels, which could be closed by steel screws with copper washers. In one of these pressure was produced by a copper plunger, forced in by a screw and lever; the other contained the solution or mixture experimented on. The pressure applied, about 900 atmospheres, was

estimated in a preliminary experiment from the amount of mercury forced into a capillary tube containing water, and opening into mercury. The iron block was placed in a bucket of ice, or of water surrounded by ice. All experiments were made with solutions carefully saturated at  $0^{\circ}$ . Pressure was applied in each case for varying times, and the gain or loss of salt estimated from the specific gravity of the solution.

Full authorities are given for the constants used in the calculations. The more important are as follows: Sal ammoniac.  $L = -34.4$ ,  $\nu_0 = 0.356$ ; and if  $\bar{\epsilon}$  = quantity of salt which goes into the saturated solution when the pressure is raised 1 atmosphere,  $\bar{\epsilon} = -0.000125$ . The saturated solution must therefore be partly precipitated by pressure.

Sodium chloride.  $\lambda$  (determined by the author) =  $-2$ , and  $\nu = -0.177$ . Here  $\nu = -0.177$  varies with the pressure, at 1530 atmospheres becoming = 0 (see later). For 100 atmospheres  $\bar{\epsilon} = 0.000062$ .

Alum.  $\lambda = -12$ , and  $\nu = -0.1033$ .  $\bar{\epsilon} = 0.0001648$ .

Sodium sulphate ( $\text{Na}_2\text{SO}_4 + 10\text{Aq}$ ).  $\lambda = -187$ ,  $\nu = -0.1496$  and  $\bar{\epsilon} = 0.0000351$ .

The three last, therefore, must show increased solubility at high pressures.

The experimental results were as follows: Saturated alum solution dissolved, after 23 hours, 1.1; after 20 hours, 1.8; after 18 hours, 1.3; after 18 hours, 2.9; after 3 hours, 3.27 grams per 100 grams of solution. The greatest change thus corresponded with a pressure of 200 atmospheres, the pressure having evidently fallen off as a result of contraction. Sodium sulphate solution dissolved, after 20 hours, 1.57, and, after 19 hours, 0.92 gram per 100 of solution. The greatest change here corresponded with 500 atmospheres. Sodium chloride solution dissolved, after 36 hours, 0.32, after 28 hours, 0.32 gram per 100 of solution. On the other hand, sal ammoniac solution *deposited* 2.18 grams per 100 of solution after 38 hours. A fall of  $10^{\circ}$  in temperature would be required to produce the same change.

The author has also measured the compressibilities of the salts given below, and of the saturated solutions, by means of Oersted's piezometer. The coefficients were first measured for the solutions,

### *Coefficients of Compressibility.*

|  | Volume.              |                       | Specific gravity. |           | Coefficient of comp. |                       |
|--|----------------------|-----------------------|-------------------|-----------|----------------------|-----------------------|
|  | Salt.                | Solution.             | Salt.             | Solution. | Salt.                | Solution.             |
| $\text{NH}_4\text{Cl}$ .....                   | 7.69 C. <sup>3</sup> | 22.99 C. <sup>3</sup> | 1.533             | 1.073     | $4.9 \times 10^{-6}$ | $38.0 \times 10^{-6}$ |
| Alum (cryst.)...                               | 17.65                | 13.76                 | 1.724             | 1.03      | $1.9 \times 10^{-6}$ | $46.0 \times 10^{-6}$ |
| $\text{NaCl}$ .....                            | 12.25                | 19.23                 | 2.15              | 1.212     | $1.4 \times 10^{-6}$ | $27.0 \times 10^{-6}$ |
| $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$ | 19.1                 | 11.54                 | 1.465             | 1.045     | $7.1 \times 10^{-6}$ | $42.5 \times 10^{-6}$ |

and subsequently from the compressibilities of mixtures of salt and solution; the constants were calculated for the solids. The unit of pressure is one atmosphere, temperature  $1^{\circ}$ .

As a rule, solution is attended by contraction; ammonium chloride, bromide, and iodide, magnesium chloride and tartaric acid, furnish the few known exceptions at ordinary temperatures and pressures. Under other conditions, the final volume of a solution may be assumed to be the same whether the water and salt are separately compressed before mixture, or compressed after mixture; and it may be shown that the rate at which the coefficient of contraction changes with pressure, or  $\partial\nu/\partial p$ , will be negative, nothing, or positive, accordingly as the change of volume of a solution by pressure is  $> = <$  the change of volume of the components. Now for the four solutions investigated, the sum of the compressibilities of the components is always considerably greater than that of the mixture. Three cases are then possible:—1st. The water in the solutions may regain its compressibility in the free state. Evidently then the dissolved salts must expand on compression, which is hardly probable. 2nd. The salts in solution may retain the above determined compressibilities. 3rd. The salts may behave as though incompressible. In either of the latter cases, it can be seen from the table that the compressibility of the water in the solution must be much less than that of pure water ( $= 51 \times 10^{-6}$ ). In all cases, the effect of solution has therefore been to make the water more *rigid*; and since  $\partial\nu/\partial p$  is always positive, the attraction attending solution must diminish, and the dilatation increase, with increased pressure. Again, since for all easily soluble salts, at least up to  $50^{\circ}$ , the coefficient of expansion by heat of a saturated solution is greater than that of a less saturated solution, or of the solid salt; it can easily be shown that  $\partial\nu/\partial t$  is likewise positive. Thus the changes of volume accompanying solution, whether produced by rise of temperature or by increased pressure, always tend toward expansion.

The author shows also that  $\lambda$  must always change in the same sense both with increasing pressure and increasing temperature. The experiments of Winkelmann prove that  $\lambda$  diminishes at high temperatures. With increasing temperature and pressure, it must, therefore, diminish rapidly; and the author suggests that the solution of a solid might mix with the solvent heated above its critical temperature, as soon as  $\lambda$  becomes  $= 0$ .

Is the variation of solubility with temperature due to a change of molecular forces, or to a specific influence of heat? It is conceivable that thermal expansion may alter the molecular forces by changing the distance between the molecules. But in this case all substances which go into solution with diminished volume should be partly precipitated by warming their saturated solutions, which is contrary to experience. The influence of heat on solubility is therefore *specific*, although its exact nature is as yet undecided. Regarding the volume changes due to pressure and to temperature as having equal effect on solubility, the author calculates that the increase due to a specific heat influence alone is equal to the actual increase multiplied by 1.107 for alum; by 1.016 for sodium sulphate; by 4.8 for sodium

chloride; and by 0.596 for sal ammoniac. For sodium chloride, the diminution of solubility due to molecular forces is insignificant when compared with the increase directly due to heat. For ammonium chloride both influences work in the same direction. CH. B.

**Liquid Diffusion.** By J. J. COLEMAN (*Phil. Mag.* [5], **23**, 1—10). Determinations of velocity of diffusion were made by Graham's jar method, and by a burette method in which the solutions were introduced, and the different strata drawn off through the tap at the bottom. The rates of diffusion of mercurous nitrate, mercuric chloride, lithium sulphate, cadmium sulphate, silver sulphate, manganese sulphate, nickel sulphate, and lead nitrate were determined.

The author finds that the velocities of liquid diffusion of the elements vary in a manner similar to that of their atomic volumes, being less for elements at the centre than for those at the ends of the horizontal series in the periodic arrangement. Thus calcium chloride is less diffusible than potassium chloride, and strontium chloride less diffusible than potassium and rubidium chlorides, which have the same diffusive velocity. In this last case, the author supposes that the effect of the large molecular volume of the rubidium chloride is neutralised by the greater molecular weight. In order to examine this point, the author diffused solutions of magnesium and zinc sulphates, which have equal molecular volumes, for 50 days. The magnesium sulphate proved the most diffusive. In the same way, chromic acid was found to be more diffusive than tungstic acid.

The author further considers the equal diffusibility of the chlorides, bromides, and iodides of potassium and sodium, to be due to the neutralisation of the effect of increase of molecular volume by that of increase in molecular weight. The diffusion rate of the sulphates of the 8th periodic group were the same as that of the 2nd or dyads, whilst the monads contrast strikingly with the latter. H. K. T.

**Catalytic Actions.** By O. LOEW (*Ber.*, **20**, 144—145).—When a 15 per cent. solution of formaldehyde is mixed with an equal volume of concentrated aqueous soda, a slight evolution of gas takes place only on warming. The addition of cuprous oxide to the mixture causes an extremely violent evolution of hydrogen, accompanied by a moderate rise of temperature; sodium formate is produced. This evolution of gas could be produced by no other metallic oxide.

Hydroxylamine is very rapidly decomposed by caustic soda in presence of platinum-black. N. H. M.

**Conditions of Equilibrium in Aqueous Solutions: Action of Aqueous Soda on some Normal Sodium Salts.** By T. THOMSEN (*J. pr. Chem.* [2], **35**, 145—161).—When sodium hydroxide is added to a solution of sodium hydrogen tartarate, the molecular rotary power at first increases, and reaches a maximum when the acid is completely converted into neutral salt (*J. pr. Chem.* [2], **34**, 81). Further addition of soda causes a diminution in the rotation, which varies both with the concentration of the solution and with the excess of alkali. Thus, if  $p$  = percentage of acid, and  $n$  = total number of

molecules of NaOH present in the solution, the initial molecular rotation,  $(m)_D = 60.6^\circ$ , of a weak solution of neutral salt ( $p = 2$ ,  $n = 2$ ) becomes  $59.7^\circ$  for  $n = 5$ . On the other hand, when  $p = 18$ ,  $n = 2$ , the initial rotation,  $(m)_D = 57.58^\circ$ , becomes  $18.57^\circ$  when  $n$  is increased to 5. For solutions of intermediate strength, or for intermediate amounts of alkali, the loss of rotatory power lies between the above limits. Other alkalis (KOH,  $\text{NH}_3$ ) produce a slight *increase* of rotation with increased concentration. The effects of the several alkalis are graphically represented by means of curves for the different values of  $n$ , of which the values of  $p$  are abscissæ, those of  $(m)_D$  ordinates. These curves appear to converge to about the same point for low values of  $p$ .

The author explains these results by assuming that in weak solutions soda, even in excess, simply neutralises tartaric acid, but that when the concentration is great a new lævorotatory compound is formed, probably by displacement of the hydroxylic hydrogen of the acid. And, in fact, by very largely increasing the excess of alkali, the rotation is rendered left-handed. Thus, for a 6 per cent. solution of tartaric acid, to which 39 mol. NaOH had been added,  $(m)_D = -38^\circ$ .

Very similar results are obtained with malic and quinic acids. The author has redetermined the molecular rotation of sodium malate. This salt crystallises with extreme difficulty from its syrupy solution, unless brought into contact with previously formed crystals, when it slowly separates as a tough mass of the formula  $\text{Na}_2\text{C}_4\text{H}_4\text{O}_6 + 4\text{H}_2\text{O}$ . The table refers to the anhydrous sodium salt.

| P.    | <i>d.</i> | $(m)_D$ . | P.    | <i>d.</i> | $(m)_D$ . |
|-------|-----------|-----------|-------|-----------|-----------|
| 59.2  | 1.4825    | +6.79°    | 33.9  | 1.2525    | - 5.8°    |
| 57.43 | 1.4615    | +5.96     | 29.93 | 1.2200    | - 7.56    |
| 53.31 | 1.4270    | +4.22     | 25.85 | 1.1880    | - 9.19    |
| 47.75 | 1.3725    | +1.21     | 20.00 | 1.1425    | -11.04    |
| 42.9  | 1.3320    | -1.38     | 15.00 | 1.1040    | -12.36    |
| 36.69 | 1.2750    | -4.52     | —     | —         | —         |

These values differ somewhat, especially for strong solutions, from those found by Schneider (Abstr., 1881, 892). The rotation is thus different in weak and in strong solutions. Excess of soda invariably causes the solution to become more dextrorotatory. For example, excess of 1 mol. NaOH added to a solution containing 14.48 per cent. of malic acid as neutral sodium salt, reduces the molecular rotation from  $-11.24^\circ$  to  $-7.21^\circ$ ; while excess of 3 mol. of alkali changes the rotation of a 20.5 per cent. solution from  $-86.1^\circ$  to  $+19.12^\circ$ . In this case also, the concentrated alkali probably acts on the hydroxyl-group.

Results of the same kind were obtained with quinic acid, which is monobasic but contains four hydroxyl-groups. On the other hand, the right-handed rotation of camphoric acid, which contains no hydroxyl-groups, was not sensibly affected by excess of soda.

The rotation of strong solutions of tartrates varies considerably

with the nature of the base. But by investigating the effect of dilution in each case, it is possible to calculate the molecular rotation for an infinitely dilute solution. Applying this method to the neutral potassium, sodium, and ammonium tartrates, the author shows that the limiting values thus obtained are approximately the same in the three cases, although the molecular rotations for strong solutions are very different. Similar limiting and nearly constant values may be calculated from Schneider's observations on the alkaline malates, and Landolt's on the alkaline quimates.

The author has already shown (Abstr., 1881, 147 and 257) that the molecular rotations of the carbohydrates in aqueous solution tend towards simple multiples of a constant as the dilution is increased; and the same holds for alcoholic solutions of the cinchona alkaloids. In all cases which have been carefully examined, heat acts in the same sense as dilution, and doubtless the action in both cases is of a chemical nature; a conclusion strengthened by the fact that when the rotation of a tartrate is changed from right to left by heat, the transition is perfectly regular (Abstr., 1881, 911).

The polarimetric method can probably be applied to determine the distribution of a base between several acids in solution. CH. B.

**Lecture Experiments.** By A. VALENTINI (*Gazzetta*, 16, 399—401).—In this paper forms of apparatus are described, to show the synthesis of ammonia by the passage of nitrogen and hydrogen over a platinum spiral rendered incandescent by an electric current, and for attaining continuously a flame of nitric oxide and carbon bisulphide. V. H. V.

## Inorganic Chemistry.

---

**Method for Obtaining Chlorine from Chloride of Lime, using Kipp's Apparatus.** By C. WINKLER (*Ber.*, 20, 184—185).—Dry chloride of lime is intimately mixed with burnt gypsum, and moistened to such a degree that it can only with difficulty be rolled into balls between the fingers. It is made homogeneous by powdering with an iron mortar, and beaten into an iron frame 10 to 12 mm. high by means of an iron mallet. It is then covered with a piece of oil-cloth, and submitted to great pressure. The plate of chloride of lime is then cut into cubes whilst still in the frame, taken out whole, and dried as quickly as possible at 20°. The cubes are then preserved in well-closed vessels. It is used in a Kipp's apparatus with hydrochloric acid (sp. gr. 1.124) diluted with an equal volume of water. The acid must be free from sulphuric acid. N. H. M.

**Action of Hydrochloric Acid on Sphalerite.** By F. STOLBA (*Chem. Centr.*, 1887, 169).—The author has previously recommended the preparation of hydrogen sulphide by the action of hydrochloric

acid on sphalerite (zinc-blende), but further experiments have shown that when using an acid of sp. gr. 1.12, the action stops when about one-half of the acid is decomposed. In spite of this, the method is advantageous, and the residual acid liquid can be used for the evolution of hydrogen or carbonic anhydride.

G. H. M.

**Constitution of Acids.** By W. A. DIXON (*Phil. Mag.*, **21**, 127—130).—Inorganic acids may be supposed to contain displaceable hydrogen, 1st, directly combined with the chlorous element,  $\text{HCl}$ , &c.; 2nd, combined as hydroxyl,  $\text{Cl(OH)}$ ,  $\text{N(OH)}$ , &c.; 3rd, as oxyhydroxyl,  $\text{S(OOH)}_2$ , &c.; or partly in each form  $\text{PH(OH)(OOH)}$ ,  $\text{P(OH)}_2(\text{OOH})$ ,  $\text{S(OH)(OOH)}$ ,  $\text{PH}_2(\text{OOH})$ . Acids of the first kind are usually feeble, and their salts have an alkaline reaction, except when they contain strongly chlorous elements. The group  $\text{OOH}$  confers high acidity, which is lost when the hydrogen is displaced by an alkaline metal.

Displacement of hydrogen in hydroxyl by an alkaline metal gives salts having an alkaline reaction. When an acid contains both  $\text{OH}$  and  $\text{OOH}$ , the hydrogen of the latter group will be first displaced; subsequent displacement of the hydroxylic hydrogen will give a salt having an alkaline reaction.

Silicic acid in solution (obtained by diffusion) may exist as  $\text{Si}_2(\text{OH})_2(\text{OOH})_2$ , instead of  $\text{Si(OH)}_4$ , and hence have an acid reaction. To meet certain cases, special assumptions must be made.

Ch. B.

**Metals of Ancient Chaldea.** By BERTHELOT (*Compt. rend.*, **104**, 265—271).—The author has examined four tablets found in a stone receptacle under one of the corner stones of the palace of Sargon, which was built 706 B.C. One of the tablets consists of beaten gold, without any notable proportion of any foreign metal; the second consists of silver, almost equally pure, but more or less altered on the surface; the third has undergone considerable alteration, but the internal metallic portion is an alloy of copper and tin, which contains the two metals in the proportions 85.25 : 10.04, and is therefore similar in composition to the majority of ancient bronzes; the fourth consists of pure crystallised magnesium carbonate, a somewhat rare mineral.

A fragment of a vase found during the excavations at Tello was found to consist of pure metallic antimony, and it is evident therefore that this metal was known to the ancients, although it is confounded with lead by Dioscorides, Pliny, and other writers. A small idol from the same excavations had undergone much superficial alteration, but the internal portion was found to consist of pure metallic copper.

C. H. B.

**Decomposition of Ammonium Chloride by Means of an Alloy of Zinc and Iron.** By H. N. WARREN (*Chem. News*, **55**, 38—39).—A mixture of dry ammonium chloride and finely powdered zinc, alloyed with 12 per cent. of iron, was put into the right-hand limb of a tube, closed at one end, and bent like the letter N, some mercury or liquid amalgam of tin was put in the lower bend, the open end was

then sealed, and the mixture heated. At the termination of the reaction there was a great pressure of hydrogen, and a considerable quantity of ammonium amalgam in the tube. When the experiment was performed without pressure, or with lime instead of zinc, no ammonium amalgam was obtained. The zinc therefore gives rise to the separation of ammonium, which at first decomposes into ammonia and hydrogen, but as the pressure increases this decomposition no longer takes place, but instead the ammonium is made to amalgamate with the mercury.

D. A. L.

**Atomic Weights of Silver and Copper.** By W. N. SHAW (*Phil. Mag.* [5], 23, 138—141).—The author determines the amount of copper deposited from a nearly saturated solution of copper sulphate by electric currents of different current density. He finds that the amount reaches a maximum at the highest limit (0.13 ampère) at which a coherent deposit is obtained. For current densities of 0.02—0.0014 ampère the amount multiplied by  $1 + \frac{0.00002}{d}$ , where  $d$  is the current density, equals that obtained with high current densities.

From these values the author obtains for the atomic weight of copper the value  $63.33 = \frac{19 \times 10}{3}$ , that of silver being taken as  $107.66 = \frac{17 \times 19}{3}$ , hence  $\frac{Ag}{Cu} = \frac{17}{10}$ . Taking one-third the weight of the hydrogen-atom as unit, the possible valencies of silver become 1, 17, and 19; of copper, 1, 2, 5, and 19. The only compound known to the author which supports this view is that formed between molten silver and oxygen, which has approximately the composition  $AgO_{\frac{1}{18}}$ . The author draws attention to the ratio  $\frac{17}{10}$  between the atomic weights of potassium and sodium.

H. K. T.

**Decomposition of Sodium Sulpharsenate with Silver Nitrate.** By K. PREIS and B. RAYMANN (*Chem. Centr.*, 1887, 32).—Silver nitrate acts on sodium sulpharsenate in a different manner when added alone, or together with acid, to what it does when the action takes place in ammoniacal solution. In the latter case, silver arsenate and sulphide are almost entirely formed, together with a little arsenite, the quantity of which depends on the amount of free acid present. Since the reaction is instantaneous, the formation of the arsenite is perhaps due to reduction. The authors suggest the following explanation of its formation:—Arsenic acid is a strong acid, whose thermal effect is equal to that of the strongest acids, whilst on the contrary arsenious oxide possesses feeble acidic properties, and even under certain conditions exhibits basic properties. Therefore if the reaction takes place in presence of ammonia, arsenic acid is formed, whilst in the presence of free acid the feebly basic arsenious trioxide is formed. This theory corresponds with the decomposition of silver nitrate by arseniuretted hydrogen; on passing this gas through

neutral silver nitrate solution, arsenious acid goes into solution, whilst if the silver solution is ammoniacal arsenic acid is formed.

G. H. M.

**Tetracalcium Phosphate and the Phosphoric Acid of Basic Slag.** By H. OTTO (*Chem. Zeit.*, **11**, 255—256).—The author's results confirm those of some other investigators; he finds the crystals separated from basic slag consist of tetracalcium phosphate, and moreover, that the phosphoric acid in the basic slag itself behaves with numerous solvents in the same way as tetracalcium phosphate; with alkaline ammonium citrate, however, this is not the case, owing to the interference of the silica and magnesia present in the slag.

D. A. L.

**Properties of some Metals.** By V. MEYER (*Ber.*, **20**, 497—500).—Magnesium melts at a temperature above the melting point of sodium bromide, melting at  $700^{\circ}$ , and slightly below that of anhydrous sodium hydroxide, melting at  $800^{\circ}$ . Experiments made with the object of determining the vapour-density of the metal have failed, inasmuch as it is impossible to volatilise magnesium at an incipient white heat in a neutral gas, such as hydrogen or carbonic oxide; combination of the elements ensues if nitrogen is employed, whilst carbonic anhydride is reduced to carbon by the metal at this temperature. Porcelain is strongly attacked by magnesium at an incipient white heat.

Germanium does not attack porcelain at about  $1350^{\circ}$ , but is only volatile to a small degree when heated either in hydrogen or nitrogen at this temperature; its vapour-density, therefore, cannot yet be determined. Antimony is completely volatilised at  $1300^{\circ}$ , but not with sufficient rapidity to allow of its vapour-density being determined; further experiments will be made to determine this constant at a higher temperature. The author finds that mercury can be obtained free from metallic impurities by repeated distillation.

W. P. W.

**Effect of Hydrochloric Acid on the Solubility of Chlorides.** By R. ENGEL (*Compt. rend.*, **104**, 433—435).—The relation previously found to exist (*Abstr.*, 1886, 505) between the solubility of chlorides and the proportion of hydrochloric acid in the liquid holds good generally, whether the chlorides belong to the same or different families, and whether they crystallise in the anhydrous or hydrated conditions. Experiments with magnesium and calcium chlorides show that in these cases the sum of the equivalents of the chlorides and hydrochloric acid in the liquid remains constant.

The author criticises Jeannel's conclusion (*Abstr.*, 1886, 972), and considers that his results were due to the fact that the proportion of water added was relatively large compared with the quantities of metallic chloride and hydrochloric acid present.

The precipitation of the chlorides cannot be attributed to the combination of the hydrochloric acid with the water. The solubility of different chlorides is very different, and it would be necessary for the hydrochloric acid to combine with a different amount of water in each case. Both the water of crystallisation of the hydrated chlorides,

and the water combined with the hydrochloric acid play the part of solvents; the action is the same both for anhydrous chlorides and for hydrated chlorides calculated to the anhydrous condition.

Similar results have been obtained with nitric acid and nitrates, but with sulphuric acid and sulphates the phenomena are different.

C. H. B.

**Pure Zinc, from the Bertha Zinc Company, Pulaski Co., Virginia.** By G. B. BIRD (*Amer. Chem. J.*, 8, 431).—By redistilling commercial spelter from a fire-clay retort with iron front, the amount of impurities is reduced with exception of the iron, which is scarcely diminished.

H. B.

**Analysis of Shot.** By H. HARDAWAY (*Amer. Chem. J.*, 8, 432).—Several commercial brands of bird-shot were analysed, especially for arsenic; the amount found, namely, 0.4—3.0 part per 1,000, proved to be less than that usually stated (3 to 8 or 10 parts).

H. B.

**Preparation of Lead Carbonate.** By W. KUBEL (*Dingl. polyt. J.*, 262, 143).—Lead oxide is readily converted into the soluble hydroxide on treatment with a moderately concentrated solution of magnesium acetate. The solution thus obtained has an alkaline reaction, and yields lead carbonate when treated with carbonic anhydride. The white precipitate is collected, washed, and dried, and the solution of magnesium acetate concentrated and used for another operation.

D. B.

**Action of Lead Oxide on Soluble Chlorides.** By G. ANDRÉ (*Compt. rend.*, 104, 359—360).—If a concentrated solution of calcium chloride is boiled with an excess of lead oxide, care being taken to prevent evaporation, and the liquid is filtered, the filtrate deposits an abundant precipitate, which after washing with alcohol and drying has the composition  $\text{CaCl}_2, \text{CaO}, 2\text{PbO} + 4\text{H}_2\text{O}$ . When boiled with water it becomes yellow. If the water is left out of account this compound may be regarded as crystallised calcium oxychloride in which 2 mols. of calcium oxide have been replaced by 2 mols. of lead oxide. When the mother-liquor, which is slightly alkaline, is poured into a large excess of cold water, the compound  $\text{PbCl}_2, 3\text{PbO} + 3\text{H}_2\text{O}$  is obtained as an amorphous white precipitate.

A solution of barium chloride when treated in a similar manner yields small slender needles which seem to be a compound of barium chloride with lead oxychloride, but they are decomposed immediately by water and yield lead oxychloride.

Strontium chloride yields small, distinct, brilliant crystals which when washed with alcohol and dried have the composition  $\text{SnCl}_2, 2\text{PbO}, 5\text{H}_2\text{O}$ . If the mother-liquor is poured into excess of water the compound  $\text{PbCl}_2, 3\text{PbO}, 3\text{H}_2\text{O}$  is precipitated.

Lead oxide is dissolved by either a hot or a cold solution of magnesium chloride, but the filtered liquid deposits no precipitate, and only a very slight precipitate is obtained when the solution is poured into an excess of water.

C. H. B.

**Analysis of a Copper Slag of Bright Red Colour.** By N. A. BERRY (*Amer. Chem. J.*, **8**, 429—430).—The slag is hard, breaks with conchoidal fracture, and contains small cavities and very minute metallic beads. Treated with hydrochloric and nitric acids, 30·23 per cent. dissolved (27·05 per cent. cuprous oxide), and there remained a yellow powder containing  $\text{Cu}_2\text{O} = 8\cdot64$ ;  $\text{FeO} = 11\cdot69$ ;  $\text{SiO}_2 = 49\cdot24$ .  
H. B.

**Composition of Mirror Amalgam.** By G. HARRISON (*Amer. Chem. J.*, **8**, 430—431).—The amalgam from a German mirror was found to contain tin 83·78 per cent., mercury 16·60 per cent.  
H. B.

**Mercurous Hydroxide.** By G. B. BIRD (*Amer. Chem. J.*, **8**, 426—427; compare *Abstr.*, 1885, 124).—Solutions of mercurous nitrate and of caustic potash in alcohol of 70 per cent., were cooled to  $-42^\circ$  and mixed; but little precipitate was formed and that slowly, its colour was a pale amber, changing with rise of temperature into the colours of mixtures of mercurous oxide, mercuric oxide, and finely divided mercury. Judging from the colours of the corresponding lead, copper, and silver compounds, it appears very probable that the pale amber-coloured precipitate obtained was mercurous hydroxide.  
H. B.

**Action of Mercuric Oxide on Dissolved Chlorides.** By G. ANDRÉ (*Compt. rend.*, **104**, 431—433).—Klinger has described a compound,  $\text{CaCl}_2 \cdot 2\text{HgO} + 4\text{H}_2\text{O}$ , and this the author has also obtained by the action of mercuric oxide on a solution of calcium chloride. The mother-liquor is not precipitated by cold water. If a solution of mercuric oxide in a boiling and concentrated solution of calcium chloride is poured into a large excess of cold water, a brick-red precipitate is obtained which when dried at  $100^\circ$  has the composition  $\text{HgCl}_2 \cdot 3\text{HgO}$ . It is analogous to and possibly identical with the oxychloride obtained by Millon by mixing equal volumes of cold saturated solutions of mercuric chloride and potassium hydrogen carbonate.

A boiling solution of barium chloride, saturated with yellow mercuric oxide and allowed to cool, deposits needles of the compound  $\text{BaCl}_2 \cdot \text{HgO} + 6\text{H}_2\text{O}$ , analogous to the barium oxychloride previously described. When treated with water, it becomes yellow. It loses nearly 5 mols.  $\text{H}_2\text{O}$  at  $100^\circ$  and the rest at  $150^\circ$ . If heated in a tube, it gives off water, becoming yellow and finally white. Red mercuric oxide gives the same compound, which, when decomposed by water, yields the red oxide. If the mother-liquor of the oxychloride is poured into cold water, only a slight precipitate is formed.

Strontium chloride solution under similar conditions yields the compound  $\text{SrCl}_2 \cdot \text{HgO} + 6\text{H}_2\text{O}$  in long, slender needles, which lose 3·5 mols.  $\text{H}_2\text{O}$  at  $100^\circ$  and the rest at  $130^\circ$ . It is analogous to strontium oxychloride but contains 3 additional mols.  $\text{H}_2\text{O}$ . Only a slight precipitate is formed when the mother-liquor is poured into cold water.

A cold saturated solution of magnesium chloride dissolves yellow mercuric oxide when heated, but the liquid deposits no compound on

cooling. If poured into a large excess of water, it yields a white amorphous precipitate of the composition  $2\text{HgCl}_2, 3\text{HgO}$ .

The general results show that these mixed compounds are true oxychlorides which are sometimes strictly analogous to the simple oxychlorides, whilst sometimes their composition is not exactly similar. Both classes of compounds agree in their alterability in contact with water.

C. H. B.

**Basic Aluminium Sulphate.** By K. J. BAYER (*Chem. Zeit.*, **11**, 38; 97—98).—A basic aluminium sulphate,  $3\text{Al}_2\text{O}_3, 2\text{SO}_3 + 9\text{H}_2\text{O}$ , is produced when excess of aluminium hydroxide, prepared by precipitation by means of carbonic anhydride, is boiled for some time with sulphuric acid. This basic sulphate is practically insoluble in sulphuric or hydrochloric acid, for even on prolonged digestion with sulphuric acid, sp. gr. 1.3—1.4, only part of it passes gradually into solution. It is, however, completely soluble in aqueous soda. At  $100^\circ$ , or over sulphuric acid, it does not lose water, but when heated to low redness it loses 9 mols.  $\text{H}_2\text{O}$  without further decomposition, whilst at a bright red heat it decomposes with evolution of sulphurous anhydride. The slightly ignited and anhydrous salt yields a basic sulphate to water which is precipitated on boiling. When the basic sulphate described above exists in aluminium sulphate, it is a sure sign that the latter has been prepared by the alkaline process.

D. A. L.

**Fluorine and Manganese Compounds.** By O. T. CHRISTENSEN (*J. pr. Chem.*, **35**, 161—181; compare this vol., p. 335).—*Chromium potassium fluoride*,  $6\text{KF}, \text{Cr}_2\text{F}_6$ , is obtained by fusing chromic hydroxide with an excess of potassium hydrogen fluoride and extracting the residue in the cold with water containing hydrogen fluoride; it is a green, crystalline powder practically insoluble in water, and yields insoluble chrome alum on evaporation with concentrated sulphuric acid. The compound  $4\text{KF}, \text{Cr}_2\text{F}_6 + 2\text{H}_2\text{O}$ , prepared by mixing solutions of its constituents, is a green salt very sparingly soluble in water, but soluble in hydrochloric acid.

*Iron potassium fluoride*,  $4\text{KF}, \text{Fe}_2\text{F}_6 + 2\text{H}_2\text{O}$ , is prepared by fusing ferric hydroxide with an excess of potassium hydrogen fluoride; it is a white, crystalline powder, very sparingly soluble in water, and the solution gives no reaction with potassium thiocyanate. This salt is probably identical with that described by Nicklès containing 1 mol.  $\text{H}_2\text{O}$  (*J. Pharm.* [4], **7**, 15).

*Manganese ammonium fluoride*,  $4\text{NH}_4\text{F}, \text{Mn}_2\text{F}_6$ , is obtained by mixing a solution of manganosomanganic oxide in hydrofluoric acid with one of ammonium fluoride, ether as a red, crystalline salt, or in dark, prismatic crystals, and is sparingly soluble in water containing hydrogen fluoride. The *sodium* salt,  $4\text{NaF}, \text{Mn}_2\text{F}_6$ , is a red, crystalline powder, consisting of microscopic, rectangular tables; the *silver* salt,  $2\text{AgF}, \text{Mn}_2\text{F}_6 + 8\text{H}_2\text{O}$ , forms dark, almost black crystals, and loses the greater part of its water of crystallisation at  $100^\circ$ , the remainder at  $110^\circ$ . When manganese fluoride is added to a solution of chloropurpureocobalt carbonate in hydrofluoric acid, chloropur-

pureocobalt manganese fluoride is obtained as a lustrous, crystalline precipitate consisting of microscopic rectangular tables.

Berzelius has shown that when aluminium hydroxide is boiled with a solution of sodium fluoride, cryolite is formed, and Schuch has pointed out that aluminium hydroxide is obtained when cryolite is boiled with sodium hydroxide; the author has endeavoured to find out the conditions of equilibrium for these changes, and proves that there is a definite limit to the first reaction, but not to the second, owing to the fact that the separated sodium fluoride encloses unaltered cryolite and protects it from further action. Sodium fluoride solution is not decomposed when boiled with ferric, chromic, or manganic hydroxides. The author considers the double fluorides and double cyanides of the iron-aluminium-group to be analogous in constitution.

W. P. W.

**Solubility of Manganese Sulphide in Fused Potassium Sulphide.** By E. CLAASSEN (*Amer. Chem. J.*, **8**, 436—437).—When fusing magnetite with soda and sulphur for the purpose of detecting vanadium, it was found that a considerable amount of manganese was also extracted from the fused mass by treatment with water.

H. B.

**Preparation of Ammonium Dichromate.** By J. J. HOOD (*Chem. Zeit.*, **11**, 55).—Chrome-iron ore is heated with sodium or potassium salts, the resulting monochromate is dissolved in water, treated with 2 equivalents of acid, and then neutralised with ammonia or ammonium carbonate. The solution containing a dichromate and a sulphate, chloride, or nitrate, as the case may be, is concentrated, the latter salts as they crystallise are removed, and finally on cooling ammonium dichromate crystallises out. The potassium or sodium salts are used again for heating with fresh chrome-iron ore.

D. A. L.

**Extraction of Vanadium and Chromium from Iron Ores, particularly from Magnetite.** By E. CLAASSEN (*Amer. Chem. J.*, **8**, 437—443; comp. Abstr., 1886, 428).—It is impossible to obtain in a soluble form all the vanadium and chromium contained in certain ores (especially hard dense ores like magnetite), by fusion with sodium carbonate and nitre or sulphur. The finely powdered ore, if treated with water (1 part) and sulphuric acid (2 parts), and then gradually heated until all sulphates are decomposed, is converted into the finest possible powder, and from this the vanadium and chromium may be completely extracted by a single fusion. If only vanadium is to be estimated, the following is the better method of procedure, as a solution free from chromium is at once obtained. The powder left after treatment with sulphuric acid is fused with three parts of soda and three of sulphur, the melt extracted with water, the filtrate containing a thiovanadate boiled with dilute nitric acid, and the precipitated vanadium sulphide collected, dried, and excess of sulphur removed by treatment with carbon bisulphide; the filtrate, which always contains some vanadium, is evaporated to dryness, mixed with the precipitated sulphide, and fused with a little soda. The fused mass is extracted with water, and the filtrate which

contains a vanadate and also nitrites, is made neutral by continued boiling with small quantities of ammonium nitrate, and precipitated by lead nitrate. The washed lead vanadate is digested with hydrochloric acid and alcohol, and the lead chloride removed by filtration and washing with alcohol; the alcoholic filtrates are evaporated, redissolved in water, and the last trace of lead removed by hydrogen sulphide; the filtrate when evaporated and ignited leaves impure vanadium pentoxide; it is oxidised by ignition with ammonium nitrate, extracted with ammonia, and finally obtained pure by evaporation and ignition.

If both vanadium and chromium are to be estimated, the following method may be substituted, both being extracted together from the ore and then separated afterwards. The ore after the treatment with sulphuric acid is fused with thrice its weight each of soda and nitre, and the soluble portion dissolved out by water. The solution is made neutral by boiling with ammonium nitrate, then precipitated by lead acetate, and the lead removed as before described. The dried residue containing chromium and vanadium is fused with three parts of soda and three of sulphur, and the mass extracted with water. The filtrate containing the vanadium is treated as before; the residue containing the chromium is fused with alkali and nitre, and precipitated as usual as lead chromate. H. B.

**Gold.** By G. KRÜSS (*Annalen*, **237**, 274—307; compare this vol., pp. 15, 340).—Only three oxides of gold exist, namely:  $\text{Au}_2\text{O}$ ,  $\text{Au}_2\text{O}$ ,  $\text{Au}_2\text{O}_3$ , and  $\text{Au}_2\text{O}_3$ . These oxides have been previously described by the author (*loc. cit.*).

Oberkampff (*Ann. Chim.*, **80**, 140), Figuier (*Ann. Chim. Phys.* [3], **11**, 336), Buisson (*J. Pharm.*, **16**, 629), and Russell (this Journ., 1874, 11) state that gold is precipitated by hydrogen from a solution of auric chloride. This is denied by Proust (*J. Phys.*, **62**, 131) and Schweigger-Seidel (*Schweigger's Journ.*, **65**, 268). The author finds that hydrogen which has been purified by passing through solutions of sodium hydroxide, silver nitrate, potassium permanganate, and over red-hot copper, has no action on auric chloride.

The discrepancies between the author's results and Raschig's (this vol., p. 112) arise from two sources. Aurous oxide prepared by the action of mercurous nitrate on auric chloride contains mercury. The formula  $\text{Au}_2\text{O} + 2\text{H}_2\text{O}$ , which Raschig obtained for the oxide dried over phosphoric anhydride, is consequently incorrect.

Auric oxide and auric chloride are not reduced by pure sodium hydroxide. If the sodium hydroxide contains organic matter, oxides of gold are precipitated, but auric acid is not formed.

W. C. W.

**Formation of Platinum Silicide.** By F. P. MILES (*Amer. Chem. J.*, **8**, 428; compare Abstr., 1886, 124).—The conditions under which platinum silicide was formed, are found to be the presence of reducing gases such as carbonic oxide, of silicon tetrafluoride, and of a basic substance such as magnesia. H. B.

---

## Mineralogical Chemistry.

**Composition of the Black Zinc Blende of Freiberg.** By A. STELZNER and A. SCHERTEL (*Chem. Centr.*, 1887, 92).—The analysis of black blende from five different veins in the Freiberg district gave the following numbers:—Zn, 49·83—51·73; Fe, 11·97—13·44; S, 32·51—33·69; Mn, 0·08—0·83; Cd, 0·19—0·42; Sn, 0·06—0·55; In, traces. The tin is present as sulphide; the ratio of zinc to iron is nearly 3·3 : 1. The mechanical impurities were small quantities of tinstone and quartz. Both these impurities, amounting to 0·6—1·0 per cent., were present in blende from 10 different localities.

The tinstone belongs to the type of needle-tinstone, and forms columnar, often twinned crystals, about 0·8 mm. long, which are often embedded in the blende, and often in the quartz. The latter is in the form of small, irregular crystals of the combination  $P\infty P$ , and sometimes encloses blende. The formation of zinc-blende, tinstone, and quartz, must, therefore, generally have taken place simultaneously in the Freiberg district. G. H. M.

**Quartzite.** By P. HOLLAND (*Chem. News*, 55, 49—50).—The specimen examined was taken from stone quarries at Nill's Hill, Pontesbury. A detailed description and a figure of its appearance under the microscope are given; it proved to be a compact felspathic quartzite. The analytical numbers obtained from it were as follows:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | K <sub>2</sub> O. | Na <sub>2</sub> O. | Carbon. | Combined water. |
|--------------------|----------------------------------|----------------------------------|-------------------|--------------------|---------|-----------------|
| 94·85              | 2·38                             | 0·62                             | 0·67              | 0·71               | 0·07    | 0·63            |

In some darker-coloured fragments the carbon amounted to 0·13 per cent. D. A. L.

**Plattnerite.** By E. KINCH (*Min. Mag.*, 7, 63—64).—A mineral from Leadhills, Lanarkshire, analysed by the author, proved to be plattnerite, a mineral not examined since it was first noticed by Breithaupt and Plattner in 1837. The following are the analytical results obtained:—

| Loss on ignition. | PbO.  | Total. |
|-------------------|-------|--------|
| 7·10              | 92·66 | 99·76  |

It is a black mineral in globulous concretions with crystalline exterior. The hardness is about 5. The sp. gr. is 8·54, or somewhat lower than that given by Breithaupt. B. H. B.

**New Variety of Dufrenite from Cornwall.** By E. KINCH, F. H. BUTLER, and H. A. MIERS (*Min. Mag.*, 7, 65—70).—The authors have examined examples of crystallised mineral from East Cornwall, presenting features dissimilar from those of any known species, but presumably referable to dufrenite. The unaltered crystals have a

vitreous lustre, and vary in colour from black to apple-green. The crystals occur in the form of rectangular tables, 1 to 2 mm. square and  $\frac{3}{4}$  mm. thick. They may be regarded as orthorhombic plates formed by the micropinacoid faces, bevelled at the sides by small faces of the prism, and bounded at the top and bottom by the basal planes. The crystallographic characters agree very closely with those of dufrenite from Waldgirmes, described by A. Streng (Abstr., 1881, 527). The green crystals have a hardness of 4·5, and a sp. gr. of 3·233. Analysis gave the following results:—

| H <sub>2</sub> O. | SiO <sub>2</sub> . | CuO. | P <sub>2</sub> O <sub>5</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | MgO.  | Total. |
|-------------------|--------------------|------|---------------------------------|----------------------------------|------|-------|--------|
| 10·62             | 0·53               | 0·95 | 30·26                           | 55·63                            | 1·50 | trace | 99·49  |

These results are compared with the various published analyses of dufrenite, and the authors conclude that the mineral described, as well as other varieties described under the head of dufrenite, contains a larger proportion of phosphoric acid to base than is compatible with the usual formula for dufrenite,  $2\text{Fe}_2\text{O}_3, \text{P}_2\text{O}_5, 3\text{H}_2\text{O}$ . The species should, therefore, be divided into two, one having the formula  $5\text{Fe}_2\text{O}_3, \text{P}_2\text{O}_5, 8\text{H}_2\text{O}$ , or possibly, in some cases, less water.

B. H. B.

**Talc used in Paper-making.** By W. I. MACADAM (*Min. Mag.*, 7, 75).—This mineral, known in commerce as *agalite*, is obtained from New Jersey. It is largely used for paper-making in place of kaolin, and gives a much purer effluent. The high glaze of American paper is largely due to the use of this mineral. It is of a highly fibrous character, insoluble in water, and greasy to the touch. In colour, it is almost pure white. Its sp. gr. varies from 2·22 to 2·562. Analysis gave the following results:—

| SiO <sub>2</sub> . | MgO.  | FeO. | Al <sub>2</sub> O <sub>3</sub> . | H <sub>2</sub> O. | Loss. | Total. |
|--------------------|-------|------|----------------------------------|-------------------|-------|--------|
| 62·08              | 33·13 | 0·10 | 0·31                             | 4·29              | 0·09  | 100·00 |

B. H. B.

**Phenacite from Colorado.** By S. L. PENFIELD (*Amer. J. Sci.*, 33, 130—134).—The occurrence of phenacite in the United States was first mentioned by Cross and Hillebrand (Abstr., 1883, 1065). Crystallographical descriptions of the phenacite from Florissant have also been published by Hidden (Abstr., 1885, 878; and 1887, 118). The crystals occur at Topaz Butte, near Florissant, and about 16 miles from Pike's Peak. They are remarkably similar to those described by N. v. Kokscharoff from the Ural. The planes observed are of especial interest as belonging to the rhombohedral-tetartohedral division of the hexagonal system.

The author also describes some remarkable crystals from a new locality, Mt. Antero, in Chaffee Co. They are terminated mainly by rhombohedra of the third order.

B. H. B.

**The Crystal Beds of Topaz Butte.** By W. B. SMITH (*Amer. J. Sci.*, 33, 134—135).—The *crystal beds* from which most of the specimens labelled *Pike's Peak* have actually come are situate 20 miles north-west of that point. Topaz Butte, a point 5 miles north of Florissant, marks the southern limit of the beds. The largest phenacite

cite ever found in this locality is a lenticular crystal, 15 mm. in diameter.

A few phenacite crystals have been observed in the interior of smoky quartz and amazon-stone crystals: these minerals showing no evidence of secondary growth. Phenacites have also been found half in quartz and half in amazon-stone, when the two minerals are in contact.

B. H. B.

**Topaz from the Thomas Range, Utah.** By A. N. ALLING (*Amer. J. Sci.*, 33, 146).—The topaz crystals examined were found in the Thomas Range, 40 miles north of Sevier Lake, where they occur in rhyolite (compare W. Cross, *Abstr.*, 1886, 991). They vary from 3 to 10 mm. in length, and are perfectly colourless. The planes observed were  $\infty P\infty$ ,  $0P$ ,  $\infty P$ ,  $\infty P2$ ,  $2P\infty$ ,  $2P\infty$ ,  $4P\infty$ ,  $\frac{2}{3}P$ ,  $P$ ,  $2P$ ,  $4P$ . The axial ratio was calculated to be

$$a : b : c = 0.5285 : 1 : 0.47715,$$

values approximating very closely to those obtained by v. Kokscharoff for the Siberian crystals, but varying very widely from the axial ratios for crystals from Ehrenfriedersdorf, Altenberg, Schneckenstein, and Brazil.

B. H. B.

**Occurrence of Strontia in Heulandite.** By P. JANNASCH (*Ber.*, 20, 346—349).—The following analyses of heulandite from different localities are given:—

|                                      | Andreasberg. | Farsathal. |       | Teigashorn. |
|--------------------------------------|--------------|------------|-------|-------------|
|                                      |              | 60.07      | 57.71 |             |
| SiO <sub>2</sub> .....               | 56.11        | 14.75      | 16.42 | 58.48       |
| Al <sub>2</sub> O <sub>3</sub> ..... | 17.15        | 0.62       | —     | 16.44       |
| Fe <sub>2</sub> O <sub>3</sub> ..... | trace        | 4.89       | 6.96  | —           |
| CaO .....                            | 4.26         | 1.60       | 0.54  | 7.00        |
| SrO .....                            | 3.63         | —          | —     | 0.35        |
| MgO .....                            | trace        | 2.36       | 1.49  | —           |
| Na <sub>2</sub> O .....              | 3.31         | 0.44       | 0.35  | 1.40        |
| K <sub>2</sub> O .....               | 0.27         | trace      | trace | 0.21        |
| Li <sub>2</sub> O .....              | trace        | 15.89      | 16.50 | trace       |
| H <sub>2</sub> O .....               | 16.28        |            |       | 16.45       |

The formula of heulandite would therefore be

In order to separate the calcium from the strontium, they are precipitated from the weak ammoniacal solution as oxalates, the precipitate redissolved and again precipitated. The ignited mixture of earths is converted into nitrates, and separated by means of alcohol and ether. The undissolved strontium salt is then dissolved in hot water, precipitated with dilute sulphuric acid in presence of alcohol, and weighed as sulphate.

N. H. M.

**Sodium Felspar from Krageroe, Norway.** By BISCHOF (*Chem. Centr.*, 1887, 169—170).—This is of a brownish colour without any

distinct foreign markings, and with fine mother-of-pearl-like laminations. Dried at 100°, its composition is—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. | H <sub>2</sub> O. |
|--------------------|----------------------------------|----------------------------------|------|------|-------------------|--------------------|-------------------|
| 65·35              | 21·66                            | 0·64                             | 1·79 | 0·16 | 0·52              | 9·88               | 0·25              |

showing that it is a sodium felspar containing a noteworthy amount of lime. It melts more easily than the potassium felspar from Norway.

G. H. M.

**Occurrence of Silver in Volcanic Ash from the Eruption of Cotopaxi, July 22nd—23rd, 1885.** By J. W. MALLET (*Chem. News*, 55, 17).—The sample was collected at Bahia de Caraguez, where ash had fallen to the depth of several inches although the place is 120 miles to the westward of Cotopaxi. The specimen consisted of a very fine, mobile powder soft to the touch and of a light brownish-grey colour. Under the microscope it appeared to consist of minute, more or less sharp or splintery-edged granules and spicules; quartz, a white and pink or reddish felspar, augite, magnetite (strongly magnetic), and thin scales of deep red specular iron oxide were easily distinguished. When strongly heated, the ash turned dark red-brown, and fused to a nearly black slag. Its sp. gr. = 2·624 at 18°; 0·21 per cent. of the ash was soluble in boiling water and 6·94 per cent. was dissolved by hydrochloric acid from the portion insoluble in water. The ash dried at 100° contained per cent.—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | MgO. | CaO. | Na <sub>2</sub> O. | K <sub>2</sub> O. | H <sub>2</sub> O. |
|--------------------|----------------------------------|----------------------------------|------|------|------|--------------------|-------------------|-------------------|
| 56·89              | 19·72                            | 4·06                             | 3·65 | 1·91 | 5·87 | 5·14               | 1·96              | 0·62              |

with traces of TiO<sub>2</sub>, MnO, Li<sub>2</sub>O, Ag, Cl, SO<sub>3</sub>, P<sub>2</sub>O<sub>5</sub>.

The silver present amounted to about 1 part in 83,600 of ash, but although the proportion is so small the total amount ejected during the eruption would be considerable when the vastness of the mass of volcanic ash is taken into consideration. The silver was probably present as chloride. This is the first time silver has been found in volcanic ash.

D. A. L.

**Diabase Porphyrite from the Neighbourhood of Petrosawodsk.** By C. v. VOGDT (*Chem. Centr.*, 1887, 200).—The masses of rock running through the diluvium in the form of *roches moutonnées* belong partly to forms rich in augite and partly to forms rich in felspar. Only the latter were submitted to further examination. The porphyritic felspar occurs as orthoclase frequently mixed with oligoclase and labradorite and entirely converted into radial aggregates; whilst the ground-mass, which is rich in epidote, appears to consist chiefly of an albitic felspar. The augite is very chloritic.

G. H. M.

**Meteoric Iron from Augusta Co., Virginia.** By G. F. KUNZ (*Amer. J. Sci.*, 33, 58—59).—This mass of meteoric iron was found near the place where the largest of the three masses from Augusta Co., described by Mallet (*Abstr.*, 1871, 1020), was found. Its present dimensions are 8·5 cm. by 6·5 cm., 7 cm. at the wider end and 3 cm. at the smaller end. The following is an analysis of the mass:—

| Fe.    | Ni.   | Co.   | Cu.   | Sn.     | P.    | S.    |
|--------|-------|-------|-------|---------|-------|-------|
| 90·293 | 8·848 | 0·486 | 0·016 | 0·005   | 0·243 | 0·012 |
| C.     |       | Si.   |       | Total.  |       |       |
| 0·177  |       | 0·092 |       | 100·072 |       |       |

with traces of manganese, chromium, and chlorine.

B. H. B.

**Coahuila Meteorites.** By O. W. HUNTINGTON (*Amer. J. Sci.*, **33**, 115—118).—The author shows that the assumed new meteorite found near Fort Duncan, Maverick Co., Texas, and described by W. E. Hidden (this vol., p. 119), belongs to the same fall as the meteorites described by J. L. Smith under the head of Coahuila irons, and supposed to belong to one fall. The irons referred to are, the Santa Rosa Sancha Estate iron, found in 1850; the Butcher iron, found in 1866; the San Gregorio iron; and the Chihuahua Hacienda de Conception iron.

B. H. B.

**Supposed Metallic Meteorite from Highland Co., Virginia.** By F. P. MILES (*Amer. Chem. J.*, **8**, 427—428).—The metal contains Fe = 99·716, P = 0·106, C = 0·032, S = 0·058, but nickel and cobalt are absent. It is probably a relic from an early bloomery fire, although there are no records of such in the neighbourhood.

H. B.

**Analysis of the Water from an Artesian Well in the Tunisian Chotts, and from the Spring at Oued Ref.** By DE LESSEPS (*Compt. rend.*, **104**, 272).

|                    | CaCO <sub>3</sub> . | MgCO <sub>3</sub> . | CaSO <sub>4</sub> . | MgSO <sub>4</sub> . | Na <sub>2</sub> SO <sub>4</sub> . |

C. H. B.

**Water from the Wells of Zemzem.** By P. v. ROMBURGH (*Rec. Trav. Chem.*, **5**, 565—273).—The waters from the wells of Zemzem, or Hagar's Wells, near Mecca, have been celebrated for centuries past as holy to Mussulmans and as possessing therapeutic value; it is even probable that to them the town of Mecca owes its origin. For some time, the water supply was taken from the wells, but as this was regarded as sacrilege, other sources were subsequently used. It appears that as the supply of water is almost inexhaustible, it arises from one stream flowing underground; there is, however, reason to believe that it is being contaminated by the sewage of Mecca. The results of analysis in gram per litre are as follows:—

| Cl.    | SO <sub>3</sub> . | N <sub>2</sub> O <sub>5</sub> . | CO <sub>2</sub> . | SiO <sub>2</sub> .              | CaO.  | MgO.  |
|--------|-------------------|---------------------------------|-------------------|---------------------------------|-------|-------|
| 0·5563 | 0·3955            | 0·7255                          | 0·317             | 0·0472                          | 0·412 | 0·152 |
|        |                   | Na <sub>2</sub> O.              | K <sub>2</sub> O. | P <sub>2</sub> O <sub>5</sub> . |       |       |
|        |                   | 0·5776                          | 0·2719            | trace                           |       |       |

The sp. gr. at 18° was 1·0025. A bacteriological examination of the water gave no particular results. P. Frankland in 1881 made an analysis of a sample of water from Hagar's Well; the results, however, were different from those given above; either the water undergoes considerable changes or, more probably, the two samples were not taken from the same source.

V. H. V.

## Organic Chemistry.

**Vaselin.** By C. ENGLER and M. BOEHM (*Dingl. polyt. J.*, **262**, 468—475 and 524—530).—The authors call vaselin the substance extracted from petroleum residues, whilst the mixture of heavy mineral oil (*Paraffinum liquidum*) with ceresine (*Paraffinum solidum*) is regarded as "artificial vaselin." For the preparation of the natural product, two Galician oils were used. Both oils were highly dichroic, had a green colour by reflected light and a colour varying from yellowish to brownish-red by transmitted light, and exhibited the following properties when subjected to distillation.

|         | Sp. gr.<br>at 15°. | Fraction below 150°. |                         | 150° to 200°.        |                         |
|---------|--------------------|----------------------|-------------------------|----------------------|-------------------------|
|         |                    | per cent.<br>by vol. | per cent.<br>by weight. | per cent.<br>by vol. | per cent.<br>by weight. |
| Oil I.. | 0·812              | 30·2                 | 26·7                    | 35·9                 | 35·5                    |
| „ II..  | 0·820              | 21·8                 | 20·0                    | 51·7                 | 51·2                    |

|            |  | 290° to 340°.        |                         | Above 340°.          |                         |
|------------|--|----------------------|-------------------------|----------------------|-------------------------|
|            |  | per cent.<br>by vol. | per cent.<br>by weight. | per cent.<br>by vol. | per cent.<br>by weight. |
| Oil I .... |  | 5·3                  | 6·5                     | 27·7                 | 31·1                    |
| „ II ....  |  | 8·8                  | 9·4                     | 17·0                 | 18·9                    |

For the production of vaselin from these oils, two methods were employed, the first consisting in dissolving the residues in petroleum spirit, bleaching the solution by filtration through animal charcoal, and expelling the solvent by distillation with steam, whilst the second method involved bleaching the oil and subjecting it to distillation in a vacuum (mercury column = 10—15 mm.) to 250°. The product obtained according to the first process formed a colourless, translucent pasty mass melting at 32° and exhibiting no crystalline structure, even on application of cold. The vaselin extracted from the bleached oils was colourless, translucent, and free from odour. It had the following properties:—

|             | Yield. | Sp. gr. | Melting point. |
|-------------|--------|---------|----------------|
| Oil I ..... | 13·8   | 0·8809  | 30—31°         |
| „ II .....  | 13·2   | 0·8785  | 30—31          |

The composition of the different vaselins is illustrated in the subjoined table.

|        | From residues. |       | From Petroleum Oil I. |       |       | From<br>Petroleum Oil II. |       |
|--------|----------------|-------|-----------------------|-------|-------|---------------------------|-------|
| C .... | 86.99          | 86.67 | 86.30                 | 86.54 | 86.55 | 86.14                     | 86.17 |
| H .... | 13.14          | 13.15 | 13.99                 | 13.73 | 13.74 | 13.50                     | 13.72 |

These results show that vaselin is composed exclusively of hydrocarbons. The oils obtained by subjecting the bleached petroleum to fractional distillation were also found to contain only carbon and hydrogen, both oxygen and sulphur being absent. The bleaching process appears to remove all oxygenated constituents and increase the amount of saturated hydrocarbons, the charcoal retaining the less highly hydrogenised hydrocarbons. Attempts were made to increase the melting point of vaselin by subjecting it to partial redistillation. It was not, however, possible to raise the melting point more than two or three degrees, whilst prolonged distillation resulted in reducing the melting point, probably owing to decomposition of the vaselin. By dissolving vaselin in ether and subjecting the ethereal solution to fractional precipitation with alcohol, the authors succeeded in separating a solid and liquid substance from vaselin. 100 grams gave 40.8 grams of solid vaselin of 0.8836 sp. gr., melting at  $40^{\circ}$ , and 59.2 grams of liquid vaselin of 0.8809 sp. gr., solidifying at  $-10^{\circ}$ . Both products had the same constitution, and approximately the same boiling points. American vaselin melting at  $32-33^{\circ}$  yielded 14 per cent. of solid vaselin melting at  $49-50^{\circ}$  and 86 per cent. of liquid vaselin. It is possible to separate "artificial vaselin" into a solid and liquid substance, but the chemical and physical properties of the component parts are essentially different.

D. B.

**Piperilene.** By G. MAGNANIMI (*Gazzetta*, **16**, 390—392).—Piperilene,  $C_8H_8$ , on bromination, forms two isomeric tetrabromo-compounds,  $C_8H_8Br_4$ , the one identical with a substance previously described by Hofmann, melting at  $114.9^{\circ}$ , the other, a colourless liquid boiling at  $115-118^{\circ}$  under a pressure of 4 mm., and exhibiting no signs of solidification when subjected to a freezing mixture.

Attempts were made to determine the molecular weight of the solid tetrabromo-compound by means of the lowering of freezing point of benzene caused by the solution therein of this substance, according to the methods proposed by Raoult and by Paternò and Nasini; the results indicated that the compound was not a polymeric modification of the liquid substance above described.

V. H. V.

**Hydrogenation of Propionitrile.** By G. PISANELLO (*Gazzetta*, **16**, 446—448).—It has recently been shown by Spica that the nitriles on hydrogenation yield, besides the corresponding primary amines, small quantities of the secondary and tertiary amines. It is here shown that propionitrile, on hydrogenation with tin and hydrochloric acid, yields besides propylamine, small quantities of di- and tri-propylamine, as evidenced by fractional crystallisation of their platino-

chlorides, and determination of the platinum therein; the formation of the secondary amines was also proved by Liebermann's colour reaction.

V. H. V.

**Etherification by Double Decomposition. New Ethereal Salts of Nitrous Acid.** By G. BERTONI (*Chem. Centr.*, 1887, 35—36; compare Abstracts, 1886, 217 and 975).—*Tertiary amyl nitrite*,  $C_8H_{17} \cdot O \cdot NO$ , is prepared by shaking together at the ordinary temperature tertiary amyl alcohol (3 mols.) with glyceryl trinitrite (1 mol.), and occasionally adding a lump of ice. The liquid separates into two layers, the upper of which is the ethereal salt. This is washed with very dilute aqueous soda, then with water, finally dried over fused calcium nitrate, and fractionally distilled. It is a mobile, slightly yellow, pleasant smelling liquid, boiling at  $92-93^\circ$ , sp. gr. at  $0^\circ = 0.9033$ , very slightly soluble in water, easily soluble in amyl alcohol, ether, chloroform, benzene, &c., decomposed by methyl and ethyl alcohol with formation of methyl and ethyl nitrites. When inspired, it does not give the same symptoms as ordinary amyl nitrite. It is violently decomposed by strong sulphuric acid, and reduced by ammonium sulphide and hydrogen sulphide, with separation of sulphur; it is saponified by alkalis.

$\alpha$ -*Propylene dinitrite*,  $ON \cdot O \cdot CH_2 \cdot CHMe \cdot O \cdot NO$ , is prepared in the same way as the preceding compound by heating a mixture of  $\alpha$ -propylene glycol and glyceryl trinitrite on the water-bath. It is a yellowish, very mobile liquid, of suffocating odour, boiling at  $108-110^\circ$ , sp. gr. at  $0^\circ = 1.144$ , insoluble in water, soluble in ether, chloroform, benzene, &c., slowly decomposed by water, quickly by methyl and ethyl alcohol, it is dissolved by cold and decomposed by hot acetic acid; dilute sulphuric acid decomposes it. When exposed to sunlight in a closed vessel, it explodes violently.

*Secondary octyl nitrite*,  $C_8H_{17} \cdot O \cdot NO$ , is prepared by treating secondary octyl alcohol (3 mols.) with glyceryl trinitrite (1 mol.) at the ordinary temperature, and proceeding as above. It is a dark yellow, mobile liquid, boiling at  $165-166^\circ$ , sp. gr. at  $0^\circ = 0.881$ , insoluble in water, soluble in the alcohols, and decomposed by the lower members, also soluble in ether, chloroform, benzene, &c. When acted on by acids, it is decomposed in the same way as the preceding compounds.

The author finds that the physiological actions of these nitrites and also of allyl nitrite (*Abstr.*, 1886, 218) is not different from that of other ethereal nitrites. The poisonous properties of these nitrites increase on the one hand with the percentage of  $NO_2$ , and on the other with their decomposibility; they stand in the following order:  $\alpha$ -propylene, allyl, tertiary amyl, secondary octyl nitrite.

G. H. M.

**Phosphoplatinous Chloride.** By E. POMEY (*Compt. rend.*, 104, 364).—Phosphoplatinous chloride dissolves readily in propyl alcohol, with subsequent development of heat and evolution of hydrogen chloride. On adding water to the liquid, a yellow, crystalline precipitate of the compound  $P(C_3H_7O)_3PtCl_2$  is obtained. It can be recrystallised from alcohol.

C. H. B.

**Formose.** By O. LOEW (*Ber.*, 20, 141—144).—The author discusses the properties of formose and its analogy with levulose, and considers it to be a sugar (compare Tollens, *Ber.*, 19, 2134).

**Reaction for Fruit-sugar.** By T. SELIWANOFF (*Ber.*, 20, 181—182).—A cold aqueous solution of cane-sugar (2 parts) and resorcinol (1 part) is treated with concentrated hydrochloric acid and quickly warmed. The mixture becomes red, and deposits on cooling an abundant dark precipitate. The latter is amorphous, and is soluble in alcohol. Fruit-sugar and raffinose give the reaction. Dextrose, galactose, maltose, milk-sugar, and inosite gave no coloration.

Levulinic acid gives Baeyer's aldehyde reaction with phenol. On adding an alkali to the alcoholic solution of the red condensation product, it becomes first blue, then green, and finally yellowish-grey. When an alcoholic solution of levulinic acid and resorcinol is treated with fuming hydrochloric acid, and water added, the solution gives a white, resinous precipitate, analogous to those obtained by Michael (*Abstr.*, 1884, 597) by the condensation of aldehydes with resorcinol. It becomes red when exposed to air. Quinones and pyruvic acid give the same reaction (compare also *Chem. Zeit.*, 9, 231).

N. H. M.

**Inosite.** By MACQUENNE (*Compt. rend.*, 104, 297—299).—Inosite heated at 170° for several hours with 15 times its weight of hydriodic acid of sp. gr. 1.85, yields a small quantity of benzene, together with triidophenol, a result which confirms the constitution previously attributed to inosite (this vol., p. 355). Zinc powder yields no definite products, and sodium amalgam exerts no reducing action.

Chromic acid oxidises inosite in the cold, with formation of formic acid and evolution of some carbonic anhydride. Potassium permanganate in neutral or alkaline solution oxidises it to carbonic anhydride. The halogens have no action in presence of water in the cold, but bromine and water at 100° yield the brown products previously described (*loc. cit.*).

Boiling dilute nitric acid has no action on inosite, but the concentrated acid attacks it regularly at 100° with formation of oxalic acid, but if the reaction is conducted in an open dish on a water-bath, no oxalic acid is formed, and if the liquid is evaporated to dryness, it leaves a white residue which dissolves in water with effervescence, forming a solution of tetrahydroxyquinone,  $C_6O_2(OH)_4$ , which may be precipitated in the form of the barium compound  $C_6O_2(OH)_2O_2Ba$ . In presence of air and a slight excess of alkali, tetrahydroxyquinone rapidly alters to dihydroxydiquinone, a very unstable substance which yields with barium salts an eosin-coloured precipitate,  $C_6O_6Ba$ .

If the solution of the products of the action of nitric acid is mixed with an excess of sodium carbonate and a small quantity of alcohol, it deposits a greenish-black crystalline powder, which contains the disodium compounds of tetrahydroxyquinone and dihydroxydiquinone. If this mixture is decomposed by hydrochloric acid, and the product recrystallised from boiling alcohol, it yields tetrahydroxyquinone which may be purified by washing with water. When the tetrahydroxyquinone is treated with cold concentrated nitric acid, heat is

developed, nitrogen oxides are evolved, and the hydrated triquinone,  $C_6O_6 + 8H_2O$ , described by Nietzki and Benckiser, is obtained as a white crystalline powder; this may be reconverted into tetrahydroxyquinone by suspending it in water, and passing a current of sulphurous anhydride into the liquid. If the triquinone is heated with water it becomes yellow, and if the liquid is evaporated after neutralising with potash, potassium croconate,  $C_5O_5K_2 + 2H_2O$ , is obtained in beautiful crystals, which are also formed when a current of air is passed into an alkaline solution of tetrahydroxyquinone or rhodizonic acid.

Inosite, in fact, yields the same products of oxidation as those which have been obtained by Nietzki and Benckiser by the oxidation of hexahydroxybenzene, a result which establishes the constitution ascribed to inosite by the author in his previous paper (*loc. cit.*).

C. H. B.

**Dry Distillation of Starch with Lime.** By V. HORVAT (*Chem. Centr.*, 1887, 38—39).—The substances were used in the proportion of 1 : 4. The products found were acetone, mesityl oxide, isophorone, boiling at  $207^\circ$ , and identical with that obtained by heating acetone with lime or soda, and isomeric with the phorone from acetone and hydrochloric acid. The fraction boiling between  $128^\circ$  and  $207^\circ$  consisted of a series of ketones of the formula  $C_nH_{2n}O$ , and that boiling above  $207^\circ$  of still higher condensation products of acetone than isophorone. The latter did not yield adipic acid when oxidised.

G. H. M.

**True Nature of Nägeli's Starch-cellulose.** By A. MAYER (*Chem. Centr.*, 1887, 6).—When starch-granules are treated with saliva or dilute acids, delicate skeletons always remain behind, and from Nägeli's researches have hitherto been considered to consist of cellulose. The starch-granule, therefore, appeared to be composed of an intimate mixture of two substances, cellulose, and a substance which Nägeli called granulose. Mayer now states that these skeletons do not consist of a substance which is contained in intact starch-granules, but are really a conversion product formed by the action of the acids or ferment employed, and are identical with amyloextrin. The use of the terms starch-cellulose and granulose must, therefore, be abandoned, and the homogeneous substance of the starch-granule be simply called starch-substance.

G. H. M.

**Paragalactin.** By E. SCHULZE and E. STEIGER (*Ber.*, 20, 290—294).—When finely-powdered seeds of *Lupinus luteus*, after removal of the fat by ether, are treated with cold, very dilute aqueous potash, both the constituents soluble in water and the albuminoids are removed; the residue is somewhat gelatinous, and contains in a very impure state the substance which the authors term paragalactin. This substance could not be obtained in a state of purity, as no solvent could be found for it which did not cause alteration. It seems to form 25 per cent. of the seed, and is probably a carbohydrate of the formula  $C_6H_{10}O_5$ ; when heated with dilute acids, it is converted into galactose, no other sugar being formed. It is not dissolved by heating with water under pressure, nor is it converted into a sugar

by diastase. By the action of tartaric acid, or of hot 10 per cent. aqueous potash, solutions are obtained from which, on addition of alcohol, white gelatinous substances separate; these, however, would seem to be decomposition products. An acetyl-derivative prepared from the substance obtained by the last method, gave numbers agreeing with the formula  $C_6H_7O_3Ac_3$ , and began to decompose at  $225^\circ$  without previous fusion.

A. J. G.

**Trimethylpropylammonium Iodide and Hydroxide.** By T. LANGELI (*Gazzetta*, **16**, 385—389).—When propylamine and methyl iodide, preferably diluted with alcohol, are heated together, trimethylpropylammonium iodide is formed, together with propylmethylamine and propylamine hydroiodides, thus:  $4PrNH_2 + 4MeI = PrMe_3NI + NHPrMe_3HI + 2NH_2Pr.HI$ . The first of these salts crystallises in long needles melting at  $190^\circ$ ; the corresponding chloride forms a crystalline mass, and the platinochloride,  $(NMe_3Pr)_2PtCl_6$ , a yellow crystalline precipitate. Trimethylpropylammonium hydroxide decomposes on distillation into propylene and trimethylamine, thus:  $CH_2Me \cdot CH_2 \cdot NMe_3 \cdot OH = CH(CH_3) : CH_2 + NMe_3 + OH_2$ .

V. H. V.

**Salts of Diisobutylamine and Triisobutylamine.** By H. MALBOT (*Compt. rend.*, **104**, 366—369).—*Diisobutyl hydrochloride*,  $N(C_4H_9)_2H.HCl$ , is easily obtained in a state of purity, and forms plates or leaflets with a greasy lustre, the transparence and aggregation of the crystals depending on the nature of the solvent. It is somewhat easily soluble in alcohol and in water, slightly soluble in isobutyl alcohol, and only very slightly soluble in ether. It sublimes somewhat rapidly at  $240^\circ$ , and if maintained for some time at  $262^\circ$  it melts partially, and sublimes completely with slight blackening and evolution of isobutylamine. If heated rapidly to a temperature somewhat higher than its melting point, it melts easily without sensible decomposition.

*Diisobutyl platinochloride*,  $2N(C_4H_9)_2H.H_2PtCl_6$ , is obtained in long, dark-red channelled prisms by mixing a concentrated solution of platinic chloride with a saturated solution of diisobutylamine hydrochloride and allowing the liquid to stand.

*Triisobutylamine platinochloride*,  $2N(C_4H_9)_3.H_2PtCl_6$ . The hydrochloride is first prepared by the action of concentrated hydrochloric acid on the amine, but combination takes place very slowly. The liquid is then evaporated to a syrup, taken up with a little ethyl alcohol, and mixed with concentrated platinic chloride solution. A precipitate of small orange prisms forms immediately, and if the liquid is filtered after 24 hours it gradually deposits large, ruby-coloured crystals with very brilliant facets.

The differences in crystalline form between the platinochloride of diisobutylamine and triisobutylamine are so well marked that the two compounds can readily be separated mechanically after they have been crystallised together from a mixture.

C. H. B.

**Isobutaldehyde and its Polymeric Modification.** By G. A. BARBAGLIA (*Gazzetta*, **16**, 430—437).—Isobutaldehyde is readily polymerised by adding to it a small quantity of iodine, the mixture being

kept cool. The rapidity of the conversion is dependent on the quantity of iodine, the lowering of the temperature, and the purity of the aldehyde; a slight variation in the conditions makes a considerable difference in the time required for the change. Even under the most favourable conditions, however, the conversion is never complete. It is difficult to explain the peculiar function of the iodine, and the author classifies the phenomenon among the so-called "catalytic changes." As regards its nature, the trimolecular or polymeric modification of the isobutaldehyde differs from the simpler or monomolecular form, in that the latter is characterised by its susceptibility to chemical change as evidenced by its oxidisability, its combination with ammonia and the alkaline hydrogen sulphites, and its conversion into the isothiobutaldehyde and isobutyric acid, whereas the former is unaltered by oxidising agents, as also by ammonia and the alkaline bisulphites, and is not readily altered by sulphur.

The polymeric modification crystallises in glistening prisms melting at  $59.5^{\circ}$  with partial sublimation, it boils at  $195.2^{\circ}$  (at 752 mm.) with but slight alteration. If heated for some time in a sealed tube at  $150^{\circ}$ , it is partially reconverted into isobutaldehyde.

Isobutaldehyde, even of a high degree of purity, becomes polymerised spontaneously after a time. V. H. V.

**Action of Sulphur on Aldehydes.** By G. A. BARBAGLIA (*Gazzetta*, 16, 426—430).—In the course of the preparation of thiovaleraldehyde from sulphur and valeraldehyde (Abstr., 1881, 34), the author observed the formation of a substance which crystallises in slender prisms, melts at  $94.5^{\circ}$ , and is insoluble in water, very soluble in alcohol and ether. More recent analytical results indicate that this compound is a trithiovaleraldehyde,  $C_5H_6S_3$ ; this might be formed as follows:  $C_5H_{10}S + 2S = C_5H_6S_3 + 2H_2S$ ; the compound having the structural formula—

If this interpretation were correct, hydrogen sulphide would be evolved in the second phase of the reaction, that between thiovaleraldehyde and sulphur; this was found to occur when the two were heated at about  $200^{\circ}$  in sealed tubes for several days, but the product did not yield trithiovaleraldehyde in the crystalline state, and the analytical results were unsatisfactory. V. H. V.

**Compounds of Aldehydes and Ketones with Mercaptans.** By H. FASBENDER (*Ber.*, 20, 460—465).—Ethylene mercaptan combines with pyruvic acid and aldehydes with evolution of heat; at first an additive product is formed, which is decomposed by water into its constituents. If hydrogen chloride is passed into an equimolecular mixture of benzaldehyde and ethylene mercaptan, *benzylidene ethylene bisulphide* is obtained which melts at  $29^{\circ}$ ; it is insoluble in water, soluble in alcohol and ether. When treated with bromine in chloroform solution, it is converted to *diethylene tetrasulphide*,  $\langle \begin{array}{c} CH_2 \cdot S \cdot S \cdot CH_2 \\ CH_2 \cdot S \cdot S \cdot CH_2 \end{array} \rangle$ ,

a compound also obtained by the direct action of bromine on ethylene mercaptan. It forms insoluble crystals, decomposing at 151—154° with carbonisation. Its isomeride, *diethylidene tetrasulphide*,

is prepared by the oxidation of thialdine hydrochloride by iodine dissolved in potassium iodide. It forms an amorphous flocculent precipitate.

V. H. V.

**Action of Nitrous Acid on Ketones.** By L. CLAISEN (*Ber.*, 20, 252).—Nitrosoketones have hitherto only been obtained by indirect methods; the author now finds that they can be obtained directly by the action of free or nascent nitrous acid on the ketones. For instance, nitrosoacetone is obtained in considerable quantity by adding hydrochloric acid to a mixture of amyl nitrite and acetone, and heating on the water-bath. In like manner, when a well-cooled mixture of acetophenone and amyl nitrite is saturated with hydrogen chloride, a white crystalline mass separates which melts at 133—134°, and seems to be nitrosoacetophenone hydrochloride. Amyl nitrite reacts also with aldehydes, yielding products now under investigation.

A. J. G.

**Derivative of Dimethylene Disulphone.** By W. AUTENRIETH (*Ber.*, 20, 373—376).—Duplosulphacetone,  $\text{S}_2(\text{:CMe}_2)_2$  (Wislicenus, *Zeit. für Chem.*, 1869, 224), is prepared as follows:—50 grams of acetone (from bisulphite compound) are heated at 120—130° with 50 grams of phosphorus trisulphide for 6—8 hours, the product poured into water and steam-distilled. The oil is dried over calcium chloride and redistilled; it boils between 180° and 190°. It yields an additive compound with methyl iodide.

*Tetramethyldimethylene disulphone*,  $\text{CMe}_2 < \begin{smallmatrix} \text{SO}_2 \\ \text{SO}_2 \end{smallmatrix} > \text{CMe}_2$ , is obtained by oxidising duplosulphacetone by means of potassium permanganate. It is extracted by ether. It crystallises from hot alcohol in slender, white needles melting at 220—225° with decomposition. It dissolves readily in alcohol, ether, and chloroform, sparingly in hot water. Concentrated sulphuric and nitric acids dissolve it unchanged. It is not changed when boiled with aqueous alkali; prolonged heating with concentrated alkali decomposes it completely.

N. H. M.

**$\gamma$ -Amidovaleric Acid.** By J. TAFEL (*Ber.*, 20, 249—251).—In a previous communication (*Abstr.*, 1886, 1008) it was suggested that the substance  $\text{C}_3\text{H}_5\text{NO}$ , obtained by heating  $\gamma$ -amidovaleric acid, was a *oxymethylpyrrolidine* having the formula  $< \begin{smallmatrix} \text{CHMe} \cdot \text{NH} \\ \text{CH}_2 - \text{CH}_2 \end{smallmatrix} > \text{CO}$  or  $< \begin{smallmatrix} \text{CHMe} \cdot \text{N} \\ \text{CH}_2 - \text{CH}_2 \end{smallmatrix} > \text{C} \cdot \text{OH}$ ; this hypothesis is now confirmed, as it is shown to yield a methylpyrrolidine on reduction; there is, however, as yet no evidence as to which of the two formulæ is correct.

*Methylpyrrolidine*,  $< \begin{smallmatrix} \text{CHMe} \cdot \text{CH}_2 \\ \text{CH}_2 - \text{CH}_2 \end{smallmatrix} > \text{NH}$ , is obtained by adding sodium

to a boiling solution of oxymethylpyrrolidine in amyl alcohol as long as hydrogen is evolved. It is a colourless, mobile liquid, boils at 96—97° under a pressure of 737 mm. (mercurial column in vapour), but volatilises rapidly at the ordinary temperature, and has a penetrating, stupefying odour; the vapour quickly produces violent headache.

The use of Ladenburg's reduction method for the removal of oxygen seems to be generally applicable not only to the pyrroline but also to the pyridine and quinoline series, seeing that by it non-oxygenated bases have been prepared from oxylepidine, methylepidone, and carbostyryl (Knorr and Klotz, this vol., p. 278).

A. J. G.

**Hydroxybutyric Acid in Diabetic Urine.** By E. STADELMANN (*Zeit. Biol.*, **32**, 456—459).—The preparation of the salts of hydroxybutyric acid in a pure state from the urine of diabetic patients is a matter of some difficulty, as they become mixed with a dark-coloured sticky mass, which is probably composed of derivatives of diabetic sugar, and which is soluble in ether. It becomes black on evaporation.

According to Minskowski the preparation of the silver salt is that which presents least difficulties. The author finds that the zinc salt is prepared with greater ease. The sugar is best removed by means of fermentation (see Külz, this vol., p. 290), but this method is not without its drawbacks, as putrefactive decomposition is apt to occur simultaneously.

Putrefaction was prevented by adding salicylic acid to the extent of 0.2 per cent., and also by letting the fermentation take place in a cool cellar. At the end of a fortnight the urine showed no signs of putrefaction and all the sugar had disappeared from 55 litres, the quantity used. Another difficulty arises from the quantity of urea, which in these cases is very abundant in the urine. The method adopted for getting rid of it was as follows:—1½ kilos. lime was added to the total quantity of urine, much ammonia came off, and after five hours the filtered liquid still showed a diminished but still a high percentage of urea; it was, therefore, evaporated down to 20 litres, when more ammonia was evolved, another kilo. of lime was added, and heat applied for 30 hours, at the end of which time no more ammonia was given off; the remaining quantity of urea was removed by mercuric nitrate. From the clear, greenish-yellow filtrate, the zinc salt of hydroxybutyric acid was then prepared and crystallised; the brown colour beforementioned was, however, still present; the crystals were therefore treated with absolute alcohol, in which they are but sparingly soluble, while the coloured mass dissolves easily. An advantage of this calcium hydroxide process is that by its means the sulphates and phosphates are also removed. The salicylic acid used in the process is removed by washing the zinc salt with alcohol.

W. D. H.

**β-Bromolevulinic Acid.** By I. WOLFF (*Ber.*, **20**, 425—433).—In order to determine the constitution of the isomeric angelolactones produced by the distillation of levulinic acid, the reactions were studied of the bromolevulinic acid obtained both from α-angelo-

lactone bromide and directly from levulinic acid. When treated with sodium carbonate, this bromo-acid yields acetoacrylic acid, so that its constitution is expressible by the formula  $\text{COMe} \cdot \text{CHBr} \cdot \text{CH}_2 \cdot \text{COOH}$ , and the angelolactone from which it is derived by  $\langle \begin{smallmatrix} -\text{CH}_2 \cdot \text{CO}- \\ \text{CH} : \text{CMe} \end{smallmatrix} \rangle \text{O}$ .

Acetoacrylic acid,  $\text{CHAc} : \text{CH} \cdot \text{COOH}$ , forms glistening scales, melting at  $125-125.5^\circ$ , sparingly soluble in alcohol and chloroform; it combines with phenylhydrazine and also with bromine to form  $\alpha$ - $\beta$ -dibromolevulinic acid; this crystallises in needles melting at  $107-108^\circ$ , and is readily soluble in alcohol, ether, and benzene. Simultaneously with acetoacrylic acid a hydroxylevulinic acid is formed, an oily liquid, which, when heated with ammonia, yields a base,  $\text{C}_8\text{H}_{12}\text{N}_2$ , besides two subsidiary products not as yet investigated. This base, which is also obtained from bromolevulinic acid, is identical with the dimethyl ketone of Gutnecht and Treadwell; it crystallises from water as a hydrate,  $\text{C}_8\text{H}_{12}\text{N}_2 \cdot 3\text{H}_2\text{O}$ , in white lustrous needles, melting with loss of water at  $74-77^\circ$ , and when dried over desiccating substances is converted into brittle, lustrous prisms of the anhydrous base; this melts at  $86^\circ$  and boils at  $190^\circ$ ; the hydrochloride,  $\text{C}_8\text{H}_{12}\text{N}_2 \cdot \text{HCl} + 2\text{H}_2\text{O}$ , melts at  $91^\circ$ ; the platinochloride crystallises in glistening needles. The *methiodide*,  $\text{C}_8\text{H}_{12}\text{N}_2 \cdot \text{MeI} + 2\text{H}_2\text{O}$ , is a citron-yellow, crystalline substance. It seems that the dimethyl ketone contains four methyl-groups and may be represented by a formula  $\text{C}_4\text{Me}_4\text{N}_2$ ; in confirmation, the silver salt of a tetracarboxylic acid,  $\text{C}_4(\text{COOH})_4\text{N}_2$ , has been obtained.

Bromolevulinic acid, when heated with aniline, yield a base,  $\text{C}_{20}\text{H}_{22}\text{N}_2$ , which crystallises in silky needles melting at  $107-108^\circ$ , soluble in alcohol, ether, and chloroform.

In conclusion, it is remarked that the above-mentioned dimethyl ketone, or azo-ketone, the benzoimide of Erdmann, the base,  $\text{C}_{28}\text{H}_{20}\text{N}_2$ , obtained by Japp and Wilson (*Trans.*, 1886, 825), and isoindole, can be represented as derived from a fundamental substance,  $\text{C}_4\text{H}_4\text{N}_2$ , which it is proposed to call pyrazine. The above substances will then be its tetra- and di-methyl-, tetra- and di-phenyl-derivatives respectively.

V. H. V.

**Composition and Constitution of Arabinosecarboxylic Acid and Arabinose.** By H. KILIANI (*Ber.*, 20, 282 and 339-346; compare this vol., p. 229).—When the lactone of arabinosecarboxylic acid is boiled with concentrated hydriodic acid (15 parts) and amorphous phosphorus, a product is obtained consisting chiefly of normal caprolactone and a small quantity of normal caproic acid. Arabinosecarboxylic acid is therefore *pentahydroxycaproic acid*,  $\text{C}_6\text{H}_{12}\text{O}_7$ , and not hexahydroxyheptylic acid, and has the same composition as gluconic and galactonic acids. When the lactone of arabinosecarboxylic acid is digested with nitric acid (sp. gr. 1.2) for 24 hours at  $50^\circ$ , the product diluted and evaporated, a viscous substance is obtained which when dissolved in a little warm water solidifies on cooling to a hard cake of crystals. This is redissolved, the oxalic acid present precipitated with lime, and the filtrate evaporated; it separates in long, colourless needles. This compound is a *double*

*lactone of metasaccharic acid*, and has the formula  $C_6H_6O_6 + 2H_2O$ . It differs from saccharic acid in having a neutral reaction. It is soluble in 8 parts of cold water, insoluble in ether, sparingly in alcohol. The *calcium salt*,  $C_6H_8O_6Ca + H_2O$ , forms microscopic spheres. When the solution of the hydrogen potassium salt is exposed to air, it acquires an intense red colour. When the double lactone is reduced by means of hydriodic acid, a small quantity of an acid is formed which melts at about  $200^\circ$ ; this when treated with sodium amalgam is converted into an acid, probably adipic acid. The lactone has probably the constitution

The above experiments show that arabinose has the formula  $C_5H_{10}O_5$ , and not  $C_6H_{12}O_6$  and the fact that it yields with hydrocyanic acid a compound containing a normal carbon-chain, shows further that it is an aldehyde of normal pentahydroxypentane:

The formation of arabonic acid from arabinose is readily explained, being analogous to that of gluconic acid.

Small quantities of arabinosecarboxylic acid are best prepared by saturating the solution from which the amide has separated with dry hydrogen chloride, and, after 12 hours, evaporating with baryta-water; the barium is then precipitated by sulphuric acid, the hydrochloric acid by silver oxide, and the solution evaporated to a syrup. During treatment with hydrochloric acid, the solution should be cooled with ice. The yield is 70 to 80 per cent.

N. H. M.

**Action of Nitric Acid on Bibasic Acids.** By H. P. N. FRANCHIMONT (*Rec. Trav. Chim.*, 5, 281—289).—In continuation of experiments on the action of nitric acid on substituted malonic acids (Abstr., 1886, 533), the author has more fully examined this reaction in the case of methylmalonic acid. The products obtained were carbonic anhydride, acetic acid, and *trinitroethane*, the last of which forms brilliant crystals, melting at  $55^\circ$ , sparingly soluble in water, volatile in the air, and volatilising rapidly in steam. Attempts were made to prepare trinitro- from bromo-dinitroethane, but without success. The trinitro-compound is also formed in small quantities in the reaction between nitric and isosuccinic acids. In the case of amylmalonic acid, no appreciable quantity of a nitro-derivative of a hydrocarbon was obtained, but only carbonic anhydride and hexylic acid. Thus the action of nitric acid on substituted malonic acids consists mainly in the production of a monobasic acid containing two atoms of carbon less than the original substance, and the evolution of 2 mols. of carbonic anhydride for each molecule of the substance employed.

V. H. V.

**Isonitroso-compounds.** By H. BERGREEN (*Ber.*, 20, 531—534).—The author finds that ethyl isosuccinate, when treated with nitrous acid, yields ethyl isonitrosopropionate (Abstr., 1878, 659). Ethylic ethylmalonate and ethyl benzylmalonate, when similarly

treated, yield oily compounds, from which pure crystalline substances have not yet been obtained. W. P. W.

**Action of Phosphoric Chloride on Ethyl Acetonedicarboxylate.** By B. S. BURTON and H. v. PECHMANN (*Ber.*, 20, 145—149).— $\beta$ -Chloroglutaconic acid,  $\text{COOH}\cdot\text{CH}:\text{CCl}\cdot\text{CH}_2\cdot\text{COOH}$ , is obtained by gradually adding 50 grams of ethyl acetonedicarboxylate to 160 grams of phosphorus pentachloride, and then heating the whole on a water-bath. The product is poured into water, the oil extracted with ether, and the ethyl salt so obtained saponified by boiling for two or three hours with 20 to 25 times the amount of strong hydrochloric acid. The acid melts at  $129^\circ$  and becomes dark at  $170^\circ$ , is readily soluble in water, ether, and alcohol, less soluble in chloroform, from which it separates in groups of white needles; it is also soluble in boiling benzene. When reduced by zinc-dust and acetic acid, an acid melting at  $132^\circ$  (the m. p. of glutaconic acid) is formed; it decomposes at a higher temperature with evolution of gas. Chloroglutaconic acid is reduced by sodium amalgam to glutaric acid.

*Glutic acid*,  $\text{COOH}\cdot\text{C}:\text{C}\cdot\text{CH}_2\cdot\text{COOH}$ , is formed when 5 grams (1 mol.) of the chlorinated acid dissolved in alcohol is gradually dropped into and shaken with a 5 per cent. alcoholic solution of potash containing rather more than the theoretical amount (3 mols.) of potash. The potash solution is previously heated at  $50$ — $60^\circ$ . It is filtered, washed with alcohol, and dried. The united products of several preparations are treated with a large excess of dilute sulphuric acid and extracted with ether. The acid is purified by washing with warm benzene and crystallising from a mixture of ether and benzene. It forms groups of slender needles which melt at  $145$ — $146^\circ$  with evolution of carbonic anhydride; it is readily soluble in water, alcohol, and ether, insoluble in chloroform and benzene. It decomposes when kept long. When a solution of the hydrogen potassium salt is heated, carbonic anhydride is evolved, and there is an odour of acetone. The *lead salt* forms a white precipitate; the *barium* and *potassium salts* crystallise in slender needles and in long, flat needles respectively; both contain water of crystallisation. N. H. M.

**Aconitic Acid.** By W. HENTSCHEL (*J. pr. Chem.*, 35, 205—206).—Aconitic acid is readily obtained when crystallised citric acid (2 parts) is heated with sulphuric acid (2 parts) and water (1 part) for 4—6 hours in a reflux apparatus; the yield amounts to 35—45 per cent. of the citric acid employed. Acetone is also formed in the reaction, and gas is evolved consisting of 2 vols. carbonic anhydride and 1 vol. carbonic oxide. W. P. W.

**Reduction of Dihydroxytartaric Acid Diphenylhydrazine.** By J. TAFEL (*Ber.*, 20, 244—249).—*Phenylhydrazineumidooxalacetic acid*,  $\text{COOH}\cdot\text{CH}(\text{NH}_2)\cdot\text{C}(:\text{N}_2\text{HPh})\cdot\text{COOH}$ , is obtained by the reduction of an alkaline solution of dihydroxytartaric acid diphenylhydrazide by the addition of successive small quantities of sodium amalgam until the intense yellow solution is just decolorised; it could not be

obtained in a state approaching purity, but when heated with sulphuric acid it is converted into the corresponding *anhydride*,  $C_{10}H_9N_3O_3$ . This crystallises in snow-white plates of fatty lustre, is insoluble in ether and hot water, sparingly soluble in hot alcohol, benzene, acetic acid, and acetone, more readily in chloroform and hot concentrated hydrochloric acid; it dissolves readily in alkalis and alkaline carbonates, and in concentrated sulphuric acid. The solutions become red or violet on exposure to air. The alkaline solution reduces Fehling's solution on gently heating, and mercuric oxide in the cold, the solution in the latter case showing an intense orange-red coloration. From its reactions, it is very probably *amido-oxyquinizinecarboxylic acid*.

If the reduction of the diphenylhydrazide with sodium amalgam is pushed further, Lehrfeld's diamidosuccinic acid (Abstr., 1882, 162) is obtained.

A. J. G.

**Gluconic Acid.** By L. BOUTROUX (*Compt. rend.*, **104**, 369—370).—The crystallised ammonium gluconate recently described by Volpert (*Ber.*, **19**, 2621) had previously been obtained by the author, and described by him as ammonium zymogluconate. Zymogluconic acid obtained from glucose by acid fermentation (Abstr., 1883, 682), is, however, identical with the gluconic acid of Hlasiwetz and Habermann.

C. H. B.

**Constitution of Trimethylenetricarboxylic Acid.** By A. MICHAEL (*J. pr. Chem.* [2], **35**, 132—136).—When ethyl sodiomalonate is treated with ethyl  $\alpha$ -bromacrylate by Conrad and Limpach's method, a very violent reaction takes place, and an ethyl salt is formed identical with that obtained by Conrad and Guthzeit from ethyl  $\alpha$ - $\beta$ -dibromopropionate. The latter compound must therefore have the constitution  $CH_2 : C(COOEt) \cdot CH(COOEt)_2$ .

When treated with sodium ethoxide and benzoic chloride, no substitution took place; the ethyl salt was recovered unchanged. This behaviour is analogous to that of the compound obtained by Perkin from ethylene bromide and ethyl sodiomalonate. This negative result can therefore no longer hold good as evidence against the constitution  $CH_2 \cdot CH \cdot CH(COOEt)_2$  for ethyl vinaconate.

N. H. M.

**Amides of Ethylsulphonic Acid.** By A. P. N. FRANCHIMONT and E. A. KLOBBIE (*Rec. Trav. Chim.*, **5**, 274—280).—In continuation of the experiments of Romburgh on the action of nitric acid on the replaced amides of phenylsulphonic acid, corresponding derivatives of ethylsulphonic acid are described, and the action on them of nitric acid is investigated. As regards the preparation of ethylsulphonic acid, preference is given to the oxidation of ethyl bisulphide. The acid is converted into the chloride, which is dissolved in ether, and an ethereal solution of the amine added. The amide formed is then fractionally distilled. The mono- and di-methylamides of ethylsulphonic acid, and the corresponding ethyl-compounds, are all colourless liquids, miscible with water, and of peculiar odour. Their physical properties are given in the following table:—

|   | Boiling<br>point. | Specific<br>gravity. |
|---|-------------------|----------------------|
| Ethylsulphonomethylamide, $\text{EtSO}_2\cdot\text{NHMe}$ | 276°              | 1.216                |
| Ethylsulphonodimethylamide, $\text{EtSO}_2\text{NMe}_2$   | 240               | 1.146                |
| Ethylsulphonethylamide, $\text{EtSO}_2\text{NHEt}$ ..     | 272               | 1.154                |
| Ethylsulphonodiethylamide, $\text{EtSO}_2\text{NEt}_2$ .. | 254               | 1.080                |

Ethylsulphonomethylamide, when treated with nitric acid (sp. gr. 1.5), yields a nitramide,  $\text{EtSO}_2\cdot\text{NMe}\cdot\text{NO}_2$ , a colourless liquid solidifying at 11°; it cannot be distilled without decomposition, and deflagrates with violence when heated at 100°. Ethylsulphonodimethylamide yields under the same conditions nitrodimethylamine. So also ethylsulphonethylamide yields a nitramide,  $\text{EtSO}_2\cdot\text{NEt}\cdot\text{NO}_2$ , a crystalline substance melting at 15°, sparingly soluble in water. The same compound is also obtained from ethylsulphonodiethylamide.

Thus the action of nitric acid on the replaced amides of ethylsulphonic acid is precisely analogous to the action on the corresponding derivatives of phenylsulphonic acid.

V. H. V.

**Calcium Urate.** By S. DELÉPIN (*Physiol. Soc.*, 1887, 2—3).—Urine containing calcium oxalate, with perhaps an excess of uric acid, sometimes contains small acicular crystals differing from the generally known urates. They sometimes occur also in the urine of gouty subjects. Crystals of uric acid and natural sediments of acid urates when allowed to stand in hard water become transformed into small masses of acicular crystals very insoluble even in hot water. This change does not occur when distilled water is used. This led to the conclusion that the crystals were urate of calcium, and that this salt might be of more importance in the economy than has been supposed. Pure urate of calcium was therefore prepared from uric acid and calcium hydroxide, and a crystalline substance was obtained similar in appearance to the crystals observed in urine, and formed by adding hard water or calcium hydroxide to a deposit of uric acid or urates in urine.

Urate of calcium is colourless or white when seen in large quantities. It forms long, needle-shaped crystals which are generally grouped in stars, but it may also be amorphous. It is more insoluble in hot water than other urates, and less easily decomposed by acids. Strong acid, however, like sulphuric acid, displaces the uric acid, which crystallises readily. The murexide reaction is easily obtained.

It was also found that in gouty deposits in the cartilages, which are generally spoken of as sodium urate, urate of calcium was found to be present in all cases, both by chemical tests and microscopical appearances.

W. D. H.

**Chloropyromucic Acid.** By H. B. HILL and L. L. JACKSON (*Ber.*, 20, 252—255).—When ethyl pyromucate tetrachloride, prepared in the cold, is treated with concentrated alcoholic soda, sodium  $\beta$ - $\gamma$ -dichloropyromucate is in the main formed; if, however, in the preparation of the tetrachloride, the temperature has been allowed to rise too high, further substitution occurs, and the sodium salts obtained

contain not inconsiderable quantities of sodium trichloropyromucate,  $\beta$ - $\gamma$ -Dichloropyromucic acid,  $C_5H_2Cl_2O_3$ , crystallises in slender interlaced needles, melts at  $168$ – $169^\circ$ , is readily soluble in alcohol, ether, and hot water, moderately in boiling benzene or chloroform. The following salts are described:—Barium (+  $3H_2O$ ), calcium (+  $4H_2O$ ), silver and potassium (both anhydrous). The *ethyl* salt crystallises in slender needles and melts at  $176^\circ$ ; the *amide* also crystallises in slender needles and melts at  $176^\circ$ . The free acid when treated with bromine-vapour does not give a stable additive compound, but is converted with evolution of bromine into an acid of high melting point (dichlorobromopyromucic acid?). With bromine-water, it is converted into mucochloric acid with evolution of carbonic anhydride. It is only completely oxidised with nitric acid after boiling for several hours; monochloric and dichloromaleic acids were identified amongst the products of the reaction.

A. J. G.

**Transformation of Furfuran into Pyrroline.** By F. CANZONERI and V. OLIVERI (*Gazzetta*, **16**, 486–497).—Although it is generally assumed that furfuran,  $C_4H_4O$ , and pyrroline are derivatives of a fundamental group,  $C_4H_4$ , yet the transformation of one into the other has not as yet been effected. When pyromucic acid is heated with ammoniacal zinc chloride and lime, and the products of the change are collected successively in a tube surrounded by a freezing mixture, in another containing hydrochloric acid, and a third containing bromine, there are obtained pyrroline, furfuran, and methylamine hydrochloride. The last is a product of a more profound change. The formation of pyrroline results in the displacement of oxygen by the  $NH$ -grouping, thus:  $C_4H_4O + NH_3 = C_4H_5N + OH_2$ . Its identity was established by the analysis of its potassium-derivative and by the pyrroline-red reaction. The furfuran was obtained as a colourless mobile liquid, of ethereal odour, boiling at  $32^\circ$ .

In order to throw some further light on the relative arrangement of the atoms in the  $C_4H_4$  residue, the authors have effected the synthesis of  $\alpha$ -naphthylamine by heating in sealed tubes pyromucic acid, lime, zinc chloride, and aniline; this result tends to show that the atoms are arranged thus:  $CH:CH:CH:CH$ . Further, as furfuran undergoes condensation with the benzene nucleus with elimination of water, it may probably be regarded as a glycide or rather as an anhydride of the unsaturated glycol  $CH(OH):CH:CH:CH(OH)$ .

V. H. V.

**Furfurylamine.** By J. TAFEL (*Ber.*, **20**, 398–400).—This compound is easily obtained by the reduction of C. Fischer's phenylfurfurazide (*Abstr.*, 1878, 310) with sodium amalgam and acetic acid, as follows:—45 grams of phenylfurfurazide is dissolved in 600 grams of alcohol and then 1350 grams of  $2\frac{1}{2}$  per cent. sodium amalgam slowly added, the solution being kept constantly acid by the addition of acetic acid, and the temperature not being allowed to rise above  $3^\circ$ . The product is then supersaturated with potash, and, after driving off the alcohol, is steam-distilled. The distillate is acidified with hydrochloric acid and evaporated to a small bulk. A red resin separates, and the filtrate, after being made slightly alkaline, is treated with

ether to remove aniline, re-acidified, and evaporated until crystallisation commences. The residue is then mixed with dry powdered potash and distilled. Furfurylamine distils over as a colourless liquid, boiling at  $135^{\circ}$  under 754 mm. The *hydrochloride* is easily soluble in water, alcohol, and hydrochloric acid; but this latter solution does not turn green when heated as stated by Ciamician and Dennstedt. The *sulphate* forms minute needles, the *acid oxalate*,  $C_5H_7NO, C_2H_2O_4 + \frac{1}{2}H_2O$ , characteristic narrow scales. The *picrate* forms golden-yellow prisms which decompose without previous fusion at  $150^{\circ}$ . When exposed to the air, the amine absorbs carbonic anhydride, forming a crystalline mass melting at  $75^{\circ}$  and decomposing at a higher temperature with evolution of carbonic anhydride. L. T. T.

**Thiophen in Aniline.** By M. T. LEKO (*Chem. Centr.*, 1887, 41).—The author endeavoured to find an amido-compound of thiophen in aniline by converting commercial aniline into the phenylhydrazine compound, and testing this for thiophen. The results were negative. G. H. M.

**Reduction of  $\alpha$ -Thiophenic Acid.** By F. ERNST (*Ber.*, 20, 518—520).— $\alpha$ -Thiophenic acid is the sole product of the oxidation of propiothiënone, and is best prepared by this method; when reduced with sodium amalgam in alkaline solution, it yields *tetrahydro- $\alpha$ -thiophencarboxylic acid*,  $C_4SH_7COOH$ . This acid crystallises in large, tabular, colourless laminæ, melts at  $51^{\circ}$  (corr.), has an intensely acid taste, and an intolerable odour; it is very readily soluble in water and alcohol, and is volatile with steam. It is decomposed on distillation, shows all the properties of a hydro-acid, and, like the tetrahydrodicarboxylic acid (this vol., p. 237), gives the indophenine reaction on heating. The *methyl* salt is a colourless, oily liquid, boiling at  $206^{\circ}$  without decomposition; the *ethyl* salt is a yellow liquid. The *calcium* salt,  $(C_4SH_7COO)_2Ca + 3H_2O$ , is crystalline; the *silver* salt,  $C_4SH_7COOAg$ , forms small, glistening crystals, sparingly soluble in water. W. P. W.

**Constituents of Coal-tar.** By K. E. SCHULZE (*Ber.*, 20, 409—414).—The author finds that amongst the benzene-derivatives (hydrocarbons and phenols) present in coal-tar, meta-compounds largely predominate. Thus, for instance, of the trimethylbenzenes the 1 : 3 : 5 compound (containing 3 meta-positions) is very largely in excess of the 1 : 3 : 4 and 1 : 2 : 3 compounds (containing each 1 meta-position: and the quantity of metacresol is much larger than that of ortho- or para-cresol.

The author has isolated from coal-tar pyridine, Ladenburg's  $\alpha$ - $\alpha$ -lutidine (Abstr., 1885, 557),  $\alpha$ - $\gamma$ -lutidine, and  $\gamma$ -picoline.

L. T. T.

**Reciprocal Transformation of Cumene- and Cymene-derivatives.** By M. FILETI (*Gazzetta*, 16, 497—503).—This paper is merely an answer to Widman's criticisms (this vol., p. 133) on the author's view regarding the mutual transformations of cumene- and cymene-derivatives. V. H. V.

**Oxidation of the Methyl Ethers of Mono- and Di-bromortho-isopropylphenols.** By A. PERATONER (*Gazzetta*, 16, 420—424).—Methyl bromisopropyl oxide, when heated with nitric acid of sp. gr. = 1.3, yields dibromo- and nitrobromo-methoxysalicylic acids,  $\text{OMe}\cdot\text{C}_6\text{H}_2\text{Br}_2\cdot\text{COOH}$ , and  $\text{OMe}\cdot\text{C}_6\text{H}_2\text{Br}(\text{NO}_2)\cdot\text{COOH}$ ; it appears that the greater part of the compound is completely burnt in the oxidation process, and the formation of a dibromo- from a monobromo-compound is due to the subsequent action of bromine liberated by the nitric acid.

Methyldibromisopropylphenyl oxide, under similar treatment, yields dibromomethoxysalicylic acid, identical with that obtained above. V. H. V.

**Compound of Orthotoluidine with Cupric Chloride.** By E. POMEY (*Compt. rend.*, 104, 365—366).—Orthotoluidine is mixed with hydrochloric acid, and, after combination has taken place, a saturated solution of cupric chloride in hydrochloric acid is added to the warm liquid, an abundant, pale-yellow, crystalline precipitate is formed. This is recrystallised from hydrochloric acid and dried below  $100^\circ$ , at which temperature it begins to decompose. It has the composition  $\text{CuCl}_2, 5(\text{C}_7\text{H}_9\text{N}, \text{HCl})$ , and is very soluble in water. The copper is completely precipitated from the solution by potassium hydroxide, and the chlorine by silver nitrate.

The compound which paratoluidine hydrochloride forms with cupric chloride contains 2 mols. of the former to 1 mol. of the latter.

C. H. B.

**Compound of Paratoluidine with Cupric Chloride.** By E. POMEY (*Compt. rend.*, 104, 300).—If cupric chloride is added to a solution of paratoluidine it produces a brown precipitate, but if both solutions contain free hydrochloric acid no precipitate is formed. If, however, the mixture is heated to boiling and is then allowed to cool, it deposits very brilliant, golden-yellow crystals which are purified by recrystallisation from hydrochloric acid, and are then dried at  $100^\circ$  until no more hydrogen chloride is given off. They have the composition  $\text{CuCl}_2, 2(\text{C}_7\text{H}_9\text{N}, \text{HCl})$ , and are soluble in water. C. H. B.

**Thioparatoluidine.** By J. TRUHLÄR (*Ber.*, 20, 664—679, and *Chem. Centr.*, 1887, 8—10).—*Thioparatoluidine* melts at  $103\text{--}104^\circ$ , and is basic. When an alcoholic solution is treated with an excess of hydrobromic acid, the hydrobromide,  $\text{C}_{14}\text{H}_{16}\text{N}_2\text{S}, 2\text{HBr}$ , is thrown down. It forms small, white needles, easily soluble in hot alcohol, less soluble in cold alcohol, and easily in water. The hydriodide is obtained in a corresponding manner; it forms light-brown needles easily soluble in water, alcohol and ether; when heated at  $100^\circ$ , it is decomposed with separation of iodine.

*Thioparacetotoluide*,  $\text{NHAc}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{S}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{NHAc}$ , is obtained by treating thioparatoluidine with an excess of acetic anhydride; it crystallises from alcohol in snow-white, stellate groups of needles, and melts at  $211^\circ$ ; it is easily soluble in alcohol and benzene, less easily in ether, and insoluble in water.

*Thioparabenzoyltoluide*,  $\text{NHBz}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{S}\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{NHBz}$ , is obtained

by warming thioparatoluidine with excess of benzoic chloride as long as hydrochloric acid is evolved. It crystallises from alcohol in snow-white, brilliant needles, easily soluble in alcohol, benzene, and ether, and melts at 186°.

*Hydroxythiotoluene*,  $S(C_6H_3Me \cdot OH)_2$ , is obtained by boiling diazo-thioparatoluidine hydrochloride with water, saturating the solution with sodium chloride, dissolving the precipitated substance in alkali, and again precipitating with dilute sulphuric acid. It can also be obtained by dissolving the crude product in benzene and fractionally precipitating with light petroleum. It forms a brown powder, soluble in alcohol, ether, and benzene; it melts at 135°.

*Thioparatolythiocarbamide*,  $S \langle \begin{smallmatrix} C_6H_3Me \cdot NH \\ C_6H_3Me \cdot NH \end{smallmatrix} \rangle CS$ , is obtained by treating an alcoholic solution of thioparatoluidine with excess of carbon bisulphide. Hydrogen sulphide is evolved and, after some time, colourless crystals mixed with crystals of sulphur separate. The latter are removed by means of carbon bisulphide. The substance is insoluble in all ordinary solvents, but dissolves in strong nitric and sulphuric acids. It melts at 234—235°. Another very stable substance is formed at the same time; it melts at 231°. Attempts to prepare thioparatolylsulphocarbamil from it were unsuccessful.

The *picrate* of thioparatoluidine,  $C_{14}H_{16}N_2S \cdot 2C_6H_2(NO_2)_3OH$ , is obtained in aggregates of fine needles by evaporating alcoholic solutions of thioparatoluidine and picric acid. It crystallises from benzene in stellate needles with brilliant lustre, and melts at 179°. When quickly heated, it explodes.

*Dithioparatolyldicarbamide*,  $S \langle \begin{smallmatrix} C_7H_6 \cdot NH \cdot CO \cdot NH \cdot C_7H_6 \\ C_7H_6 \cdot NH \cdot CO \cdot NH \cdot C_7H_6 \end{smallmatrix} \rangle S$ , is obtained as a yellow, amorphous powder, together with thioparatoluidine hydrochloride, by passing carbonyl chloride (1 mol.) into a solution of thioparatoluidine (2 mols.) in benzene. By solution in alcohol and reprecipitation, it forms a whitish, amorphous powder which is decomposed at 130°. It is only slightly soluble in ether and in cold alcohol, but easily in hot. It is not acted on by concentrated hydrochloric acid, but is soluble in strong nitric and sulphuric acids.

G. H. M.

**Secondary and Tertiary Quinones.** By R. NIETZKI and F. KEHRMANN (*Ber.*, 20, 322—328).—When sodium rhodizonate (*Abstr.*, 1885, 1127) is dissolved in dilute hydrochloric acid and treated with

an orthotoluylenediamine salt, the compound  $\begin{array}{c} CO \cdot C(OH) : C \cdot N \\ | \quad | \quad | \\ CO \cdot C(OH) : C \cdot N \end{array} \rangle C_7H_6$

is obtained. It is a gelatinous substance, sparingly soluble in water, readily in alcohol. Alkali solutions dissolve it with a fine violet colour. When oxidised with dilute nitric acid, it is converted into a derivative of triquinoyl, *diquinoyltolazine*,

This forms yellow needles, almost insoluble in cold water, ether, and

alcohol, readily soluble in warm glacial acetic acid. When the compound  $C_{13}H_6N_2O_4$  is warmed with an excess of an orthotoluylenediamine salt, *benzotritolazine*,  $C_6(N_2:C_7H_6)_3$ , is obtained. This is a yellow, crystalline substance, very readily soluble in alcohol and in chloroform; it crystallises from the latter in long needles (with 1 mol.  $CHCl_3$ ). It has feeble basic properties.

When sodium rhodizonate, dissolved in water, is treated with an excess of a salt of orthotoluylenediamine and sodium acetate, a compound is obtained containing three toluylenediamine-groups; when oxidised, it is converted into the triazine,  $C_{27}H_{18}N_6$ , already described.

The above experiments show that triquinoyl contains six quinone oxygen-atoms. It is probable that the hydroxyl-groups in rhodizonic acid have the para-position. This view being accepted, the fact that adjacent oxygen-atoms react like an orthoquinone-group and are independent of para-oxygen, forms an important support for the ketonic formulæ of quinones.

N. H. M.

**Preparation of Dimethylaniline on a Large Scale.** By P. SCHOOP (*Chem. Zeit.*, 11, 253—254).—The author describes the preparation of dimethylaniline from aniline, wood spirit, and hydrochloric acid. It is important to use pure materials, therefore the aniline is tested by quantitative fractional distillation, by its sp. gr., and by its solubility in hydrochloric acid; the wood spirit must be free from acetone and ethyl alcohol, and is tested by the iodoform test. The materials are mixed in the proportions of 93 parts of aniline, of which 18 are saturated with hydrochloric acid, and 75 parts of methyl alcohol. The excess of methyl alcohol and the comparatively small quantity of hydrochloric acid tend to produce a purer oil. With more hydrochloric acid, the reaction takes place at a lower temperature, but there is danger of the formation of toluidine. The mixture is heated in a closed vessel, the temperature (from 270—230°) and pressure (of which a table is given in the paper) being carefully regulated; a fall of pressure with a constant temperature (230°) indicates the completion of the operation. The product consists of an oily and watery portion which are separated; the latter is then treated with soda and the oil which separates is removed, the alkaline water being finally distilled and the oil from this collected in a separate receiver. Each of these three lots of oil is rectified by itself, the product obtained from the first lot being the best and that from the third the worst. Many modes of testing the purity of the product are given; it is especially important to have a pure substance for the preparation of green dyes.

D. A. L.

**Ortho- and Para-chlorodimethylaniline.** By T. HEIDELBERG (*Ber.*, 20, 149—151).—*Orthochlorodimethylaniline*,  $C_6H_4Cl \cdot NMe_2$ , is obtained by Staedel's method, which consists in heating the hydrobromide of the chloraniline with rather more than 2 mols. of methyl alcohol at 145°. It is a clear, colourless liquid boiling at 206—207°. The *hydrochloride* forms white, hygroscopic needles; the *platinochloride* crystallises in lustrous yellow prisms. *Nitrosorthochlorodimethylaniline* crystallises from alcohol in yellow needles.

*Parachlorodimethylaniline* was prepared by Sandmeyer's method:

50 grams of amidomethylaniline was dissolved in 82 grams of hydrochloric acid; 300 c.c. of water is added and then a solution of 26 grams of sodium nitrite in 60 c.c. of water. The whole is added to a boiling solution of 10 per cent. cuprous chloride solution. It crystallises in large, lustrous, flat needles, soluble in alcohol, ether, and benzene, insoluble in water; it melts at 230—231°. The *hydrochloride* is a syrup which crystallises with difficulty; the *ferrocyanide* forms microscopic prisms. The *platinochloride*,  $(C_6H_4Cl \cdot NMe_2)_2 \cdot H_2PtCl_6$ , crystallises in gold-coloured prisms. *Nitrosoparachlorodimethylaniline* crystallises in splendid, orange-yellow needles melting at 56°; it is soluble in alcohol, ether, and benzene, &c. Like the ortho-compound it is a very feeble base.

N. H. M.

**Carvole-derivatives.** By H. GOLDSCHMIDT and E. KISSER (*Ber.*, 20, 486—492).—Carvylamine (this vol., p. 249), a primary amine, is a colourless liquid, and yields a benzoyl-derivative which crystallises in white needles melting at 169°. The *hydrochloride*,  $C_{10}H_{17}N \cdot HCl$ , crystallises from absolute alcohol in small, white, silky needles, and melts at about 180° with decomposition; when heated with sodium nitrite, an oil, probably identical with Leuckart's carveol, is obtained (this vol., p. 376).

From carvole, by the action of dry hydrogen chloride, hydrochlorocarvole,  $C_{10}H_{15}OCl$ , is obtained; this decomposes on distillation with evolution of hydrogen chloride, and when treated with hydroxylamine yields hydrochlorocarvoxime (Abstr., 1885, 1058). The phenylhydrazine-derivative,  $C_{10}H_{15}Cl : N_2HPh$ , crystallises in small, white prisms, and melts at 137°. When a mixture of carvole and ethyl acetoacetate in equimolecular proportions is treated with hydrogen chloride, the product poured into water and afterwards extracted with ether, two compounds are obtained, one an oil, and the other a crystalline substance of the formula  $C_{16}H_{25}ClO_4$ , which forms lustrous, white, hard prisms, melts at 146°, and does not yield a derivative with acetic chloride.

The constitution of carvole is now represented by the formula  $CPr \begin{smallmatrix} \text{CH} \cdot \text{CO} \\ \text{CH} : \text{CH} \end{smallmatrix} > CHMe$ , and that of limonene by the formula

W. P. W.

**Action of Aromatic Diamines on Sugars.** By P. GRIESS and G. HARROW (*Ber.*, 20, 281—282).—The diamidobenzenes and their carboxylic acids react with some sugars to form compounds analogous to those obtained by Fischer with phenylhydrazine and sugars. Those with the orthodiamine are especially interesting, as they are relatively easily prepared and show well-characterised physical properties.

If, for instance, concentrated aqueous solutions of orthophenylenediamine (1 part) and dextrose (2 parts) are mixed, a few drops of hydrochloric acid added, and the whole allowed to remain eight days in a moderately warm place, a feebly basic substance is formed. This crystallises in lustrous, white needles, which are moderately soluble in

hot water and alcohol; it also dissolves very readily in hydrochloric acid, and is reprecipitated unaltered from the solution by ammonia. It has a bitter taste, and reduces Fehling's solution. If in the above reaction the corresponding  $\gamma$ -diamidobenzoic acid [ $\text{COOH} : (\text{NH}_2)_2 = 1 : 2 : 3$ ] is substituted for the diamine, a substance having the character of an amido-acid is obtained. It crystallises in lustrous, white plates, is very sparingly soluble even in boiling water or alcohol, does not reduce Fehling's solution to any marked extent, and behaves like sugars when heated in a tube. A very similar acid was prepared from maltose.

A. J. G.

**Action of Orthotoluylenediamine on Dextrose.** By O. HINSBERG (*Ber.*, **20**, 495—497).—An almost quantitative yield of a condensation-compound,  $\text{C}_{19}\text{H}_{30}\text{N}_2\text{O}_{10}$ , is obtained when an alcoholic solution of orthotoluylenediamine (1 mol.) is heated with dextrose (2 mols.) on a water-bath. The compound crystallises from dilute alcohol in slender, white, silky needles, which become brown when heated at  $100^\circ$  in a capillary tube, and melt at about  $160^\circ$  with evolution of gas; it is readily soluble in water, sparingly soluble in alcohol and ether, and gives a red coloration with ferric chloride. A loss of about 4 per cent. in weight occurs if the compound is heated at  $100^\circ$ , and it then gives figures showing a slightly lower percentage of carbon. Dilute alkalis are without action on it, but mineral acids, on warming if dilute, reconvert it into orthotoluylenediamine and, probably, dextrose. The constitution of this compound is probably

and its instability in the presence of acids raises the question whether the view that dextrose contains the aldehyde-group is correct. Other aromatic diamines yield compounds analogous to dextrose; no well-crystallised compound can be obtained from orthotoluylenediamine and lactose.

W. P. W.

**Tetramidobenzene and its Derivatives.** By R. NIETZKI and E. HAGENBACH (*Ber.*, **20**, 328—338).—*Diethenyltetramidobenzene*,  $\text{C}_6\text{H}_2(\text{<}\overset{\text{N}}{\text{NH}}\text{>C}_2\text{H}_3)_2$ , is obtained by reducing diacetyldinitrophenylenediamine with hydrochloric acid and tin. It crystallises in long, colourless needles, sparingly soluble in cold water, readily in hot water and in alcohol. It melts at  $210^\circ$ . The *platinochloride*,  $\text{C}_{10}\text{H}_{10}\text{N}_4 \cdot \text{H}_2\text{PtCl}_6 + \text{H}_2\text{O}$ , crystallises in long gold-coloured needles; the *sulphate* (with 1 mol.  $\text{H}_2\text{O}$ ) crystallises from hot water in colourless needles almost insoluble in alcohol. When the sulphate is dissolved in fuming nitric acid (5 parts), a *mononitro-derivative*,  $\text{C}_{10}\text{H}_9\text{N}_4\text{NO}_2 + \frac{1}{2}\text{H}_2\text{O}$ , is obtained; this forms orange-red needles melting at  $276^\circ$ . The *platinochloride*,  $\text{C}_{10}\text{H}_9\text{N}_5\text{O}_2 \cdot \text{H}_2\text{PtCl}_6 + \frac{1}{2}\text{H}_2\text{O}$ , crystallises in long, gold-coloured needles.

*Ethenylnitrotriamidobenzene*,  $\text{C}_2\text{H}_3\text{<}\overset{\text{NH}}{\text{N}}\text{>C}_6\text{H}_2(\text{NH}_2) \cdot \text{NO}_2$ , is formed when diacetyldinitrophenylenediamine is heated with alcoholic ammonia

at 150°. It melts at 295—300°. The *hydrochloride* and *sulphate* were prepared.

*Ethylenetetramidobenzene*,  $C_6H_5\begin{smallmatrix} \text{NH} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix} > C_6H_5(NH_2)_2$ , is obtained by reducing the nitrotri-amido-compound with stannous chloride and hydrochloric acid. It only exists in the form of its salts. The picrate crystallises in sparingly soluble yellow needles.

*Diacetyldinitrometaphenylenediamine*,  $C_6H_4(NHAc)_2(NO_2)_2$ , is obtained by treating diacetylmetaphenylenediamine with nitric acid (sp. gr. 1.533); it forms pale-yellow needles which melt at 228°. *Dinitrometaphenylenediamine* is prepared by heating the acetyl-derivative with dilute sulphuric acid. It is an orange-yellow substance, sparingly soluble in alcohol; it melts at about 300°.

*Tetramidobenzene*,  $C_6H_4(NH_2)_4$  [= 1 : 2 : 4 : 5], is formed when freshly prepared dinitrometaphenylenediamine is added to a warm, strongly acid solution of stannous chloride containing an excess of metallic tin. The *hydrochloride* is very soluble in water, sparingly in hydrochloric acid. The *dinitrate*,  $C_6H_4(NH_2)_4 \cdot 2HNO_3$ , forms small, green needles. All the salts absorb oxygen from the air, becoming blue-violet or brown. When the nitrate or hydrochloride is treated with sodium carbonate solution, the *base* is obtained in small, brown needles.

The constitution ascribed to tetramidobenzene is shown by the fact that the diethylenetetramidobenzene from metaphenylenediamine is not identical with that obtained from paraphenylenediamine, and that the nitrogen of the diethylenetetramidobenzene from paraphenylenediamine must be attached to adjacent carbon-atoms.

*Diethylenetetramidobenzene*, obtained by reducing dinitrodiacetylmetaphenylenediamine, melts above the range of the thermometer. The *sulphate* and *platinochloride* were prepared.

Tetramidobenzene reacts with phenanthraquinone, with formation of the compound  $C_{14}H_8\begin{smallmatrix} \text{N} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix} > C_6H_4(NH_2)_2$ . This is a feeble base, and dissolves in sulphuric acid with a greenish-blue colour which changes to violet and red when diluted.  
N. H. M.

**Carbonylorthamidophenol and Thiocarborthamidophenol.**  
By S. v. CHETMICKI (*Ber.*, 20, 177—179).—When ethyl thiocarbamidophenol,  $C_7H_7NOS$ , is heated with strong hydrochloric acid at 156—160°, amidophenol, mercaptan, and carbonic anhydride are formed; the formation of mercaptan can only be explained on the supposition that the ethyl-group in the thiocarbamidophenol is combined with sulphur. Thiocarbamidophenol dissolved in hydrochloric acid, when oxidised with chloride of lime, yields a bisulphide,  $S_2(C_6H_4\begin{smallmatrix} \text{N} \\ \diagup \quad \diagdown \\ \text{O} \end{smallmatrix} > C)_2$ ; the same compound is also formed when the sodium salt of thiocarbamidophenol is treated with iodine solution. These results confirm the formula  $C_6H_4\begin{smallmatrix} \text{N} \\ \diagup \quad \diagdown \\ \text{O} \end{smallmatrix} > C \cdot SH$ , ascribed by Kalekhoff to thiocarborthamidophenol.

The reactions of carbonylorthamidophenol point to the constitution

$$\text{C}_6\text{H}_4 \begin{array}{c} \text{NH} \\ \diagup \quad \diagdown \\ \text{---O---} \end{array} \text{CO}.$$

N. H. M.

**Displacement of the Amido-group in Aromatic Compounds by Hydrothionyl and Oxysulphuryl.** By P. KLASON (*Ber.*, 20, 349—350).—When diazosulphonic acids are treated in small quantities with warm alcoholic solution of potassium sulphide, nitrogen is evolved, and the diazo-group is displaced by SH; in this way thio-cresolsulphonic acid was prepared. The sulphonic acids can be readily purified by precipitating with an ammoniacal solution of lead acetate, and decomposing the lead salt by means of hydrogen sulphide.

When the thiophenolsulphonic acids are treated with potassium permanganate in the cold, toluenedisulphonic acids are formed in which oxysulphuryl has taken the place occupied by the amido-group in the original amido-acid.

The method above described can be employed for introducing selenium and probably also tellurium into aromatic compounds.

N. H. M.

**Halogen-derivatives of Azobenzene and Hydrazobenzene.** By J. V. JANOVSKY and L. ERB (*Ber.*, 20, 357—362; compare *Abstr.*, 1886, 1024).—*Parabromazobenzene* is the chief product obtained by brominating azobenzene dissolved in glacial acetic acid. It melts at 82°, and can be sublimed; it dissolves readily in alcohol, ether, and acetone, less in light petroleum. When the alcoholic solution is treated with ammonia and then with hydrogen sulphide, a *hydrazo-bromo-compound* is formed which crystallises in lustrous plates, melting at about 115°.

*Dinitromonobromazobenzene*,  $\text{C}_{12}\text{H}_7(\text{NO}_2)_2\text{BrN}_2$ , and *nitroparabromazobenzene*,  $\text{C}_{12}\text{H}_8(\text{NO}_2)\text{BrN}_2$ , are obtained by nitrating parabromazobenzene; the former crystallises in orange-red, sparingly soluble needles; the latter forms yellow needles readily soluble in alcohol. When parabromazobenzene is dissolved in fuming sulphuric acid at 140°, a *sulphonic acid* is formed identical with the parabromoparasulphonic acid of azobenzene previously described (*Sitzungsber. Akad. Wissen.*, 1884, 647).

*Metabromazobenzene* is prepared from the product obtained by the action of bromine on azobenzene by extracting the precipitated bromides with a little 80 per cent. alcohol. It forms yellowish-green, lustrous plates, readily soluble in alcohol, ether, and acetone; it melts at 53—56°. *Metabromazobenzeneparasulphonic acid* is obtained by heating a solution of metabromazobenzene in fuming sulphuric acid (5 parts) at 160°. It crystallises in plates with a golden lustre. The *potassium salt* crystallises in yellow, lustrous, microscopic needles. The *sodium salt* is sparingly soluble.

*Nitrazobenzene*,  $\text{NPh}:\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$ , is obtained by dissolving azobenzene (20 grams) in 100 c.c. of glacial acetic acid, heating at 100°, and adding 25 c.c. of nitric acid (sp. gr. 1.51). The product is filtered and purified by crystallising from a mixture of acetone and alcohol. It forms orange-yellow, microscopic needles, readily soluble in alcohol,

&c. It melts at 122—123°. When the alcoholic solution is boiled with alkali, it acquires a splendid emerald colour. The *sulphonic acid* forms hygroscopic needles; the solution of the acid gives with potassium carbonate a purple-red precipitate consisting of woolly needles; with sodium salts a green, and with silver salts a red precipitate.

*Nitrazoxybenzene* is prepared by nitrating azobenzene at 75°. It crystallises from alcohol, ether, chloroform, and acetone in red plates, melting at 127°.

*Hexazoxybenzene*,  $C_{24}H_{18}N_6O$ , is formed when orthonitrazobenzene or nitrazoxybenzene (m. p. 127°) is reduced with sodium amalgam. It is almost insoluble in ether, alcohol, and acetone, readily in boiling benzene, toluene, and xylene, separating therefrom in orange-coloured plates. Warm fuming sulphuric acid dissolves it with a violet-blue colour.

N. H. M.

**Direct Substitution Products of Parazotoluene; Hydrazobromobenzenes, and Hydrazobromotoluenes.** By J. V. JANOVSKY and L. ERB (*Ber.*, 20, 362—364).—When 10 grams of parazotoluene dissolved in 200 c.c. of glacial acetic acid is gradually treated with 15 c.c. of nitric acid (sp. gr. 1.5), and the product precipitated with water and dissolved in hot alcohol, two nitro-compounds are obtained. The one crystallises in orange-yellow, monoclinic needles melting at 114°, the other separates from the mother-liquor as an oil which gradually crystallises. When parazotoluene is treated directly with fuming nitric acid in the cold, two nitro-products are also formed, one of which is sparingly soluble in alcohol and acetone, and forms honey-coloured monoclinic crystals melting at 185—187°. It is a dinitrazotoluene, and is possibly identical with that described by Petrieff (*Jahresber.*, 1873), to which, however, the melting point 110° is ascribed. No mononitro-compound melting at 76° (Petrieff, *loc. cit.*) could be obtained.

By the action of bromine on a boiling solution of azotoluene, a bromide crystallising in large, ruby-coloured prisms, melting at 138.5°, is formed; it is probably identical with Petrieff's monobromide (m. p. 136°). The mother-liquor from the bromide yielded a second bromide melting at 115°.

*Parabromhydrazobenzene*,  $NHPh \cdot NH \cdot C_6H_4Br$ , is prepared by reducing parabromazobenzene with alcoholic solution of hydrogen ammonium sulphide. It crystallises from dilute alcohol in lustrous scales which melt at 115°. It is very stable in the air, and only becomes slightly coloured in four to six weeks. When treated with sulphuric acid, and the sulphate thus obtained decomposed with ammonia, a *monobromobenzydine* is obtained which crystallises in silvery plates.

*Dibromohydrazobenzene* melting at 82° was obtained from diortho-bromazobenzene.

*Bromoparahydrazotoluene* was prepared in a similar manner from bromoparazotoluene; it melts at 117°.

N. H. M.

**Action of Acetone on Paramidoazobenzene.** By C. ENGLER and C. SCHESTOPAL (*Ber.*, 20, 480—482).—When acetone (1 mol.) is

heated with paramidoazobenzene hydrochloride (2 mols.) in sealed tubes at 150—160° for two to three days, methane is formed together with a solid condensation product from which hydrochloric acid extracts a base,  $C_{17}H_{15}N_3$ ; this is probably a quinoline or benzidine derivative, and after fractional precipitation with aqueous potash and distillation in a vacuum is found in the fraction boiling at 280°. It crystallises in bright yellow needles, melts at 204—205°, and is soluble in alcohol and ether; the aqueous solutions of its salts show a strong blue fluorescence. The *sulphate*,  $C_{17}H_{15}N_3.H_2SO_4$ , crystallises from aqueous alcohol in small, monoclinic prisms, and is very soluble in water; the *chromate*,  $C_{17}H_{15}N_3.H_2Cr_2O_7$ , forms orange-yellow, crystalline aggregates; and the *platinochloride*,  $C_{17}H_{15}N_3.H_2PtCl_6$ , crystallises in golden-yellow, flat needles sparingly soluble in cold water.

When reduced with tin and hydrochloric acid, a well-crystallised stannochloride of a base is obtained; this base crystallises in brilliant white needles, melts at 185°, dissolves readily in alcohol and ether, and yields well-crystallised salts.

W. P. W.

**Action of Phenol on Diazoamidobenzene.** By K. HEUMANN and L. OECONOMIDES (*Ber.*, 20, 372—373).—When diazoamidobenzene is heated on a water-bath with phenol, parahydroxyazobenzene is formed together with aniline. Resorcinol, and  $\alpha$ - and  $\beta$ -naphthol react in a similar manner.

N. H. M.

**Constitution of Safranines.** By A. BERNTHSEN (*Ber.*, 20, 179—180).—The constitution previously suggested (this vol., p. 139) for the safranines is supported by the explanation of the constitution of toluylene-red (p. 139). The author considers the unsymmetrical formula proposed by Witt and by Nietzki (this vol., p. 250) as the most probable.

N. H. M.

**Manufacture of Methylene-blue.** By O. MÜHLHÄUSER (*Dingl. polyt. J.*, 262, 371—379).—For the production of methylene-blue on a large scale two processes are in use: (1.) Oxidation of dimethyl-paraphenylenediamine in acid solution, in presence of hydrogen sulphide (Caro's method); (2.) Oxidation of a base containing sulphur, obtained by the action of hydrogen sulphide on nitrosodimethylaniline dissolved in strong sulphuric acid (Oehler's process). The author describes in detail the manufacture of methylene-blue by the "soda waste" and "zinc sulphide" processes. The former comprises the following operations:—(1.) Preparation of a solution of nitrosodimethylaniline by treating dimethylaniline with hydrochloric acid, and nitrating the hydrochloride thus obtained. (2.) Treatment of the nitrosodimethylaniline with soda waste in order to reduce the nitroso-compound to an amine. (3.) Oxidation with ferric chloride. (4.) Extraction of the raw colour with salt and zinc chloride solution. (5.) Filtration.

The zinc sulphide process.—When hydrogen sulphide is passed into sulphuric acid of 40—50° B., sulphur is deposited and sulphurous anhydride evolved thus:  $H_2SO_4 + H_2S = SO_2 + S + 2H_2O$ . On bringing the sulphurous anhydride into contact with hydrogen

sulphide further precipitation of sulphur takes place according to the following equation:  $\text{SO}_2 + 2\text{H}_2\text{S} = 2\text{H}_2\text{O} + 3\text{S}$ . When these reactions occur in the presence of nitrosodimethylaniline sulphate a colourless base containing sulphur is obtained, yielding a blue dye on oxidation. The methylene-blue obtained in this manner is said to be purer and stronger in tinctorial power than that yielded by the soda waste process. D. B.

**Thiophen-green.** By L. E. LEVI (*Ber.*, **20**, 513—517).—*Tetra-methyldiamidodiphenylthiënylmethane*,  $\text{C}_4\text{SH}_3\cdot\text{CH}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2$ , the leuco-base of thiophen-green, is obtained by heating a mixture of thiophen-aldehyde (1 part) and dimethylaniline (2 parts) with a small quantity of alcohol at  $100^\circ$  for six hours, and gradually adding three to four parts of zinc chloride. The base crystallises in compact needles, melts at  $92\text{--}93^\circ$ , and is insoluble in water, readily soluble in ether, benzene, toluene, and alcohol; the alcoholic solution very quickly becomes coloured green on exposure to the air. The *platino-chloride* has the formula  $\text{C}_{21}\text{H}_{24}\text{N}_2\text{S}, \text{H}_2\text{PtCl}_6$ ; the *picrate*,

forms yellowish-green needles, melts at about  $208^\circ$ , and is sparingly soluble in cold water, readily soluble in alcohol, ether, &c.; the *methiodide*,  $\text{C}_{21}\text{H}_{24}\text{N}_2\text{S}, 2\text{MeI}$ , crystallises from alcohol and water in white scales, and melts at  $210\text{--}212^\circ$ .

When the leuco-base is oxidised, preferably with manganese dioxide and dilute sulphuric acid, *thiophen-green*,  $\text{C}_4\text{SH}_3\cdot\text{C}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2\cdot\text{OH}$ , is obtained as a dark-brown, uncrystallisable oil, insoluble in water, but soluble in alcohol, benzene, chloroform, and, when recently prepared, in ether; it cannot be distilled. Thiophen-green forms salts with the elimination of the elements of 1 mol. of water. The *zinc salt*,  $3(\text{C}_{21}\text{H}_{22}\text{N}_2\text{S}), \text{ZnCl}_2 + 2\text{H}_2\text{O}$ , crystallises in scales showing a beautiful coppery lustre, and is readily soluble in all ordinary solvents; the solution in water is coloured a deep bluish-green, which becomes reddish-yellow on adding an acid. The colour imparted to silk and wool very nearly resembles that produced by benzaldehyde-green, but is somewhat more yellow. The *picrate*,

forms scales showing a coppery lustre, and is very sparingly soluble in water; the *sulphate*,  $\text{C}_{21}\text{H}_{22}\text{N}_2\text{S}, \text{H}_2\text{SO}_4$ , crystallises in beautiful scales, readily soluble in water; and the *oxalate*,

crystallises in scales showing a metallic lustre, is readily soluble in water, alcohol, &c., and decomposes very readily. W. P. W.

**Action of Phosphorus Pentachloride on Acetanilide.** By A. MICHAEL (*J. pr. Chem.* **35**, 207—208).—When phosphorus pentachloride is allowed to act on acetanilide at moderate temperatures, compounds very different in composition to the unstable chloro-derivatives described by Gerhardt and by Wallach are obtained.

Thus, when a mixture of acetanilide (1 mol.) and phosphorus pentachloride (3 mols.), after the first reaction is over, is allowed to remain at the ordinary temperature until evolution of hydrogen chloride has practically ceased, then heated at  $100^{\circ}$  to complete the reaction, and poured into water, a compound,  $C_8H_8Cl_2N_2$ , is formed, which crystallises in large, white, monoclinic prisms, melts at  $116.5-117^{\circ}$ , is insoluble in water, soluble in alcohol, and shows both acid and basic properties. If, instead of completing the reaction at  $100^{\circ}$ , the mixture is allowed to remain in the cold for some time longer, and then poured into water, long, citron-yellow needles of a compound  $C_{38}H_{36}Cl_7N_4$  are obtained. This melts at  $227-229^{\circ}$ , is soluble in alcohol, and shows both acid and basic properties. Two other compounds are also formed in this reaction, one of which crystallises in large tables, whilst the other is a thick liquid which only becomes solid after long standing.

The author finds that acetamide, when treated with 2 mols. of phosphorus pentachloride and subsequently with water, yields a compound in the form of a thick liquid. W. P. W.

**Action of Hydroxylamine and Phenylhydrazine on Dialdehydes and Ketones.** By F. MÜNCHMEYER (*Ber.*, 20, 507—513).—Isophthalaldehyde reacts with hydroxylamine hydrochloride and soda to form the *aldoxime*  $C_6H_4(CH:NOH)_2 = [1:3]$ ; this crystallises in lustrous, white scales, melts at  $211-212^{\circ}$ , and is soluble in alcohol and ether. When treated with an excess of acetic chloride, isophthalaldoxime yields metadicyanobenzene; the *methyl*-derivative,  $C_6H_4(CH:NOMe)_2$ , crystallises in colourless needles melting at  $77^{\circ}$ , the *ethyl*-derivative in small needles melting at  $165^{\circ}$ .

Orthophthalaldehyde (which, according to a foot-note by V. Meyer, has been recently obtained by Faust, and will shortly be described), when heated with hydroxylamine hydrochloride and soda, yields *orthophthalaldoxime*,  $C_6H_4(CH:NOH)_2 [1:2]$ , it crystallises in small needles, melts at  $245^{\circ}$ , and is soluble in alcohol.

Tetramethyldiamidobenzophenone, although it reacts with hydroxylamine hydrochloride (*Abstr.*, 1886, 877), does not yield a hydrazide when treated either with phenylhydrazine or its hydrochloride; further investigation of the action of these reagents on amidophenones shows that this behaviour is exceptional. When  $\beta$ -dinitrobenzophenone is heated with hydroxylamine hydrochloride and soda, the *oxime* is obtained in small, golden-yellow needles melting at  $205-207^{\circ}$ ; and by treatment with phenylhydrazine hydrochloride the ketone yields a *hydrazide*,  $(C_6H_4NO_2)_2C:N:NHPh$ , this is a red powder melting at  $219-220^{\circ}$ , and is soluble in acetic acid, sparingly soluble in hot alcohol.  $\beta$ -Diamidobenzophenone under these conditions yields a crystalline *oxime* melting at  $177-178^{\circ}$ , and a *hydrazide*,  $(NH_2 \cdot C_6H_4)_2C:N_2HPh$ , in the form of yellow needles melting at  $183^{\circ}$ . Also, when similarly treated, paramidoacetophenone is converted into an *oxime* crystallising in small needles which melt at  $147-148^{\circ}$ ; and the hydrochloride of a *hydrazide*,  $NH_2 \cdot C_6H_4 \cdot CMe:N_2HPh \cdot HCl$ , which is crystalline, and evolves gas when heated at  $205-207^{\circ}$ . W. P. W.

**Preparation of Vanillin from Metachloroparanitrobenzaldehyde.** By L. LANDSBERG (*Dingl. polyt. J.*, 262. 139).—It is proposed to convert metachloroparanitrotoluene into chloronitrobenzyl chloride or bromide, and to treat the latter with lead or copper nitrate, in order to obtain metachloroparanitrobenzaldehyde. On treating this aldehyde with an alkaline methoxide or the hydroxide dissolved in methyl alcohol, the chlorine is displaced by the methoxyl-group with formation of metamethoxyparanitrobenzaldehyde. The same compound is obtained when the chlorine in metachloroparanitrobenzaldehyde is displaced by hydroxyl, and the resultant hydroxynitrobenzaldehyde converted into its methyl ether. Metamethoxyparanitrobenzaldehyde crystallises from boiling water in white needles melting at  $62^{\circ}$ , and is converted into vanillin according to the known methods. When heated with acetic anhydride or sodium acetate, it is resolved into metamethoxyparanitrocinnamic acid, melting at  $218^{\circ}$ . D. B.

**Action of Potassium Ferricyanide on Acetophenone.** By K. BUCHKA and P. H. IRISH (*Ber.*, 20, 386—395).—All attempts to obtain phenylglyoxylic acid by the oxidation of acetophenone have hitherto proved unavailing, the methyl-group always being eliminated and benzoic acid produced. The author finds that by the continued action of an alkaline solution of potassium ferricyanide on acetophenone, phenylglyoxylic acid is produced. The quantity is, however, very small, and appears to be due to a secondary reaction, and not to direct oxidation, a great deal of benzoic acid being formed.

When 3 grams of acetophenone are added to a solution of 50 grams of potassium ferricyanide and 5 grams of potassium hydroxide in half a litre of water, and the whole allowed to stand for about 12 hours, small quantities of a crystalline substance are deposited. This substance, when recrystallised from benzene, is obtained in minute colourless needles having the formula  $C_{16}H_{15}O_2N$ . When heated with caustic potash, ammonia is evolved, and the *potassium* salt  $C_{16}H_5O_4K$  of a new acid is produced; it crystallises in minute needles. The corresponding *barium salt* yields concentric groups of needles, and contains  $3\frac{1}{2}$  mols.  $H_2O$ . The free *acid* is crystalline, and melts at  $99-101^{\circ}$  (uncorr.). The compound  $C_{16}H_{15}O_2N$  thus seems to be the nitrile of the acid. Both the acid and the nitrile dissolve in concentrated sulphuric acid with a violet-red coloration, but the coloration is destroyed by dilution. The coloration produced by dissolving phenylglyoxylic acid in strong sulphuric acid is, on the other hand, not destroyed by dilution. By continued boiling with concentrated potash, both the nitrile and the acid yield phenylglyoxylic acid and acetophenone.

The author is inclined to think that the formation of these compounds is due to a part of the acetophenone becoming oxidised to benzaldehyde, which then unites with undecomposed acetophenone and hydrocyanic acid to form a cyanhydrin;  $Ph\cdot COH + Ph\cdot COMe + HCN = CPhMe(OH)\cdot CPh(OH)\cdot CN$ .

Other mixed aromatic and fatty ketones seem to act in a similar way towards alkaline ferricyanide. These reactions are being further studied.

L. T. T.

**Metacyanobenzoic Acid.** By W. BRÖMME (*Ber.*, **20**, 524—530).—The *silver*, *barium* (with  $3\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ ), *calcium* (with 3 mols.  $\text{H}_2\text{O}$ ), and *zinc* salts are described; the *methyl* salt melts at  $65^\circ$ , and is sparingly soluble in alcohol, ether, benzene, and carbon bisulphide, sparingly soluble in water; the *ethyl* salt melts at  $56^\circ$  (comp. Müller, *Abstr.*, 1886, 802); and the *amide* melts above  $300^\circ$ , and is soluble in alcohol and ether, insoluble in water. Metacyanobenzoic acid does not yield a nitro-derivative when treated with nitric acid or with a mixture of nitric and fuming sulphuric acids, and is neither reduced by sodium amalgam nor by sodium under various conditions. An alcoholic solution of hydroxylamine hydrochloride and soda converts the acid into the *amidoxime* (*loc. cit.*).

When metacyanobenzoic acid is dissolved in strong aqueous ammonia and the solution saturated with carbon bisulphide, a crystalline acid,  $(\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{C}:\text{NH})_2\text{S}$ , is obtained, which melts at  $199^\circ$ , and is soluble in hot water, alcohol, and ether. When reduced with zinc and hydrochloric acid, this compound is converted into an acid of the formula  $(\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2)_2\text{NH}$  [1 : 3]; it is crystalline, melts above  $300^\circ$ , sublimes without decomposition, and is sparingly soluble in hot water, soluble in alcohol, ether, benzene, and carbon bisulphide. The *zinc* salt is very hygroscopic, and is readily soluble in all ordinary solvents. An acid of the formula

is formed when metacyanobenzoic acid and benzene are added to fuming sulphuric acid, allowed to remain for 24 hours, and then poured into cold water; it is crystalline, melts above  $300^\circ$ , shows both acid and feeble basic properties, and is soluble in alcohol and ether, insoluble in water. The *silver* salt,  $\text{C}_{16}\text{H}_8\text{O}_5\text{N}_2\text{Ag}_4$ , is insoluble in water.

W. P. W.

**Behaviour of Cyanobenzoic Acids on Dry Distillation.** By W. BRÖMME (*Ber.*, **20**, 521—524).—Why dry calcium metacyanobenzoate is submitted to dry distillation, metadicyanobenzene is obtained in addition to benzonitrile; the melting point of the dicyanobenzene is  $157\cdot5^\circ$ . If, however, calcium paracyanobenzoate is similarly treated, benzonitrile and paradicyanobenzophenone are obtained.

*Paradicyanobenzophenone*,  $\text{CO}(\text{C}_6\text{H}_4\cdot\text{CN})_2$  [ $\text{CN}:\text{CO} = 1:4$ ], crystallises in nodules, melts at  $204\cdot5$ , sublimes without decomposition, and is sparingly soluble in hot water and light petroleum, soluble in carbon bisulphide, readily soluble in alcohol, ether, and benzene. With phenylhydrazine, it yields a *triphenylhydrazide*; this crystallises in nodules, melts at  $212^\circ$ , is soluble in alcohol, ether, &c., and when heated is decomposed into the ketone.

*Benzophenoneparadicarboxylic acid*,  $\text{CO}(\text{C}_6\text{H}_4\cdot\text{COOH})_2$ , formed by hydrolysis of the ketone, sublimes without previous fusion, is very sparingly soluble in ether and benzene, sparingly soluble in alcohol, soluble in hot water to the extent of 1 in 50,000, and is obtained from this solution in microscopic needles. The *methyl* salt crystallises in large needles, and melts at  $138^\circ$ ; the *silver* salt,  $\text{C}_{16}\text{H}_8\text{O}_6\text{Ag}_2 +$

$\text{Ag}_2\text{O}$ , prepared by hydrolysis of the pure methyl salt, is insoluble in water. The acid and its methyl salt show a remarkable similarity to terephthalic acid and methyl terephthalate respectively.

Benzonitrile forms a solid compound when treated with phenylhydrazine. W. P. W.

**Meta- and Para-hydroxynitrobenzoic Acids.** By P. GRIESS (*Ber.*, 20, 403—409).—Of the four possible meta-hydroxynitrobenzoic acids [ $\text{COOH} : \text{OH} : \text{NO}_2 = 1 : 3 : 6, 1 : 3 : 4, 1 : 3 : 2,$  and  $1 : 3 : 5$ ], the author has already described the first three under the names of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -metahydroxynitrobenzoic acids respectively; and also one of the two possible parahydroxynitrobenzoic acids,  $1 : 4 : 3$  and  $1 : 4 : 2$  (the former), under the name  $\delta$ -hydroxynitrobenzoic acid (*Ber.*, 5, 856, and *Abstr.*, 1879, 246). Gerland (*Annalen*, 91, 192) has described the formation of a hydroxynitrobenzoic acid by the dissolution of metahydroxybenzoic acid in nitric acid of sp. gr. 1.36. The author finds that in this way di- or tri-nitro-compounds are always produced, but by employing only a slight excess of very dilute acid, a mixture of mononitro-compounds may be obtained; this contains three isomerides, his  $\alpha$ - and  $\beta$ -acids, and a third  $\zeta$ -hydroxynitrobenzoic acid, which is undoubtedly the missing acid,  $1 : 3 : 5$ . The separation of the three acids is effected by means of the sparing solubility of the  $\beta$ -acid in water, and the greater solubility of the barium salt of the  $\gamma$ -acid than of that of the  $\zeta$ -acid.

$\zeta$ -Hydroxynitrobenzoic acid,

crystallises in white scales or plates. It is easily soluble in alcohol, ether, and boiling water, melts at  $167^\circ$ , and decomposes at a higher temperature with evolution of black fumes. It has an acid and astringent taste; its barium salt crystallises with  $6\text{H}_2\text{O}$  in pale-yellow prisms. The acid to which Grube and Hübner ascribe the above formula (*Ber.*, 10, 1704) is, the author considers, undoubtedly identical with V. Meyer and Michler's diazoxybenzoic acid (*Ber.*, 3, 746).

Barth's parahydroxynitrobenzoic acid, obtained by dissolving parahydroxybenzoic acid in nitric acid of sp. gr. 1.46 (*Zeit. f. Chem.*, 1866, 647), is identical with the author's  $\delta$ -acid. L. T. T.

**Derivatives of Orthamidophenylvaleric Acid.** By L. DIEHL and A. EINHORN (*Ber.*, 20, 377—386).—*Orthamidocinnamenylpropionic acid*,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH} : \text{CH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$ , is prepared by dissolving orthamidocinnamenylacrylic acid in 50 parts of water in presence of alkali, and adding 5 per cent. sodium amalgam gradually; the solution must be kept almost neutral by addition of sulphuric acid. In 3 or 4 days it is treated with sulphuric acid, filtered, saturated with ammonia, and evaporated to dryness on a water-bath; ammonia is given off, and the free acid is extracted from the residue by absolute alcohol. The alcoholic solution is treated with water, heated to drive off the alcohol, and cooled with ice; the acid separates with 1 mol.  $\text{H}_2\text{O}$ . The ethereal solution shows green fluorescence.

*Orthamidodibromophenyl-γ-δ-dibromovaleric acid,*

is obtained by adding a solution of bromine in glacial acetic acid to a cooled solution of orthamidocinnamenylpropionic acid, also in glacial acetic acid. The product is poured into water containing sulphurous acid, and the precipitated substance dried and recrystallised from chloroform. It forms microscopic needles, which melt at 167°, with decomposition. It is readily soluble in alcohol, ether, and glacial acetic acid, less soluble in chloroform, insoluble in carbon bisulphide, water, and dilute mineral acids. Aqueous alkali solutions dissolve it readily.

*Orthamidodibromophenylvaleric acid*,  $\text{NH}_2 \cdot \text{C}_6\text{H}_2\text{Br}_2 \cdot (\text{CH}_2)_4 \cdot \text{COOH}$ , is formed when a solution of orthamidotetrabromophenylvaleric acid in 5 parts of alcohol and 2 parts of strong hydrochloric acid, is treated with granulated zinc for a quarter of an hour, and then poured into water. It is extracted with ether, and the oil thus obtained dissolved in the smallest possible amount of 10 per cent. aqueous caustic soda and warmed. The acid crystallises from aqueous alcohol in splendid long needles (with 1 mol.  $\text{H}_2\text{O}$ ). It melts at 96°, and decomposes with evolution of gas at 223°. It dissolves readily in the usual solvents, except cold water, in which it is insoluble. The alkali salts are readily soluble. *Ethyl orthamidodibromophenylvalerate hydrochloride*,  $\text{C}_{13}\text{H}_{18}\text{NO}_2\text{Br}_2\text{Cl}$ , forms slender, white needles, which melt at 135–136°. The *acetyl-derivative*,  $\text{C}_{13}\text{H}_{15}\text{NO}_3\text{Br}_2$ , crystallises from 80 per cent. hot alcohol in tufts of slender, white needles, melting at 205–206°. It is readily soluble. The *ethyl salt* of the acetyl compound crystallises from dilute alcohol in stellate groups of needles. It melts at 139°, dissolves readily in alcohol, ether, &c., more sparingly in benzene, and can be distilled in small quantities without decomposition.

*Orthamidophenylvaleric acid*,  $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{COOH}$ , is obtained by reducing orthamidodibromophenylvaleric acid dissolved in absolute alcohol with sodium amalgam. The product is made slightly acid with hydrochloric acid, treated with water, and boiled until free from alcohol. It is then made slightly ammoniacal, evaporated repeatedly until no more ammonia comes off, and the free acid thus obtained is crystallised from water containing a little alcohol. It forms white needles, melting at 60–62°. N. H. M.

**Substituted Mono- and Di-bromosalicylic Acids.** By A. PERATONER (*Gazzetta*, 16, 405–420).—In this paper are described a series of substituted mono- and di-bromosalicylic acids, obtained by heating the methyl salts of the mono- and di-bromo-acids with the alkyl iodides in presence of potash.

*Methyl bromosalicylate*,  $\text{OH} \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOMe}$  [ $\text{COOMe} : \text{OH} : \text{Br} = 1 : 2 : 5$ ], obtained by the bromination of methyl salicylate dissolved in carbon bisulphide, crystallises in colourless needles or small prisms of the trimetric system, melting at 61°, and boiling without decomposition at 264–266°, insoluble in water, sparingly soluble in methyl alcohol. On hydrolysis, it yields a bromosalicylic acid melting at 164–165°.

*Methyl methoxybromosalicylate*,  $\text{OMe} \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOMe}$ , obtained by the methylation of the above, crystallises in colourless needles melting at  $39-40^\circ$ , and distilling without decomposition at  $295^\circ$ , insoluble in water, soluble in other menstrua. The corresponding *acid* crystallises in long needles melting at  $119^\circ$ , resembling the methyl salt, as regards its solubility. Its alkaline salts are very soluble, the *calcium*, *magnesium*, and *silver* salts crystallise in needles.

*Ethoxybromosalicylic acid*,  $\text{OEt} \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOH}$ , crystallises in colourless needles melting at  $130^\circ$ ; its metallic salts resemble those of the methoxy-acid; the methyl salt crystallises in colourless needles, melting at  $49^\circ$ , and boiling at  $300-302^\circ$ .

*Propoxybromosalicylic acid*,  $\text{OPr}^a \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOH}$ , melts at  $62^\circ$ ; its *methyl* salt is a colourless liquid boiling at  $321-324^\circ$ , and solidifying in a freezing mixture; the isopropyl acid,  $\text{OPr}^b \cdot \text{C}_6\text{H}_3\text{Br} \cdot \text{COOH}$ , crystallises in needles melting at  $101^\circ$ .

*Methoxydibromosalicylic acid*,

crystallises in long needles melting at  $193-194^\circ$ , and its barium salt, with  $2.5\text{H}_2\text{O}$ , in grouped needles; the methyl salt forms colourless needles melting at  $53^\circ$ . Methyl dibromosalicylate,

obtained as one of the products of the bromination of methyl salicylate, crystallises in long needles, melting at  $148-149^\circ$ .

*Ethoxydibromosalicylic acid*,  $\text{OEt} \cdot \text{C}_6\text{H}_2\text{Br}_2 \cdot \text{COOH}$ , crystallises in colourless needles melting at  $155-156^\circ$ , and its methyl salt in interlaced needles melting at  $43^\circ$ .

None of the above described acids give any coloration with ferric chloride.

V. H. V.

**Constitution of Dibromosalicylic Acid.** By A. PERATONER (*Gazzetta*, 16, 401—404).—The dibromosalicylic acid, obtained by the direct bromination of salicylic acid, when heated in sealed tubes with dilute sulphuric acid (1 : 3), yields the dibromophenol melting at  $36^\circ$  ( $40^\circ$  Körner), the constitution of which is known to be  $[\text{OH} : \text{Br} : \text{Br} = 2 : 3 : 5]$ ; the carboxylic acid must then be represented by the formula  $[\text{COOH} : \text{OH} : \text{Br} : \text{Br} = 1 : 2 : 3 : 5]$ . Tribromo- and 1 : 2 bromophenol are also formed as subsidiary products in the above reaction: their formation is due to the ulterior decomposition of the dibromophenol, thus:  $2\text{C}_6\text{H}_3\text{Br}_2 \cdot \text{OH} = \text{C}_6\text{H}_2\text{Br}_3 \cdot \text{OH} + \text{C}_6\text{H}_4\text{Br} \cdot \text{OH}$ .

V. H. V.

**Formation of Phenylglyoxylic Acid from Benzoic Cyanide.** By K. BUCHKA (*Ber.*, 20, 395—398).—The author has repeated his former experiments (this Journal, 1877, ii, 485) on the action of hydrochloric acid on an acetic solution of benzoic cyanide. He finds that his phenoxylic acid is identical with Claisen's phenylglyoxylic acid, the melting point given (*loc. cit.*) being due to an admixture of

benzoic acid. Besides this acid, its  $\alpha$ -amide,  $\text{Ph}\cdot\text{CO}\cdot\text{CONH}_2$ , and the so-called  $\gamma$ -amide,  $(\text{C}_8\text{H}_7\text{NO}_2)_2$ , are produced, as well as the compound  $\text{C}_{16}\text{H}_{12}\text{N}_2\text{O}_3$  previously described (*loc. cit.*). The latter compound is probably somewhat analogous in formation and constitution to the nitrile described in the Abstract, p. 483. It is very stable towards acids, alkalis, and reducing and oxidising agents, and is now being investigated. The phenylglyoxylic acid is probably formed from the  $\alpha$ -amide, and not from the compound  $\text{C}_{16}\text{H}_{12}\text{N}_2\text{O}_3$ . L. T. T.

**Methyl Salt of Methyl dibromopara coumaric Acid.** By A. VALENTINI (*Gazzetta*, 16, 424—425).—The methyl salt of paramethoxycoumaric acid,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{C}_2\text{H}_2\cdot\text{COOMe}$ , crystallises in laminæ melting at  $89^\circ$ ; when dissolved in chloroform it readily takes up a molecule of bromine to form a compound,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CHBr}\cdot\text{CHBr}\cdot\text{COOMe}$ , which may be regarded as a dibromo-derivative of methylhydropara coumaric acid. This substance melts at  $118^\circ$ , and forms minute white crystals. V. H. V.

**Oxidation of  $\alpha$ - and  $\beta$ -Hydropiperic Acids.** By C. REGEL (*Ber.*, 20, 414—425).—By the oxidation of the  $\alpha$ -acid in alkaline solution by very dilute potassium permanganate, *hydroxypiperohydrolactone*,  $\text{CH}_2<\overset{\text{O}}{\underset{\text{O}}{\text{C}}}>\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{CH}<\overset{\text{CH}(\text{OH})\cdot\text{CH}_2}{\text{O}\text{-----}\text{CO}}>$ , and small quantities of piperonal, piperonylic acid, and oxalic acid are produced. This lactone crystallises in long, glistening, colourless needles, soluble in water, ether, and chloroform, insoluble in light petroleum. It melts at  $104\cdot5^\circ$ . Bromine acts on it readily, hydrogen bromide being evolved and a bromo-derivative formed; this crystallises in needles. When the lactone is dissolved in a small quantity of warm concentrated potash, and the product cooled in a freezing mixture and treated with a very slight excess of sulphuric acid,  $\beta$ - $\gamma$ -*dihydroxypiperohydronic acid*,  $\text{CH}_2<\overset{\text{O}}{\underset{\text{O}}{\text{C}}}>\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{COOH}$ , separates. This acid forms minute white crystals melting at  $123^\circ$ , at the same time giving off water and re-forming the lactone. When an aqueous solution of the acid is boiled, it is partially converted into the lactone, but, on the other hand, an aqueous solution of the lactone is by long-continued boiling partially converted into the acid. The addition of a few drops of hydrochloric or sulphuric acid facilitates the conversion of the acid into the lactone, and even determines it in the cold. The *barium salt* is soluble in water, the *silver salt* sparingly so.

When  $\beta$ -hydropiperic acid is similarly treated with permanganate, it yields, besides piperonal and oxalic acid, methylenehydrocaffeic (piperopropionic) acid,  $\text{CH}_2:\text{O}_2:\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$  (Lorenz, *Abstr.*, 1881, 49), and  $\alpha$ - $\beta$ -*dihydroxypiperohydronic acid*,

The latter is easily soluble in alcohol and boiling water, sparingly so in benzene, carbon bisulphide, chloroform, light petroleum, and cold water. It crystallises in colourless, concentrically grouped

needles, and melts at  $165^{\circ}$ . Its *calcium salt* ( $+ \text{H}_2\text{O}$ ) and *silver salt* are sparingly soluble. It does not form a lactone.

The oxidation of the hydropiperic acids appears to take place by the addition of oxygen and the elements of water to the two doubly-linked carbon-atoms. The non-formation of a lactone and the production of methylenecaffeic acid from the  $\beta$ -acid leaves little doubt that the formula for  $\beta$ -hydropiperic acid is

and of the dihydroxy-acid that given above. The formation of a lactone from the  $\alpha$ -acid proves that one of the doubly-linked carbon-atoms must be in the  $\gamma$ -position to the carboxyl-group, but whether the second occupies the  $\beta$ - or  $\delta$ -position is still uncertain. The author believes the former probably to be the case when the formula  $\text{CH}_2:\text{O}_2:\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{CH}:\text{CH}\cdot\text{CH}_2\cdot\text{COOH}$ , given by Fittig to  $\alpha$ -hydropiperic acid, would be the correct one, and those of its derivatives would be those given above.

L. T. T.

**Action of Bibasic Acids on Thiocarbimides.** By F. MOINÉ (*Chem. Centr.*, 1887, 39—40).—When equal molecules of phthalic acid and allylthiocarbimide are heated together at  $145^{\circ}$ , allylphthalimide is formed; when treated with bromine in carbon bisulphide solution, it yields the dibromide melting at  $108$ — $109^{\circ}$ .

*Allylsuccinimide*,  $\text{C}_2\text{H}_4\langle\text{CO}\rangle\text{N}\cdot\text{C}_3\text{H}_5$ , is obtained by heating together equivalent amounts of succinic acid and allylthiocarbimide. It is a mobile, colourless, not unpleasant smelling oil, boiling at  $244$ — $245^{\circ}$ ; sp. gr. =  $1\cdot1543$  at  $0^{\circ}$ ,  $1\cdot1432$  at  $12^{\circ}$ ,  $1\cdot1112$  at  $50^{\circ}$ , and  $1\cdot0677$  at  $100^{\circ}$ , compared with water at  $4^{\circ}$ . It is easily soluble in water, alcohol, and ether, has a neutral reaction, is decomposed on boiling, and gives a semi-solid compound with bromine.

*Phenylsuccinimide*,  $\text{C}_2\text{H}_4\langle\text{CO}\rangle\text{NPh}$ , is obtained by heating succinic acid and phenylthiocarbimide at  $140^{\circ}$ ; it melts at  $253$ — $255^{\circ}$ . There is also formed a little *succinanilide*,  $\text{C}_2\text{H}_4(\text{CONHPh})_2$ . Malonic acid and phenylthiocarbimide yield malondianilide (*Abstr.*, 1884, 729).

*Allylcamphorimide*,  $\text{C}_8\text{H}_4\langle\text{CO}\rangle\text{N}\cdot\text{C}_3\text{H}_5$ , is formed when camphoric acid is heated with allylthiocarbimide. It forms colourless plates, and melts at  $48$ — $49^{\circ}$ . It is almost insoluble in water, soluble in alcohol and ether.

When the anhydrides of phthalic and camphoric acids are heated with allylthiocarbimide, the corresponding imides are formed, together with the above compounds.

G. H. M.

**Action of Phenylhydrazine on Lactones.** By W. WISLICENUS (*Ber.*, 20, 401—403).—V. Meyer and Münchmeyer have shown (*Abstr.*, 1886, 883) that phthalide reacts with phenylhydrazine to form a nitrogenous compound. The author has investigated this reaction, and finds the compound formed to be a simple additive pro-

duct,  $C_{14}H_{14}N_2O_2$ , and not a substance,  $C_{14}H_{12}N_2O$ , formed by the elimination of water (*loc. cit.*). The compound  $C_{14}H_{14}N_2O_2$  crystallises in minute, glistening needles, easily soluble in boiling alcohol, insoluble in water and benzene. It melts at  $173-174^\circ$  with partial decomposition into its constituents. It is very unstable towards dilute acids and alkalis, thus differing from the hydrazine condensation products of the aldehydes and ketones. It dissolves to a colourless solution in strong sulphuric acid, but the addition of a trace of an oxidising agent such as ferric chloride produces a reddish-violet coloration. Bulow has observed a similar reaction with the acid hydrazides, and the author considers that the constitution of the compound is probably  $OH \cdot CH_2 \cdot C_6H_4 \cdot CO \cdot N_2H_2Ph$ .

Valerolactone reacts with phenylhydrazine in an exactly similar manner, producing a compound which crystallises in small flat needles. It seems to have the formula  $C_{11}H_{16}N_2O_2$ , and the melting point  $76-79^\circ$ , but the author has not yet succeeded in obtaining it in a pure state. It is soluble in alcohol, benzene, chloroform, and water, insoluble in ether.

L. T. T.

**Nitrobenzyl-derivatives of Ethyl Malonate.** By E. LELLMANN and C. SCHLEICH (*Ber.*, **20**, 434—442).—In the reaction between paranitrobenzyl chloride and ethyl sodiomalonate there are formed simultaneously ethyl mono- and di-nitrobenzylmalonate, of which the latter,  $C(CH_2 \cdot C_6H_4 \cdot NO_2)_2(COOEt)_2$ , crystallises in silky needles melting at  $170^\circ$ , sparingly soluble in alcohol, chloroform, and benzene; the former,  $CH(CH_2 \cdot C_6H_4 \cdot NO_2)(COOEt)_2$ , crystallises in golden-green prisms. On treatment with alkali, the di-derivative is unaltered, whilst the mono-derivative is converted into paranitrobenzylmalonic acid,  $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot CH(COOH)_2$ , a light yellow powder, which carbonises at  $240^\circ$  without fusion. An ammoniacal solution of this acid gives precipitates with solutions of salts of the heavy metals. The above di-derivative when reduced gives an amido-derivative,  $C(CH_2 \cdot C_6H_4 \cdot NH_2)_2(COOEt)_2$ , a hard crystalline mass, the platinum-chloride of which crystallises in leaflets, the sulphate and the oxalate in scales. In a similar manner *ethyl nitrobenzylethylmalonate*,  $CEt(CH_2 \cdot C_6H_4 \cdot NO_2)(COOEt)_2$ , is produced from paranitrobenzyl chloride and sodium ethylmalonate; this crystallises in colourless needles, melts at  $52^\circ$ , and is soluble in alcohol, ether, and benzene. On treatment with potash and subsequent acidification, this compound is converted into *paranitrobenzylethylacetic acid*,

a sparingly soluble substance, carbonising at  $300^\circ$  without fusion.

Similarly from ethyl sodiomalonate and orthonitrobenzyl chloride the corresponding ortho-compound,  $C(CH_2 \cdot C_6H_4 \cdot NO_2)_2(COOEt)_2$ , is produced, which forms golden crystals melting at  $97^\circ$ , soluble in alcohol and ether. Ethyl orthonitrobenzylethylmalonate was not obtained in a definite state; on hydrogenation, the impure product is converted into ethyl  $\beta$ -ethylhydrocarbostyryl- $\beta$ -carbonate,

which crystallises in colourless silky needles melting at  $114^{\circ}$ . Similar experiments on the reduction of ethyl orthodinitrobenzylmalonate led to indefinite results.

V. H. V.

**Synthesis of the Ethereal Salts of Trimesic Acid.** By A. PIUTTI (*Ber.*, 20, 537—539; *Chem. Centr.*, 1887, 36—37).—*Ethyl trimesate*,  $C_6H_3(COOEt)_3$ , is formed when 16 grams of sodium are added to 72 grams (1 mol.) of ethyl formate and 86 grams (1 mol.) of ethyl acetate in the cold and the mixture then heated, but by acting on a mixture of ethyl acetate and formic acid with sodium, ethyl formylacetate is not formed but only ethyl acetoacetate. The author considers that the ethereal salt of trimesic acid is formed by the condensation of three molecules of ethyl formylacetate with elimination of three molecules of water. When sodium acts on a mixture of methyl formate with ethyl acetate or of ethyl formate with methyl acetate in molecular proportions, a mixture of methyl and ethyl trimesates is formed in each case. The reaction takes place much more readily when a mixture of the two radicles is used than when one radicle only is present.

*Methyl trimesate*,  $C_6H_3(COOMe)_3$ , crystallises from dilute alcohol in small needles and melts at  $143^{\circ}$ .

When ethyl formate is added to a solution of sodium in ethyl acetate, it is decomposed into alcoholate and carbonic anhydride.

G. H. M.

**The Six Isomeric Toluenedisulphonic Acids.** By P. KLASON (*Ber.*, 20, 350—357).—Toluenedisulphonic acid,  $[Me:(SO_3H)_2 = 1:2:6]$ , was prepared by Komatzki (*Abstr.*, 1884, 70). The constitution ascribed to it by the author is shown by the fact that it is formed from parabromotoluene (hence neither sulphonic group can have the para-position), and by its non-identity with the three acids which are shown to have a sulphonic group in the meta-position.

Tolueneorthometadisulphonic acid,  $[Me:(SO_3H)_2 = 1:2:3]$  (this vol., p. 264), was obtained by Limpricht and Richter (*Abstr.*, 1885, 1233) from paratoluidine, and by the author (*loc. cit.*) from toluene-metasulphonic acid.

*Tolueneorthometadisulphonic acid*  $[1:2:5]$  was first obtained by Håkansson (*Ber.*, 5, 1088), who named it  $\beta$ -toluenedisulphonic acid. It was prepared by the author (*loc. cit.*) by heating toluene-monosulphonic acid with fuming sulphuric acid at  $180^{\circ}$ . When orthotoluidine is heated with sulphuric acid, orthotoluidinemetasulphonic acid  $[1:2:5]$  (Neville and Winther, *Trans.*, 1882, 421) is formed. Orthotoluidinemetasulphonic acid was converted into the diazo-compound, and the latter, after being carefully dried (it explodes easily), gradually added to a warm alcoholic solution of potassium sulphide. The product is diluted with water and treated with lead acetate, filtered and treated with ammoniacal solution of lead acetate; the precipitate is washed and decomposed by hydrogen sulphide. The impure orthothiocresolmetasulphonic acid  $[1:2:5]$  is oxidised by potassium permanganate, the tolueneorthometadisulphonic acid thus formed treated with phosphoric chloride, and the acid chloride converted into the corresponding acid by heating it with water at  $140^{\circ}$ .

The acid thus obtained is identical with  $\beta$ -toluenedisulphonic acid, and has the constitution [1 : 2 : 5].

Toluenearthoparadisulphonic acid [1 : 2 : 4] is the  $\alpha$ -toluenedisulphonic acid prepared by Blomstrand (*Ber.*, **4**, 717); it was also prepared by Senhofer (*Annalen*, **164**, 129), who described it as  $\gamma$ -toluenedisulphonic acid, supposing it to be different from the  $\alpha$ -acid, and by Håkansson (*loc. cit.*). It is formed both from tolueneparasulphonic acid (Fahlberg, *Abstr.*, 1879, 804) and from tolueneorthosulphonic acid (Klason and Berg, *Abstr.*, 1880, 889), and has, therefore, the constitution given by the author.

Toluenemetadisulphonic acid [1 : 3 : 5] was prepared by Limpricht and Hasse (*Ber.*, **18**, 2177). Orthotoluidinemetasulphonic acid was converted into orthotoluidinedisulphonic acid, which has the constitution [1 : 2 : 3 : 5] (Nevile and Winther, *loc. cit.*). This was converted by means of the diazo-compound into the iodotoluenedisulphonic acid, from which the iodine was eliminated by boiling with strong hydrochloric acid.

*Toluenemetaparadisulphonic acid* [1 : 3 : 4] is prepared in the following manner:—Paratoluidinemetasulphonic acid is converted into a toluidinedisulphonic acid. The latter is converted into the diazo-compound, which is converted successively into parathiocresolmetasulphonic acid and toluenedisulphonic acid. The potassium salt of the acid is treated with phosphoric chloride, and the chloride, after being recrystallised from chloroform several times, is converted into the acid by heating it with water at  $140^\circ$ . Like all toluenedisulphonic acids, it is extremely soluble in water. The *potassium salt* (with 1 mol.  $\text{H}_2\text{O}$ ) crystallises in needles and is readily soluble; the *barium salt* (with 2 mols.  $\text{H}_2\text{O}$ ) forms lustrous prisms soluble in 666 parts of cold water. The *chloride*,  $\text{C}_7\text{H}_6(\text{SO}_2\text{Cl})_2$ , melts at  $111^\circ$ , and dissolves readily in chloroform, less in ether. The *amide* melts at  $235$ — $239^\circ$  with slight decomposition; it dissolves readily in water and alcohol.

*Dithiocresolsulphonic acid*,  $\text{S}(\text{C}_7\text{H}_6\cdot\text{SO}_2\cdot\text{OH})_2$ , was obtained in small quantity; the *chloride* melts at  $192^\circ$ , and is very sparingly soluble in all solvents except glacial acetic acid. N. H. M.

**Diphenylhydroxyethylamine.** By H. GOLDSCHMIDT and N. POLONOWSKA (*Ber.*, **20**, 492—495).—When benzoïnoxime is reduced with sodium amalgam and acetic acid (compare this vol., p. 249), diphenylhydroxyethylamine,  $\text{OH}\cdot\text{CHPh}\cdot\text{CHPh}\cdot\text{NH}_2$ , is obtained; it crystallises in small, white, transparent needles, melts at  $161^\circ$ , and is insoluble in water, sparingly soluble in ether and cold alcohol. The *hydrochloride*,  $\text{C}_{14}\text{H}_{15}\text{NO}\cdot\text{HCl}$ , crystallises in long needles, melts at  $210^\circ$  with decomposition, and is readily soluble in water; the *platinochloride*,  $(\text{C}_{14}\text{H}_{15}\text{NO})_2\cdot\text{H}_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , forms microscopic, golden-yellow scales; the *acetate* crystallises in prisms showing a vitreous lustre and melts at  $156^\circ$ . By the action of acetic anhydride on the base, a *diacetyl*-derivative is obtained; it is a white crystalline powder, melts at  $159^\circ$ , and is soluble in benzene. Diphenylhydroxyethylamine, when heated with methyl iodide, yields a tertiary base,  $\text{OH}\cdot\text{CHPh}\cdot\text{CHPh}\cdot\text{NMe}_2$ ; this crystallises in long, white needles, melts at  $108$ — $110^\circ$  and forms a *platinochloride*,  $(\text{C}_{16}\text{H}_{19}\text{NO})_2\cdot\text{H}_2\text{PtCl}_6 + \frac{1}{2}\text{H}_2\text{O}$ . W. P. W.

**Condensation-derivatives of Ethylenediamine.** By A. T. MASON (*Ber.*, **20**, 267—277).—In a previous communication (*Abstr.*, 1886, 329), the author described a condensation product of ethylenediamine and phenanthraquinone, to which he now assigns the name

*xenylenedihydropyrazine*,  $\begin{array}{c} \text{C}_6\text{H}_4\cdot\text{C}\cdot\text{N}\cdot\text{CH}_2 \\ | \quad \parallel \quad | \quad | \\ \text{C}_6\text{H}_4\cdot\text{C}\cdot\text{N}\cdot\text{CH}_2 \end{array}$ . Its basic powers are very

feeble, the hydrochloride even decomposing in dry air; the platino-chloride,  $(\text{C}_{16}\text{H}_{12}\text{N}_2)_2\cdot\text{H}_2\text{PtCl}_6$ , crystallises in small, slender, pale-yellow needles. It is not decomposed when heated with concentrated hydrochloric acid, even at  $230^\circ$ .

*Diphenyldihydropyrazine*,  $\text{C}_4\text{N}_2\text{H}_4\text{Ph}_2$ , is prepared by heating equimolecular proportions of benzil and ethylenediamine in alcoholic solution in a reflux apparatus for  $\frac{1}{2}$  hour. It crystallises in pale-yellow prisms, melts at  $160$ — $161^\circ$ , is sparingly soluble in cold, readily in hot alcohol, in ether and benzene, and is insoluble in water. It is insoluble in cold mineral acids, but is decomposed by them into its components on warming. When hydrogen chloride is passed into its solution in benzene or ether, ethylenediamine hydrochloride separates whilst benzil remains in solution. This ready decomposibility points to its constitution being dissimilar to that of the stable xenylenedihydropyrazine; it is probably represented by  $\langle \text{CPh}:\text{N}\cdot\text{CH}_2 \rangle$ .

Ethylenediamine reacts readily with aldehydes with formation of condensation products which, like that last described, are but little stable towards acids.

*Dibenzylidenethylenediamine*,  $\text{C}_2\text{H}_4(\text{N}:\text{CHPh})_2$ , is prepared by mixing ethylenediamine (1 mol.) and benzaldehyde (2 mols.), when considerable evolution of heat occurs; the reaction is completed by heating for half an hour at  $120^\circ$ . It crystallises in large, colourless tables, melts at  $53$ — $54^\circ$ , is insoluble in water, and readily soluble in alcohol and benzene. Dilute acids reconvert it into its components. It is quickly decomposed by boiling with water, or even by exposure to moist air.

*Diisopropylbenzylidenemethylenediamine*,  $\text{C}_2\text{H}_4(\text{N}:\text{CH}\cdot\text{C}_6\text{H}_4\text{Pr})_2$ , is obtained by heating cuminaldehyde and ethylenediamine for about a quarter of an hour at  $120^\circ$ . It crystallises in long, pale-yellow needles, melts at  $63$ — $64^\circ$ , is readily soluble in ether, alcohol, benzene, chloroform, and light petroleum, and resembles the preceding compound in its behaviour with water and acids.

*Diphenylallidenethylenediamine*,  $\text{C}_2\text{H}_4(\text{N}:\text{CH}\cdot\text{CH}:\text{CHPh})_2$ , is obtained by mixing cinnamaldehyde with ethylenediamine, external heating being unnecessary; it forms large, colourless tables, melts at  $109$ — $110^\circ$ , is but moderately soluble in ether, readily in alcohol and benzene. When treated with acids, cinnamaldehyde separates.

*Diorthohydroxybenzylidenethylenediamine*,  $\text{C}_2\text{H}_4(\text{N}:\text{CH}\cdot\text{C}_6\text{H}_4\cdot\text{OH})_2$ , prepared by boiling salicylaldehyde and ethylenediamine in alcoholic solution, crystallises in large, yellow tables, melts at  $125$ — $126^\circ$ , is sparingly soluble in cold alcohol or ether, readily in hot, or in benzene. Cold dilute acids do not seem to act on it, but on heating it is resolved into its components.

*Diorthomethoxybenzylidenethylenediamine*,  $\text{C}_2\text{H}_4(\text{N}:\text{CH}\cdot\text{C}_6\text{H}_4\cdot\text{OMe})_2$ ,

prepared from methylsalicylaldehyde, crystallises in colourless rhombohedrons, melts at about  $113^{\circ}$ , and is sparingly soluble in ether, readily in alcohol and benzene. The corresponding para-compound, prepared from anisaldehyde and ethylenediamine, forms large pale-yellow tables, melts at  $110-111^{\circ}$ , and is sparingly soluble in cold benzene, readily in ether or alcohol. Both compounds are readily decomposed by acids.

*Dimethylbenzylidenethylenediamine*,  $C_2H_4(N : CMePh)_2$ , is prepared by mixing phenyl methyl ketone with ethylenediamine and completing the reaction by heating for a short time at  $120^{\circ}$ . It crystallises in white needles, softens at  $95^{\circ}$ , melts at  $103-105^{\circ}$ , is sparingly soluble in ether, readily in alcohol and benzene; it is very readily reconverted into the ketone and amine.

*Ethyl ethylenedi- $\beta$ -amido- $\alpha$ -crotonate*,  $C_2H_4(NH \cdot CMe : CH \cdot COOEt)_2$ , is obtained by mixing ethylenediamine and ethyl acetoacetate together with a little water or, better, by employing alcoholic solutions of the two substances. It crystallises in large, well-formed prisms, melts at  $126-127^{\circ}$ ; is decomposed on distillation with formation of a basic substance, and is insoluble in water, very sparingly soluble in light petroleum, sparingly in cold but readily in hot alcohol, ether, and benzene. The *free acid* is obtained by heating the ethyl salt with water, or the formation and hydrolysis of the ethyl salt may be combined by heating ethylenediamine and ethyl acetoacetate in sealed tubes at  $120-140^{\circ}$ . It forms white scales of silky lustre, melts at  $167-168^{\circ}$ , is readily soluble in water, sparingly in ether, benzene, and cold alcohol, does not show any reaction to litmus-paper, and in aqueous solution gives an intense violet coloration with ferric chloride. Much ethylenediamidopropylene is formed at the same time as the acid.

A. J. G.

**Condensation of Aldehydes with Phenols and Aromatic Amines.** By L. CLAISEN (*Annalen*, **237**, 261—274).—The action of benzaldehyde on  $\beta$ -naphthol has been described by Trzeinski (*Abstr.*, 1884, 1185) and also by the author (this vol., p. 270). The product, benzal dinaphthal oxide, cannot be directly prepared by the action of  $\beta$ -dinaphthyl oxide on benzaldehyde.

Ethylidene dinaphthyl acetal and ethylidene  $\beta$ -dinaphthyl oxide have been previously described by the author (*loc. cit.*).

Benzaldehyde unites with  $\beta$ -naphthylamine, forming *benzal- $\beta$ -naphthylamine*,  $Ph \cdot CH : N \cdot C_{10}H_7$ , a crystalline compound soluble in chloroform. It melts at  $102-103^{\circ}$ . At a higher temperature, and under suitable conditions, the aldehyde and amine condense, forming phenylhydronaphthacridine. This substance is insoluble in alcohol. On oxidation, it yields phenyl- $\beta$ -naphthacridine (m. p. 294), which has been described by Claus and Richter (*Abstr.*, 1884, 1358).

W. C. W.

**Action of Chlorine on Aceto- $\alpha$ -naphthalide.** By P. T. CLEVE (*Ber.*, **20**, 448—451).—When chlorine is passed into a solution of acet- $\alpha$ -naphthalide in acetic acid, crystals of a *dichloro-derivative*,  $C_{10}H_6Cl_2 \cdot NHAc$ , separate out; this compound melts at  $214^{\circ}$ , is readily soluble in acetic acid, alcohol, and chloroform. When boiled with

concentrated potash, it yields *dichloronaphthylamine*,  $C_{10}H_7Cl_2 \cdot NH_2$ , melting at  $82^\circ$ , soluble in alcohol, volatile in steam; it yields phthalic acid when heated with nitric acid. By the diazo-reaction, the amine is converted into *dichloronaphthalene*, crystallising in needles which melt at  $60^\circ$ ; on oxidation, it yields phthalic acid. It has been shown by Claus that  $\beta_1$ - $\beta_2$ -dichloronaphthalene melts at  $60^\circ$ , whereas the author has obtained a dichloronaphthalene of the same melting point from two isomeric nitronaphthalene- $\beta$ -sulphonic acids; hence there are either two isomeric dichloronaphthalenes of the same melting point or an isomeric transformation occurs. If the above dichloroacetonaphthalide is treated with tin and hydrochloric acid, a tin salt,  $C_{10}H_6Cl \cdot NH_2 \cdot HSnCl_3$ , separates, from which *monochloronaphthylamine* may be obtained; this crystallises in white needles, melting at  $56^\circ$ , and is sparingly soluble in boiling water, soluble in alcohol. Its *hydrochloride* and *sulphate* crystallise with 1 mol.  $H_2O$  in delicate white needles. It is not identical with the monochloronaphthylamine prepared by Atterberg.

V. H. V.

**Naphthoxyacetic Acids.** By M. SPICA (*Gazzetta*, 16, 437—445).—The  $\alpha$ - and  $\beta$ -naphthoxyacetic acids are readily obtained by heating monochloroacetic acid with the corresponding naphthol in equimolecular proportions, and gradually adding potash solution; the product is most conveniently purified by acidifying the crude product and separating the unaltered naphthol by solution in ammonium carbonate.

$\alpha$ -Naphthoxyacetic acid crystallises in small prisms of pale-rose tint, soluble in ether and alcohol, sparingly soluble in water. It melts at  $190^\circ$ , and is slightly altered by light, especially when moist. The *ammonium* salt crystallises in stellate groups of needles or scales, soluble in water, more so in alcohol; it melts at  $119$ — $120^\circ$ ; the *potassium* salt with  $1H_2O$  forms long silky needles: the *magnesium* with  $6.5H_2O$  crystallises in rose-coloured laminæ; the *lead* salt and the *barium* salt with  $4.5H_2O$  in sparingly soluble laminæ. The *ethyl* salt crystallises in small colourless crystals, soluble in alcohol and ether, melting at  $173$ — $174^\circ$ , and the *amide* in colourless needles, sparingly soluble, and melting at  $155^\circ$ .

The corresponding  $\beta$ -acid crystallises in the trimetric system, and is coloured an azure-green tint on exposure to light; it melts at  $151$ — $152^\circ$ . Its *ammonium* and *potassium* salts crystallise in white micaceous scales, the *barium* salt with  $3.5H_2O$  in laminæ; whilst the *lead* salt is a white, sparingly soluble crystalline powder. The *ethyl* salt crystallises in large, transparent scales, melting at  $48$ — $49^\circ$ , and the *amide* in long tablets, melting at  $147^\circ$ , very soluble in alcohol and ether.

The above acids are isomeric with the naphthylglycollic acid, of which the  $\alpha$ -modification has been described.

V. H. V.

**Constitution of Acenaphthene and of Naphthalic Acid.** By E. BAMBERGER and M. PHILIP (*Ber.*, 20, 237—244).—Naphthalic acid, obtained from acenaphthene by oxidation, has been generally regarded as a 1 : 2 derivative of naphthalene, inasmuch as it yields an anhydride and an imide—properties characteristic of the ortho-position in the benzene molecule. Starting, however, from 1 : 1' nitro-

naphthoic acid (melting at  $215^{\circ}$ ), the authors have effected the synthesis of naphthalic acid, and hence have proved that both it and acenaphthene are 1 : 1' derivatives of naphthalene; this fact, taken in conjunction with Ekstrand's observation (Abstr., 1886, 155) that 1 : 1' nitronaphthoic acid when reduced yields an amido-acid which undergoes spontaneous conversion into naphthostyryl (an "internal" anhydride), and the fact that 1 : 1' diamidonaphthalene reacts with benzaldehyde as though it were an orthodiamine, proves that in naphthalene the position 1 : 1' functions as an ortho-position, and renders inevitable an extension of our conception of the latter in hydrocarbons built up of two or more benzene nuclei. The authors propose to distinguish the 1 : 1' position in naphthalene by the prefix "peri," and term naphthalic acid, for example, perinaphthalene-dicarboxylic acid.

To obtain naphthalic acid, the hydrochloride of the amido-acid prepared from naphthostyryl by boiling it with aqueous soda and adding hydrochloric acid to the cold solution was converted into cyanonaphthoic acid by diazotising, and from it, by hydrolysis with aqueous potash, an acid was obtained which agreed with naphthalic acid in all its properties.

$\alpha$ -Naphthamide,  $C_{10}H_7 \cdot CONH_2$ , crystallises in large, white, monoclinic tables, showing a satiny lustre, and melting at  $202^{\circ}$ . W. P. W.

**Pyrene.** By E. BAMBERGER and M. PHILIP (*Ber.*, 20, 365—371; compare Abstr., 1886, 718, 948, this vol., p. 271).—The formation of naphthalenetetracarboxylic acid by the oxidation of pyrenic acid shows that the latter has the constitution  $C_{10}H_4(C_2H_2CO)(COOH)_2$ . The positions of the four carboxyl-groups in naphthalenetetracarboxylic acid, which are shown to be [1 : 4 : 1' : 4'], point to the further

developed constitutional formula  $CO \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \\ \text{CH} \end{array} C_{10}H_4 \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \\ \text{CH} \end{array} CO$  [CH : CH = 1 : 1' and (COOH)<sub>2</sub> = 4 : 4'] for pyrenic acid.

The constitution of pyrene is represented by a combination of a naphthalene nucleus with two benzene-rings thus:—

The constitutional formulæ of pyrene quinone and pyrene ketone are respectively  $CO \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \\ \text{CH} \end{array} C_{10}H_4 \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \\ \text{CH} \end{array} CO$  [CH : CH = 1 : 1' and 4 : 4']

and  $CO \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \\ \text{CH} \end{array} C_{10}H_6$ .

N. H. M.

**Derivatives of Camphoroxime.** By H. GOLDSCHMIDT (*Ber.*, 20, 483—485).—A reply to Leuckart (this vol., p. 376) in which the author maintains the correctness of his formulæ for camphoroxime-derivatives. Calcium campholenate by dry distillation yields a hydro-

carbon boiling chiefly between  $130^{\circ}$  and  $140^{\circ}$ ; an imperfect analysis points to the formula  $C_9H_{16}$ , and the compound is possibly identical with campholene.

W. P. W.

**Naringin.** By W. WILL (*Ber.*, 20, 294—304).—Methylnaringenic acid (Abstr., 1885, 906), when oxidised, yields anisaldehyde and anisic acid: the conclusion that this leads to, that methylnaringenic acid is paramethylcoumaric acid, and that naringenic acid is paracoumaric acid was at once confirmed by a comparison of these various acids and their derivatives. As previously shown (*loc. cit.*), naringenin yields phloroglucinol and "naringenic acid" when heated with aqueous potash, it must therefore be *phloroglucinolparacoumarate*,

naringin being a compound of this substance with isodulcitol.

Naringin in aqueous solution has a rotatory power  $[\alpha]_D = -84.5$ , in alcoholic solution the rotation is stronger,  $[\alpha]_D = -87.6$ .

A. J. G.

**Substances Extracted from the *Illicium Religiosum*.** By J. T. EIJKMAN (*Rec. Trav. Chim.*, 5, 299—304; compare Abstr., 1886, 95).—From various portions and especially from the fruit of the species of the *illicium* genus, the author has extracted an acid,  $C_7H_{10}O_5$ , soluble in alcohol and ether, insoluble in chloroform and benzene. It is proposed to designate this substance *shikimic acid*. On distillation, it is for the most part decomposed into phenol and carbonic anhydride, but small quantities of protocatechuic acid are obtained; this acid is also present in the above-mentioned plants.

Shikimic acid is thus probably an additive product of protocatechuic acid,  $C_6H_6(OH)_3COOH$ , and is thus analogous to quinic acid, with whose anhydride it is isomeric. The specific rotatory power of the acid in aqueous solution is  $[\alpha]_D = -179.3$ ; it shows some slight aptitude for etherification. The ammonium salt crystallises well, and on dry distillation yields a basic substance which gives precipitates with the reagents for the alkaloïds.

V. H. V.

**Andromedotoxim.** By H. G. DE ZAAIJER (*Rec. Trav. Chim.*, 5, 313—322).—*Andromedotoxim*, a toxical substance, present in various species of the *Andromeda*, was first isolated by Plugge; it can also be extracted from the *Rhododendron ponticum* by infusion with water, concentration of the extract, precipitation of the albuminous substances with basic acetate of lead, and evaporation of the filtrate. It is best purified from accompanying impurities by frequent recrystallisations from chloroform and ether. Thus obtained, it crystallises in long needles, melts at  $228^{\circ}$ , is more soluble in cold water than in hot, soluble in alcohol. Its specific rotatory power in aqueous solution is  $-9.7$ , in alcohol  $-14$ , but in chloroform is  $+10$  to  $+12$ . Its composition is  $C_{31}H_{51}O_{10}$ ; thus it appears not to be identical with asbetoxime. In its chemical properties it is neither acidic nor basic, and is not of the nature of a glucoside; it does not reduce silver salts, and gives no precipitate with the salts of the heavy metals and the reagents for the alkaloïds. Heated with dilute sulphuric acid, it gives

a rose-red and, with hydrochloric acid, a pale-yellow coloration. It acts as a powerful poison, diminishing the rate of respiration, and producing paralysis; in these effects, it surpasses apomorphine.

V. H. V.

**Crystalline Compound from "Kamala."** By L. JAWELN (*Ber.*, 20, 182—183).—Andersen obtained (*Jahresber.*, 1855, 669) from kamala a compound which he described as rottlerin,  $C_{11}H_{10}O_3$ . The author, by extracting kamala with carbon bisulphide or benzene, obtained a yellow crystalline substance melting at  $200^\circ$ . It resembles Andersen's compound in its solubility and in giving a red liquid with alkali, but the analytical results do not agree with the formula suggested by Andersen. (Compare A. G. Perkin and W. H. Perkin, this vol., p. 272.)  
N. H. M.

**Algaborilla.** By G. H. HURST (*Dingl. polyt. J.*, 262, 288).—This yellow dye is a species of tannin obtained from the pods yielded by two plants, namely, *Prosopis pallida* and *P. algarobo*, which are indigenous in the mountainous regions of South America. 52 to 55 per cent. of the pods consist of soluble matter containing 27—29 per cent. of tannin. Algaborilla forms yellow precipitates with the salts of zinc, antimony, lead, or aluminium, and imparts to cotton or wool mordanted with metallic salts a yellow colour which bears light very well, and resists weak acids. Alkalis change the colour to brown.

D. B.

**Indian-yellow and Glycuronic Acid.** By E. KÜLZ (*Zeit. Biol.*, 23, 475—485).—Baeyer (*Annalen*, 155, 257) showed that euxanthic acid, which is combined with magnesia in the purree of commerce, can be decomposed by heating with hydrochloric acid, thus:  $C_{19}H_{16}O_{10} + H_2O = C_{13}H_8O_4 + C_6H_{10}O_7$ ; that is, two substances, euxanthone and an acid which was shown by Spiegel (*Abstr.*, 1883, 219) to be glycuronic acid. From glycuronic acid a crystalline anhydride ( $C_6H_8O_6$ ) can be obtained. From the glycuronic acid, obtained from purree, an anhydride with the same formula is also obtainable. The melting point is  $160^\circ$ , when the heat is gradually applied;  $170$ — $180^\circ$  when it is rapidly applied. Its specific rotation is  $(\alpha)_D = +19.4$ .

Euxanthone was obtained free from glycuronic acid by crystallising out the anhydride; it was obtained free from the remainder of the euxanthic acid by treating with ether in which euxanthone is readily soluble. The statement of text-books that euxanthic acid is readily soluble in ether is an error. The separation may also be performed by treating with benzene.

A rabbit was fed on 0.7 gram of euxanthone; the urine was collected, evaporated to a small bulk, and hydrochloric acid added. After standing, a deposit of yellow needles was formed which were dissolved in alcohol and then recrystallised; they consisted of euxanthic acid. In order to settle the question whether purree is of animal or vegetable origin, urea, uric acid, and hippuric acid were sought for in it with positive results.

Purree is stated by some to be a deposit in the urine of camels if they eat the fruit of the *Garcinia mangostana*, from which Schmid separated the principle *mangostin*. When, however, rabbits are fed

upon the fruit or on mangostin, no euxanthic acid appears in the urine.

Schmiedeberg and Meyer regard the glycuronic acid as formed from the grape-sugar in the body. But if its formula, its optical properties, and its reduction power be considered, it is possible that it may have its origin in inosite.

W. D. H.

**Pyrrolidine.** By A. LADENBURG (*Ber.*, **20**, 442—444).—Pyrrolidine is formed in small quantities during reduction of ethylene cyanide (*Abstr.*, 1886, 528); the base is more conveniently prepared by the dry distillation of tetramethylenediamine hydrochloride. It boils at 85—88°, and fumes in the air when slightly warmed. The *platinochloride* forms orange-yellow crystals, and the *bismuthiodide*,  $3C_4H_9NHI, 2BiI_3$ , red prisms.

V. H. V.

**Preparation of Pyridine Bases.** By E. DÜRKOPF (*Ber.*, **20**, 444).—The aldehyde-ammonias, when heated with the aldehydes, yield bases of the pyridine series; thus collidine is formed from ethaldehyde and its ammonia compound. It appears probable that the ketones also undergo a similar change.

V. H. V.

**Lutidines of Coal-tar.** By G. LUNGE and J. ROSENBERG (*Ber.*, **20**, 127—137).—The sulphuric acid used in purifying coal-oil was diluted with 3 or 4 times the volume of water, left for several days and filtered. The filtrate was evaporated, treated with aqueous soda, and the oil so obtained separated and steam-distilled. It was then dried by means of caustic alkali and fractionally distilled. 20 litres of sulphuric acid yielded 800 grams of mixed bases. The fraction boiling at 141—144° yielded by precipitation with mercuric chloride (Ladenburg and Roth, *Abstr.*, 1885, 557) the mercuriochloride of lutidine, from which the pure base was separated and identified. The fraction boiling at 153—156° yielded  $\alpha$ - $\gamma$ -lutidine; this was converted by oxidation into  $\alpha$ -lutidinic acid. When the fraction boiling below 170° was oxidised with potassium permanganate,  $\alpha$ -lutidinic and isochincheronic acids were obtained. The formation of the latter acid points to the presence of  $\alpha$ - $\beta$ -lutidine in the mixed bases. The acid was separated by the method of Weidel and Herzig (*Wien. Akad. Ber.*, **80**, 821).

N. H. M.

**Ethoxylutidine.** By F. CANZONERI and G. SPICA (*Gazzetta*, **16**, 449—453).—When ethyl acetoacetate is heated with excess of ammoniacal zinc chloride in sealed tubes at 100—110°, an ethoxylutidine is formed along with other products, and a considerable quantity of carbonic anhydride is evolved; the reaction is as follows:— $2C_4H_7O_2 + NH_3 = C_5H_7N + CO_2 + EtOH + 2H_2O$ . This compound is a pale-yellow liquid boiling at 245—247°, and resembling pyridine in odour.

On repetition of former experiments (*Abstr.*, 1885, 751) on the condensation of ethyl acetoacetate and formamide, an ethyl monolutidinecarboxylate was obtained as a transparent, yellow liquid of peculiar odour, boiling at 250—255°; this compound appears to be

isomeric with the ethyl monolutidinedicarboxylate obtained by Michael from aldehyde, aldehyde ammonia, and ethyl acetoacetate (Abstr., 1885, 1244). V. H. V.

**Action of Ammonia and of Primary Amines on Ethyl Dimethylpyrnedicarboxylate.** By M. CONRAD and M. GUTHZEIT (*Ber.*, 20, 154—162).—*Ethyl acetyl lutidonedicarboxylate*,

is obtained by heating ethyl lutidonedicarboxylate (Abstr., 1886, 334) with an excess of acetic anhydride at 140—150°. It dissolves readily in ether and in boiling alcohol; it melts at 65°.

*Lutidonedicarboxylic acid*,  $\text{CO} < \begin{matrix} \text{C}(\text{COOH}) : \text{CMe} \\ \text{C}(\text{COOH}) : \text{CMe} \end{matrix} > \text{NH}$ , separates from its aqueous solution in prisms which melt at 267° with evolution of carbonic anhydride. It is very sparingly soluble in hot water, alcohol, and ether. The *calcium salt* (with 2 mols.  $\text{H}_2\text{O}$ ) is readily soluble in hot water; the *copper salt* (with  $1\frac{1}{2}$  mol.  $\text{H}_2\text{O}$ ) and other salts were prepared.

*Lutidone* (2, 6-dimethylpyridine),  $\text{CO} < \begin{matrix} \text{CH} : \text{CMe} \\ \text{CH} : \text{CMe} \end{matrix} > \text{NH}$ , is formed when the carboxylic acid is heated at 270—290° until no more carbonic anhydride is given off; it is best purified by distillation. It is very readily soluble in water and alcohol, almost insoluble in ether, benzene, and chloroform. It separates from the aqueous solution in lustrous, monoclinic needles (with 3 mols.  $\text{H}_2\text{O}$ );  $a : b : c = 1.1396 : 1 : 2.6179$ ;  $\beta = 85.11^\circ$ . The anhydrous substance melts at 225° and boils at 349—351°. It gives a brown-red coloration with ferric chloride. It is identical with the compound obtained by Haitinger from dehydracetic acid (Abstr., 1885, 761). The *platinochloride*,  $(\text{C}_7\text{H}_9\text{NO})_2, \text{H}_2\text{PtCl}_6$ , forms microscopic, transparent plates which melt at 224—225°. The *chromate* crystallises in well-formed, yellowish-red prisms, readily soluble in water, sparingly in alcohol. It melts at 125° with decomposition. The *picrate* crystallises in slender needles melting at 219—220°.

*Ethyl methyl lutidonedicarboxylate*,  $\text{CO} < \begin{matrix} \text{C}(\text{COOEt}) : \text{CMe} \\ \text{C}(\text{COOEt}) : \text{CMe} \end{matrix} > \text{NMe}$ , is formed when solutions of ethyl dimethylpyrnedicarboxylate and methylamine in acetic acid are mixed. It crystallises in rosettes of needles melting at 193°. The *free acid* melts at 255°, and at the same time decomposes into carbonic anhydride and *methyl lutidone*. The latter crystallises in long, lustrous needles which melt at 110—111°; it dissolves readily in alcohol and water.

*Phenyl lutidonedicarboxylic acid*,  $\text{CO} < \begin{matrix} \text{C}(\text{COOH}) : \text{CMe} \\ \text{C}(\text{COOH}) : \text{CMe} \end{matrix} > \text{NPh}$ , is prepared by the hydrolysis of the ethyl salt (Abstr., 1886, 334). It crystallises in prisms readily soluble in boiling alcohol, sparingly in ether, benzene, and water. The *hydrogen barium salt*,  $(\text{C}_{15}\text{H}_{12}\text{NO}_6)_2\text{Ba} + \text{H}_2\text{O}$ , is readily soluble; other salts were prepared.

*Phenyllutidonemonocarboxylic acid*,  $\text{CMe} \begin{smallmatrix} \text{NPh} \cdot \text{CMe} \\ \text{CH} - \text{CO} \end{smallmatrix} \text{C} \cdot \text{COOH}$ , is obtained by heating the dicarboxylic acid at  $227^\circ$ . It crystallises in long, lustrous needles which melt at  $257^\circ$ ; it dissolves in hot water and alcohol.

*Phenyllutidone*,  $\text{CO} \begin{smallmatrix} \text{CH} : \text{CMe} \\ \text{CH} : \text{CMe} \end{smallmatrix} \text{NPh}$ , is prepared by heating phenyllutidonedicarboxylic acid at  $270^\circ$ . It is identical with the compound obtained by Perkin from aniline and dehydracetic acid (Abstr., 1885, 762). N. H. M.

**Lutidine-derivatives from Lutidinedicarboxylic Acid.** By M. CONRAD and W. EPSTEIN (*Ber.*, 20, 162—166).—When lutidone is distilled with zinc-dust, lutidine is formed. It boils at  $144\text{--}145^\circ$ , and is identical with that obtained by Epstein (Abstr., 1886, 257) from 2, 6-dimethylpyridinetricarboxylic acid.

*Chlorolutidinedicarboxylic acid*,  $\text{CCl} \begin{smallmatrix} \text{C}(\text{COOH}) \cdot \text{CMe} \\ \text{C}(\text{COOH}) \cdot \text{CMe} \end{smallmatrix} \text{N}$ , is prepared by heating lutidonedicarboxylic acid with three times its weight of phosphorus pentachloride and some phosphorus oxychloride at  $140^\circ$ . The oxychloride is then mostly distilled off, the residue treated with water, filtered, and evaporated. It crystallises from water in white prisms, which become brown at  $217^\circ$  and melt at  $224^\circ$ .

*Chlorolutidine*,  $\text{C}_7\text{NH}_5\text{Cl}$ , is obtained by heating dry lutidone (20 grams) with phosphoric chloride (35 grams), and some phosphorus oxychloride at  $140^\circ$ . It is purified by steam distilling. It is a clear colourless oil having an odour resembling that of lutidine; it boils at  $178^\circ$ ; sp. gr. at  $17^\circ = 1.105$ . The *hydrochloride* forms slender needles. The *platinochloride* and *mercurichloride* melt at  $225^\circ$  and  $155^\circ$  respectively. Chlorolutidine suspended in water gives with picric acid a yellow compound melting at  $150\text{--}156^\circ$ . The *chromate* forms orange-coloured crystals which blacken at  $140^\circ$ . *Ethoxylutidine*, obtained by heating chlorolutidine with alcoholic solution of sodium ethoxide, is a colourless oil boiling at  $217^\circ$ .

*Phenylamidolutidine*,  $\text{C}_5\text{NH}_2\text{Me}_2\text{NHPH}$  [ $\text{Me} : \text{NH} : \text{Me} = 2 : 4 : 6$ ], is formed when chlorolutidine and aniline are heated at  $195^\circ$  for one hour. It melts at  $150^\circ$ , and boils at  $335\text{--}338^\circ$ , and dissolves readily in alcohol, ether, and dilute acids. When treated with sulphuric acid, and then with a trace of nitric acid, it gives a blood-red coloration, which disappears on adding water or more nitric acid. The *platinochloride* forms slender needles which melt at  $209^\circ$ .

N. H. M.

**Condensation Product of Ethyl Amidoacetoacetate with Hydrochloric Acid.** By N. COLLIE (*Ber.*, 20, 445—447).—In a former paper it has been shown that ethylic amidoacetate yields pyridine-derivatives on condensation (Abstr., 1885, 373). If hydrogen chloride is passed into an ethereal solution of this substance an additive compound,  $\text{C}_6\text{H}_{11}\text{NO}_2\text{HCl}$ , is produced, which forms deliquescent crystals, and is decomposed in aqueous solution into ethyl acetoacetate and ammonium chloride, but when heated by itself it

yields a substance,  $C_{10}H_{13}NO_3$ , isomeric with the ethyl salt of a hydroxylutidinecarboxylic acid, melting at  $137^\circ$ , and showing remarkable stability towards reagents. On treatment with concentrated potash, and acidification of the product, an acid,  $C_8H_9NO_3$ , is formed; this is an insoluble crystalline powder which melts at  $300^\circ$ , with evolution of carbonic anhydride and distillation of a white crystalline substance,  $C_7H_9NO$ , which melts at  $176^\circ$ , and boils without decomposition at  $306.5^\circ$ . From these properties, it is probably identical with pseudolutidinecarbostyryl. In like manner ethyl amidoacetoacetate hydrochloride when heated with 1 mol. of the amido-acid itself yields ethyl pseudolutidostyrylcarboxylate, from which the carbostyryl is obtained by hydrolysis.

V. H. V.

**Ethyl Dimethylpyrnedicarboxylate.** By M. CONRAD and M. GUTHZEIT (*Ber.*, **20**, 151—154).—Ethyl 2, 6-dimethyl-3, 5-pyrnedicarboxylate,  $C_{15}H_{16}O_6$  (Abstr., 1886, 333), melts at  $80^\circ$ . When 1 gram of the ether is boiled with aqueous baryta, acetone (0.08 gram), barium malonate (0.17 gram), and barium acetate are formed; no oxalate is produced. This decomposition corresponds with that of dehydracetic acid, which was shown by Oppenheim and Precht (*Ber.*, **9**, 323) to be decomposed by bases into acetone, acetic acid, and carbonic anhydride. Wislicenus (*Ber. chem. Gesell. Würzburg*, **17**, 16) found that malonic acid is also formed in larger or smaller amount, in the decomposition of dehydracetic acid, according to the strength of the baryta solution.

N. H. M.

**Quinoline.** By E. LELLMANN and H. ALT (*Annalen*, **237**, 307—327).—1, 4-Dimethylquinoline,  $C_9NH_5Me_2$ , prepared by the action of sulphuric acid on a mixture of paraxylidine sulphate, nitrobenzene, and glycerol. The product is poured into water, and the excess of nitrobenzene removed by distillation in a current of steam. The base is liberated by the addition of an alkali, and distilled in a current of steam. It is a liquid boiling at  $265^\circ$  under 736 mm. pressure. It solidifies in a freezing mixture, forming colourless crystals which melt between  $4^\circ$  and  $5^\circ$ . The sp. gr. of the liquid is 1.070 at  $21^\circ$ . The dichromate,  $(C_{11}H_{11}N)_2 \cdot H_2Cr_2O_7$ , melts at  $149^\circ$ , and crystallises in orange-coloured needles. The platinochloride forms anhydrous needles. When oxidised with nitric acid (22 per cent.) at  $170^\circ$ , the base is converted into 1, 4-methylquinolinecarboxylic acid,  $C_9NH_5Me \cdot COOH$ . This acid melts at  $286^\circ$ . The hydrochloride,  $C_{11}H_9O_2N \cdot HCl + H_2O$ , forms silky needles, which are decomposed by water. The platinochloride contains 6 mols.  $H_2O$ .

The ammonium salt gives a crystalline precipitate with calcium chloride, and amorphous precipitates with ferrous sulphate, lead acetate, and copper salts. The methylquinoline which is produced when this acid is heated with lime is identical with the methylquinoline from orthotoluidine.

1, 4-Bromoquinolinecarboxylic acid,  $C_9NH_5Br \cdot COOH$ , is prepared by heating at  $160^\circ$  a mixture of parabromometamidobenzoic acid, ortho-nitrophenol, glycerol, and sulphuric acid. The product is mixed with water, and the excess of nitrophenol distilled off in a current of steam.

Baryta is added to the residue, the precipitated barium sulphate removed by filtration, and the excess of baryta precipitated by carbonic anhydride. On acidifying the filtrate with acetic acid, bromoquinolinecarboxylic acid is deposited as a white powder. The pure acid melts at  $275^{\circ}$ . It is insoluble in water, but dissolves in boiling alcohol and in hot acetic acid. The ammonium salt yields crystalline precipitates with barium and calcium chlorides, and with potassium dichromate, and amorphous precipitates with lead acetate and mercuric chloride.

The platinumchloride,  $(C_{10}H_8O_2NBr)_2 \cdot H_2PtCl_6 + 4H_2O$ , is crystalline. Reduction with tin and hydrochloric acid converts bromoquinolinecarboxylic acid into *tetrahydroquinolineanacarboxylic acid*,

this forms colourless needles, and melts at  $146-147^{\circ}$ . The *hydrochloride*,  $C_{10}H_{11}O_2N \cdot HCl + H_2O$ , crystallises in colourless needles. The *nitrosamine* is deposited from alcohol in yellow prisms, which melt at  $186^{\circ}$  with decomposition. This tetrahydro-derivative is identical with the tetrahydroquinolinecarboxylic acid described by Fischer and Körner (Abstr., 1884, 1197).

Skraup and Brunner (Abstr., 1886, 811) have recently shown that the carboxyl in quinolinecarboxylic acid from metamidobenzoic acid (which is identical with Fischer's acid) occupies the 4 (ana) position.

The quinolinecarboxylic acid which the authors prepared from metamidobenzoic acid differed in many of its properties from the acid which Skraup obtained from the same source. The chief points of difference are as follows:—The acid melts at  $338^{\circ}$ . The hydrochloride,  $C_{10}H_7O_2N \cdot HCl$ , crystallises in colourless needles or prisms containing 1 mol.  $H_2O$ . The aqueous solution of the ammonium salt gives with lead acetate a white precipitate *insoluble* in acetic acid, no precipitate with nickel sulphate, and a pale blue precipitate with copper salts, soluble in excess of the reagent on boiling, and crystallising out on cooling.

Both quinolinecarboxylic acids yield the same tetrahydro-derivative. The following formulæ are proposed for these isomerides.

W. C. W.

**Synthesis of Metaquinolinecarboxylic Acid.** By M. TORTELLI (*Gazzetta*, 16, 366).—When a mixture of the stannochloride of amidophthalic acid,  $C_8H_5(NH_2)O_4 \cdot HSnCl_3 + 2H_2O$ , and nitronaphthalic acid is heated with glycerol and sulphuric acid, as in Skraup's reaction, it yields a mixture of quinoline- mono- and di-carboxylic acids; these may be separated by repeated sublimation, the latter being gradually converted into the former with elimination of the carbonic anhydride. The monocarboxylic acid crystallises in minute needles which melt at  $248.5-250^{\circ}$ ; it is insoluble in ether, almost insoluble in benzene and cold water, readily soluble in alcohol. Its solutions give various

precipitates with ferrous and ferric, copper, silver, cobalt, and nickel salts. This acid is identical with one recently obtained by Skraup from metamidobenzoic acid (this vol., p. 160). V. H. V.

**$\alpha$ -Alkylcinchonic Acids.** By O. DOEBNER (*Ber.*, **20**, 277—281). The author explains the formation of aniluvitonic acid (2' : 4' methylquinolinecarboxylic acid) from aniline and pyruvic acid by assuming that acetaldehyde is intermediately formed by the splitting up of a molecule of pyruvic acid, and then condenses with aniline and a second molecule of pyruvic acid after the manner of the quinaldine synthesis. The correctness of this assumption has been proved by preparing the whole series of  $\alpha$ -alkylcinchonic acids by the action on aniline of a mixture of pyruvic acid with the homologues of acetaldehyde, the reaction being expressed by the general equation 
$$R \cdot \text{CHO} + \text{CMeO} \cdot \text{COOH} + \text{C}_6\text{H}_5 \cdot \text{NH}_2 = \text{C}_6\text{H}_4 \left\langle \begin{array}{c} \text{N} : \text{CR} \\ \text{C}(\text{COOH}) \end{array} \right\rangle \text{CH} + 2\text{H}_2\text{O} + \text{H}_2.$$
 These acids, on distillation with lime, are readily converted into the  $\alpha$ -alkylquinolines. A more detailed description of these substances will be given later.

If an aldehyde and aniline in alcoholic or ethereal solution are allowed to react with pyruvic acid in the cold, neutral crystalline compounds are formed, which are not related to the quinoline series, and from which aniline can again be readily obtained; these will be described later. If, on the other hand, the mixture in alcoholic solution is heated for four hours on the water-bath in a reflux apparatus, then the  $\alpha$ -alkylcinchonic acids are formed and in part separate on cooling, in part are obtained on evaporating the solution. They are readily purified by crystallisation from acetic acid or alcohol.

**$\alpha$ -Ethylcinchonic acid**,  $\text{C}_9\text{NH}_5\text{Et} \cdot \text{COOH}$  [2' : 4'], prepared from propaldehyde, pyruvic acid, and aniline, crystallises in colourless plates, melts at 173°, and is soluble in both acids and alkalis. The silver salt,  $\text{C}_{12}\text{H}_{10}\text{NO}_2\text{Ag}$ , forms white plates soluble in water.  **$\alpha$ -Ethylquinoline**,  $\text{C}_9\text{NH}_6\text{Et}$  [Et = 2'], prepared by distilling the acid with soda-lime, is a colourless oil of quinaldine-like odour, and boils at 245—246°. The platinochloride,  $(\text{C}_{11}\text{H}_{11}\text{N})_2\text{H}_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , crystallises in orange-red needles.

**$\alpha$ -Isopropylcinchonic acid**,  $\text{C}_9\text{NH}_5\text{Pr}^\beta \cdot \text{COOH}$  [2' : 4'], obtained from isobutaldehyde, pyruvic acid, and aniline, in well-formed crystals, melts at 146°. When heated with soda-lime, it yields  **$\alpha$ -isopropylquinoline**,  $\text{C}_9\text{NH}_6\text{Pr}^\beta$ , a colourless oil boiling at 255°; the platinochloride,  $(\text{C}_{12}\text{H}_{13}\text{N})_2\text{H}_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , crystallises in yellow needles.

**$\alpha$ -Isobutylcinchonic acid**,  $\text{C}_4\text{H}_9^\beta \cdot \text{C}_9\text{NH}_5 \cdot \text{COOH}$  [2' : 4'], prepared from isovaleraldehyde, pyruvic acid, and aniline, crystallises in silky, white plates, melting at 186°. When distilled with soda-lime it gives  **$\alpha$ -isobutylquinoline**,  $\text{C}_9\text{NH}_6 \cdot \text{C}_4\text{H}_9$ , as a colourless oily liquid of peculiar odour, boiling at 270—271°. The platinochloride forms large, orange-red, anhydrous needles.

**$\alpha$ -Phenylcinchonic acid**,  $\text{C}_9\text{NH}_5\text{Ph} \cdot \text{COOH}$  [2' : 4'], prepared as above from benzaldehyde, crystallises in colourless needles, melts at 202—203°, forms a platinochloride crystallising in orange-red needles, and when distilled with soda-lime yields the known  $\alpha$ -phenylquinoline.

A. J. G.

**Isoquinoline and its Derivatives.** By S. HOOGWERFF and W. A. VAN DORP (*Rec. Trav. Chim.*, **5**, 305—312).—Isoquinoline, isolated from coal-tar, can be regarded as a  $\beta$ -derivative of naphthalene. It is best obtained in a state of purity by recrystallising its sulphate from alcohol until the melting point of the salt ( $205^{\circ}$ ) is constant; the free base melts at  $22^{\circ}$  and boils at  $240$ — $245^{\circ}$ . It forms crystalline combinations with various metallic salts, and unites with the alkyl iodides, to form replaced ammonium iodides such as isoquinoline-methylammonium iodide,  $C_9H_7N, MeI$ , crystallising in plates melting at  $158$ — $161^{\circ}$ , and the corresponding ethyl compound,  $C_9H_7N, EtI$ , which crystallises in tables melting at  $147^{\circ}$ . The substances are distinguished from similar derivatives of quinoline in not forming cyanines.

Isoquinoline yields a sulphonic acid, the barium salt,

of which crystallises in needles. On hydrogenation, the base yields a tetrahydro-additive product,  $C_9H_{11}N$ , a liquid boiling at  $232^{\circ}$ , and not solidifying at  $-15^{\circ}$ ; it absorbs carbonic anhydride to form a crystalline carbonate; a hydrochloride, crystallising in small tables melting at  $232^{\circ}$ , and a platinochloride in reddish-yellow tables, were also obtained. It seems that these quinoline-derivatives are of therapeutic value.

V. H. V.

**Acid Morphine Meconate.** By D. B. DOTT (*Pharm. J. Trans.* [3], **17**, 690).—The author has not succeeded in preparing and identifying morphine hydrogen meconate.

**Constitution of Brucine.** By A. HANSSEN (*Ber.*, **20**, 451—460).—With the view of throwing further light upon the constitution of brucine, the preparation and composition of kakotheline, originally obtained by Strecker, have been further investigated. To this substance is ascribed the formula  $C_{21}H_{22}N_4O_9$ , instead of  $C_{20}H_{22}N_4O_9$ , hitherto accepted. When reduced, it yields a base, the analysis of whose hydrochloride pointed to a formula  $C_{21}H_{25}N_3O_5$ , derived from kakotheline by the reduction of one nitro-group and elimination of another. With bromine, kakotheline yields an acid substance,  $C_{19}H_{24}N_2O_7$ , the platinochloride of which crystallises in orange-yellow needles, its silver salt in glistening needles; its methyl salt could not, however, be obtained, but the crude product treated with ammonium chloride yielded a base,  $C_{19}H_{22}Me_2N_2O_7$ , crystallising in yellow, sparingly soluble prisms. In this reaction, the acid seems to be analogous to nicotinic acid, and thus it would appear that in kakotheline, as also in brucine, a pyridine grouping is present. The above acid when oxidised with chromic acid yields the base  $C_{16}H_{18}N_2O_4$ , obtained formerly as a product of decomposition of brucine. According to the author there is present in brucine, besides a quinoline-group, also a dimethoxyphenylpyridine, and in strychnine, a phenylpyridine residue; the stability of brucine seems to indicate a ring-arrangement.

V. H. V.

**Hydrastine.** By J. F. EIJKMAN (*Rec. Trav. Chim.*, **5**, 290—298).—Mahla, Power, and more recently Freund and Will (this vol., p. 174),

have examined hydrastine, a principle obtained from the *Hydrastis canadensis*. The formula assigned to this substance by these chemists is  $C_{22}H_{23}NO_6$ , that of the author is more in accordance with the formula  $C_{21}H_{21}NO_6$ , and the results are also confirmed by analysis of the auro- and platino-chlorides, as also of the sulphate. The specific rotatory power is  $[\alpha]_D = -66.3$ ,  $l = 200$ , in chloroform solution, a value practically equal to that of Freund and Will. On decomposition with nitric acid, it yields opianic acid and a 12-carbon nitrogenous compound, a result more simply explained by the above formula, thus:  $C_{21}H_{21}NO_6 + H_2O + O = C_{11}H_{13}NO_3 + C_{10}H_{10}O_5$ . V. H. V.

*Note.*—Freund and Will, in a more recent communication than that referred to above, have independently shown the formula to be  $C_{21}H_{21}NO_6$  (see this vol., p. 383). A. J. G.

**Optical Behaviour of Cocaine. Method for Determining the Purity of Cocaine Hydrochloride.** By O. ANTRICK (*Ber.*, 20, 310—322).—Analyses of cocaine hydrochloride pointed to Lossen's formula,  $C_{12}H_{21}NO_4 \cdot HCl$ . Solutions of cocaine are laevorotatory. Determinations of the specific rotatory power of cocaine hydrochloride from different sources in dilute alcoholic solution lead to the equations  $[\alpha]_D = 52.180 + 0.1588 \times q$  ( $q$  = solvent) and  $[\alpha]_D = 67.982 - 0.15827 \times c$  ( $c$  = concentration of solution). When  $q = 0$   $[\alpha]_D = 52.180$ ; when  $q = 100$   $[\alpha]_D = 68.060$ . To determine the purity of a preparation, the angle is measured at which the plane of polarised light is turned by the solution. A solution is conveniently used in which 100 c.c. (at  $20^\circ$ ) contain 10 or 20 grams of dry cocaine salt to be tested. A 10 per cent. solution should give (with a tube 200 mm. long) at  $20^\circ$  an angle  $13.280^\circ$ ; a 20 per cent. solution an angle  $25.927^\circ$ . When with a 10 per cent. solution the angle is between  $13.25^\circ$  and  $13.31^\circ$ , and with a 20 per cent. solution between  $25.90^\circ$  and  $25.96^\circ$ , the sample is pure. Free cocaine melts at  $98^\circ$ . The solution in chloroform at  $20^\circ$  has the specific rotatory power  $[\alpha]_D = 15.827 + 0.005848 \times q$ . When  $q = 0$   $[\alpha]_D = -15.827$ .

N. H. M.

**Action of Pepsin on Amyloid.** By S. KOSTIURINA (*Chem. Centr.*, 1887, 120).—Working with pure amyloid, the author found, contrary to the usual statements, that it was soluble in pepsin solution acidified with hydrochloric acid. The probable cause of the mistake is that the organs containing amyloid have not been divided sufficiently fine before being examined. In order to prepare the amyloid, the diseased organ was cut in small pieces, the blood washed out with water, then boiled with water, alcohol, and ether, and the purified product submitted to the action of pepsin. After acting on diseased liver so purified with pepsin for 48 hours, a residue remained with the properties of amyloid; this, when finely powdered and again submitted to the action of a strong digestive solution at  $40$ — $50^\circ$  for 48 hours, was almost entirely dissolved, only a very slight residue of nuclein and tissue remaining. A similar result was obtained with finely chopped diseased spleen.

G. H. M.

**Vegetable Globulins.** By S. H. C. MARTIN (*Proc. Physiol. Soc.*, 1887, 8—9).—Vegetable globulins can be divided into two classes, namely, vegetable myosins and vegetable paraglobulins. The myosins, obtained from the flours of wheat, rye, and barley, have similar properties; they are all readily soluble in 10—15 per cent. sodium chloride solution, and are precipitable from this solution by saturation with sodium chloride or magnesium sulphate. They are soluble in 10 per cent. magnesium sulphate solution, and are coagulated in this solution at a temperature of 55—60°. If the salt is dialysed away from the saline solution of myosins, the latter is precipitated; but the precipitate is no longer a globulin, since it is insoluble in saline solutions. It is soluble in dilute acid and alkalis (0·2 per cent.); it is precipitable from these solutions by neutralisation, the precipitate being soluble in excess of alkali or acid; that is, the myosin has been converted into a proteid, having the properties of an albuminate. If the saline solution of myosin be placed in an incubator at a temperature of 35—40°, in 12 to 18 hours a fine flocculent precipitate falls, while the globulin disappears from the solution; this takes place more rapidly if the saline solution is diluted. The precipitate exhibits the same properties as the precipitate of the globulin by dialysis; that is, at a temperature of 35—40° the globulin is transformed into an albuminate. The ready transformation of the soluble globulin of wheaten flour into an insoluble albuminate is one of the phenomena which takes place during the formation of gluten (Abstr., 1886, 1065).

The second class of vegetable globulins, the paraglobulins, is in distinct contrast with that of the myosins. Two proteids of this class have been found, one in papaw juice (Abstr., 1886, 642), the other in the seeds of *Abrus precatorius* (jequirity). Both these globulins exhibit the following properties: they are soluble in saline solutions, and are precipitated by saturation with sodium chloride and magnesium sulphate. In a 10 per cent. solution of magnesium sulphate, they coagulate between 70° and 75°. When precipitated from their saline solutions by dialysis, they are still soluble in solutions of sodium chloride and magnesium sulphate of 10—15 per cent., not being transformed into albuminates. Nor are they precipitated by long exposure (over three days) to a temperature of 35—40°.

**Estimation of the Carbonic Anhydride Expired, and the Oxygen Absorbed in Respiration.** By M. HANRIOT and C. RICHET (*Compt. rend.*, 104, 435—437).—The inspired air passes through a meter, and the expired air passes through two meters, between which is the apparatus for absorbing the carbonic anhydride. The difference between the readings of the first and third meter gives the volume of oxygen absorbed, and the difference between the second and third

gives the volume of carbonic anhydride produced. The carbonic anhydride is absorbed in a large tube filled with broken glass, kept moistened by a solution of potassium hydroxide falling from the top. The meters are constructed on the principle of an ordinary gas-meter, and give very accurate measurements. Special arrangements are made to neutralise the effects of the rapid and considerable variations in pressure which take place during the vigorous respiration. A number of test experiments show that the apparatus gives very accurate results.

C. H. B.

**Formation of Lactic Acid during Muscular Activity, and its Fate in the Organism.** By W. MARCEUSE (*Bied. Centr.*, 1887, 92—94).—The author draws the following conclusions from his researches:—Sarcolactic acid is formed during muscular activity. In the frog, by far the greater part of the lactic acid so formed is destroyed in the liver; but a small portion passes into the urine. During activity, the urine of mammalia is free from lactic acid.

A. J. G.

**Formation of Methæmoglobin in Blood by the Action of Alloxantin.** By N. KOWALEWSKY (*Chem. Centr.*, 1887, 164).—Defibrinated blood is changed in colour to brown and then to black by the addition of alloxantin. The absorption-bands of oxyhæmoglobin disappear, and a new band appears in the red, which points to the probable formation of methæmoglobin. When ammonium sulphide is added and the liquid examined spectroscopically, the result shows that methæmoglobin is undoubtedly formed when alloxantin is added to oxyhæmoglobin. Since alloxantin possesses reducing power, this is a new example of the formation of methæmoglobin by reduction. The action of alloxantin does not, however, stop at the formation of this substance, but by further reduction hæmoglobin, and finally an undetermined brown substance, is formed.

G. H. M.

**Decomposition of Bromides and Iodides by the Stomach.** By E. KÜLZ (*Zeit. Biol.*, 23, 460—474).—Maly (*Sitzungsb. d. K. Akad. d. Wissensch.*, 76), has shown that free hydrochloric acid is produced by the action of sodium and calcium chlorides on sodium dihydrogen phosphate and disodium hydrogen phosphate, but whether this reaction between the salts of the blood will account for the presence of free hydrochloric acid in the stomach is doubtful. The absence of the acid in the stomach of animals after a fast of 24 hours, and also in new-born animals, places some difficulty in the way of accepting the theory, as it cannot be supposed that diffusion processes stop, or that the salts disappear from the blood. It was thought interesting, therefore, to investigate the question whether the administration of bromides and iodides caused the appearance in the stomach of hydrobromic and hydriodic acids respectively.

As a preliminary investigation, it was found that by distilling bromide of potassium or sodium with hydrochloric acid, no trace of bromine was found in the distillate, whilst minimal quantities of hydrobromic acid added to hydrochloric acid could be detected without difficulty. The method adopted for detecting the acids in the stomach was a

modification of Rabuteau's (*Compt. rend.*, **80**, 61). The gastric juice was collected, in a dog which had fasted 24 hours, by washing out the stomach with distilled water until the washings gave no acid reaction, allowing 200 c.c. of distilled water to remain in the stomach 30—40 minutes, and then withdrawing it. This turned methylaniline-violet blue; it was digested with freshly precipitated quinine at 60°, and evaporated to a thick syrup which crystallised on cooling. This was dried over sulphuric acid and powdered and shaken up with pure chloroform.

The dried chloroform residue was divided into two parts, in one portion the ash, and in the other the chloride (as silver chloride) was estimated. Lactic acid was in all cases absent. The next question was whether this method would avail to detect free hydrobromic or hydriodic acids in the presence of hydrochloric acid and salts of those acids; in artificial mixtures, the silver precipitate consisting of chloride and bromide of silver was obtained by the method just described; the precipitate was weighed, then heated in a tube and a stream of chlorine passed over it; from the loss of weight so produced the amount of bromide in the mixture was calculated. Experiments were then performed in which bromide of sodium, bromide of potassium, and iodide of potassium were respectively given to dogs for several days, the animal was then allowed to fast 24 hours, and the gastric juice collected as described; full details of the analyses are given; they show that after the administration of bromides small quantities of free hydrobromic acid, after the administration of iodides small quantities of free hydriodic acid are present mixed with free hydrochloric acid in each case.

**Nutritive Value of Glycerol.** By L. ARNSCHINK (*Zeit. Biol.*, **23**, 413—432).—Several previous investigations have been made to determine the influence exerted by glycerol on the metabolism of proteïds; the general results obtained being that small doses produced no alteration, while large doses such as those given by Lewin and Tschirwinsky (*Abstr.*, 1880, 817) produced an increase in the total amount of urine, with a slight rise also in the total amount of urea excreted. From these experiments, glycerol does not seem to effect any saving in the decomposition of proteïds, such as is brought about by other substances free from nitrogen, like fats and carbohydrates. Scheremetjewski (*Arbeit. aus d. physiol. Anstalt, Leipzig*, 1869, 194) found that the injection of 2 grams of glycerol into the blood-vessels of rabbits produced an increase in the amount of carbonic anhydride expired for the space of an hour after the injection.

The present investigation takes into account the output both of nitrogen and carbon; the urine, fæces, expired air, and perspiration, being analysed from a dog who was fed on two occasions each lasting three days, on 50—80 grams of glycerol in addition to 200 grams of meat and water, and these results are compared with those obtained when the dog was fed on meat and water alone. The results relating to the excretion of nitrogen were as follows:—

| Day of experiment. | Amount of glycerol. | Daily amount of nitrogen excreted. |                 |
|--------------------|---------------------|------------------------------------|-----------------|
|                    |                     | 1st experiment.                    | 2nd experiment. |
| 1, 2               | none                | 6·85 grams                         | 7·47 grams      |
| 3, 4               | 50 grams            | 7·00 "                             | 7·50 "          |
| 5                  | 80 "                | 7·60 "                             | 8·05 "          |
| 6                  | none                | 8·16 "                             | 8·89 "          |
| 7                  | none                | 8·30 "                             | 8·61 "          |

The increase with the larger dose is seen to be marked (10—20 per cent.), and to last for the two days following its administration. A certain amount of unchanged glycerol was found in the urine, but its amount was not proportional to the amount ingested; it therefore had to be estimated daily. The amount of carbon in the urine during the period when glycerol was given as compared with that when it was not given, showed that the increase during the former period was simply due to the unchanged glycerol present, and not to any other compound containing carbon, the result of its decomposition. The fæces were also examined for unchanged glycerol, and a mere trace (0·53 per cent. of the glycerol ingested) was all that was found.

The next question investigated was the effect of glycerol on the laying on of fat. The following table compares the output of nitrogen and carbon:—

| Day. | Nitrogen. | Carbon. |               |                |           |
|------|-----------|---------|---------------|----------------|-----------|
|      |           | Total.  | From proteid. | From glycerol. | From fat. |
| 1    | 6·72      | 42·99   | 22·04         | —              | 20·95     |
| 2    | 6·98      | 42·15   | 22·89         | —              | 19·26     |
| 3    | 7·08      | 45·89   | 23·22         | 12·93          | 9·74      |
| 4    | 6·93      | 48·28   | 22·73         | 11·64          | 13·91     |
| 5    | 7·60      | 56·26   | 24·93         | 21·15          | 10·18     |
| 6    | 8·16      | 47·14   | 26·76         | —              | 20·38     |
| 7    | 8·30      | 41·31   | 27·22         | —              | 14·09     |

That is to say, the glycerol furnishes a good deal of the carbon, and so economises the amount of fat which undergoes combustion; a similar table was made as the result of a second experiment.

Upon the data that the combustion of 1 gram of the carbon of fat gives rise to 12·35 cal., of glycerol to 11·01 cal., and 1 of the nitrogen of meat to 25·95 cal., other tables to show the heat value of glycerol have been calculated, of which the following is an example:—

| Day.] | Cal. from N. | Cal. from glycerol. | Cal. from fat. | Total. |
|-------|--------------|---------------------|----------------|--------|
| 1     | 174·38       | —                   | 258·73         | 433·11 |
| 2     | 181·13       | —                   | 237·86         | 418·99 |
| 3     | 183·73       | 142·36              | 130·29         | 456·38 |
| 4     | 179·83       | 128·16              | 169·69         | 477·68 |
| 5     | 197·22       | 232·86              | 124·86         | 554·94 |
| 6     | 211·75       | —                   | 250·70         | 462·45 |
| 7     | 215·38       | —                   | 173·02         | 388·40 |

This shows that although the glycerol saves the combustion of fat, yet more than an equivalent amount of glycerol undergoes combustion, giving rise to an unnecessarily large production of heat; the final calculation showing that on the three days of its administration, 21, 41, and 55 per cent. of it respectively underwent combustion over and above that which was necessary to compensate for the fat saved.

**Addition of Sugar to Cattle Foods.** By T. PFEIFFER and F. LEHMANN (*Bied. Centr.*, 1887, 46—50).—These experiments were made in continuation of those of Henneberg and Holdefleiss (*Abstr.*, 1885, 1252; 1886, 727). Two sheep were fed on different kinds of fodder for certain periods, and afterwards on a mixture containing a considerable proportion of sugar; the protein, fat, cellulose, and mineral matters digested were carefully estimated in the usual manner; the conclusion arrived at was that the addition of sugar had no influence on the digestibility of the other substances.

J. F.

**Wheaten Gluten as a Food.** By A. CONSTANTINIDI (*Zeit. Biol.*, 23, 433—455).—This research was undertaken first on dogs and then on men, to ascertain the value of wheaten gluten as a food, and consequently its use among the poorer classes on account of its cheapness. The following results were obtained from a three days' experiment on a dog, 100 grams of the gluten with 100 grams of fat being given daily; the intake of nitrogen was 37·44 grams, the output in the urine 35·2 grams, and in the fæces 1·3, a total of 36·5. Moreover, some of the nitrogen in the fæces is doubtless derived from the digestive juices and mucus secreted in the alimentary canal. 3·05 per cent. of the fat given was all that was left undigested. In a second experiment, lasting five days, a gain of nitrogen was also noted, the figures being as follows:—The intake of nitrogen was 123·16 grams; the output 124·27 grams (in the urine 121·01, in the fæces 3·26 grams). The fat given was all absorbed with the exception of 2·8 per cent. of it found in the fæces.

Similar experiments were then performed on the laboratory servant, who had eaten so many kinds of food given him by other experimenters, that he took this artificial mixture with relish. The food given consisted of potatoes, gluten (200 grams daily), lard, beer, common salt and water, all of which were previously analysed. The result of a three days' experiment was as follows:—Intake of nitrogen

95.091 grams; output in urine 72.25, and in fæces 6.07, total 78.32 grams. The amount of nitrogen retained in the body was therefore 16.76. 6.4 per cent. of the nitrogen given was not absorbed from the alimentary canal, and 2.5 per cent. of the fat given also appeared in the fæces; of the starch given only 0.38 per cent. remained unabsorbed; whereas the fæces contained 78 per cent. of the cellulose contained in the food.

A second research, lasting three days, was also performed, and the diet was the same with the exception that no gluten was given, and the result showed that the gain in nitrogen observed in the first experiment was clearly due to the gluten; in this second experiment the intake of nitrogen being 21.522 grams, and the output 28.67 grams (24.47 in the urine, 4.2 in the fæces). The conclusion is drawn that this food is an exceedingly valuable one.

W. D. H.

**Digestion in the Pig.** By ELLENBERGER and HOFMEISTER (*Bied. Centr.*, 1886, 833—837).—The pigs, after a hunger period; were fed with oats, and then killed in 1, 2, 3, 6, 8, 10, and 12 hours after feeding. It appeared on examination of the pig that digestion takes place in two or three stages. The first and principal is the amylolytic digestion, when all the starch is rendered soluble in 1—2 hours—simultaneously the lactic fermentation commences when a not inconsiderable quantity of sugar is converted; the formation of methane was not proved. In two hours, 34 per cent. of the insoluble albumin becomes soluble. The mucous membrane of the cardiac sac, where are located peculiar glands, contains a weak diastatic ferment; during the first period the reaction is alkaline for a short period only, and as the acidity which later on appears, is due to lactic acid, the conversion of starch still continues.

The second period, when starch is being converted in the cardiac, and albumin in the pylorus, is of a mixed character, commencing at the third hour, and continuing to the ninth to twelfth. There appeared to be only 60—70 per cent. of water in the stomach.

The stomach is not emptied of food until 24 to 36 hours have elapsed since feeding, even if the food has been easily digestible. The amount of acid present seems to rise gradually from 0.002 per cent. to 0.05 per cent., immediately after feeding; to 0.7 in the cardiac half, and to 0.2 in the pyloric half. As observed in the horse, lactic acid is present at first, then later on hydrochloric acid appears (8—9 hours).

E. W. P.

**Amido-compounds in the Animal System.** By P. BAHLMANN (*Bied. Centr.*, 1886, 833).—Asparagine reduces the decomposition of albumin in the bodies of rabbits, sheep, and geese, but appears not to have a like effect in dogs. Tyrosine, taurine, guanidine, and thiocyanates in small doses raise the decomposition of albumin to 168 per cent., as compared with the decomposition occurring in animals fed with non-nitrogenous food; but if leucine be substituted for a part of the asparagine, the great increase is very considerably modified. The nitrogenous compounds in extract of meat neither affect loss of albumin, nor increase the feeding value of non-nitrogenous foods.

E. W. P.

**Pepsin versus Animal Digestion.** By E. F. LUDD (*Amer. Chem. J.*, 8, 433—436; compare *Abstr.*, 1886, 646).—It is shown that the artificial pepsin digestion yields results which are practically concordant with those obtained by animal digestion, as given in Kuhn's tables, &c. Armsby's statement that in a fodder over-rich in starch the digestibility of the albuminoids is decreased, holds in the case of artificial pepsin digestion; and in a compound ration the results are not the same as with each separate component of the ration.

H. B.

**Formates in the Organism.** By GRÉHANT and QUINQUAUD (*Compt. rend.*, 104, 437—439).—Experiments with dogs show that when sodium formate is introduced into the blood or the digestive canal, the greater part is eliminated in the urine without undergoing any alteration. At the same time, the urine contains no excess of carbonates.

The organic liquid was acidified with sulphuric acid and distilled in a vacuum on a water-bath. The distillate was neutralised, evaporated to a small bulk, and the formate thus obtained was decomposed with strong sulphuric acid, and the volume of evolved carbonic oxide measured. Experiments with an aqueous solution of the formate, and with urine to which a known quantity of formate had been added, gave the necessary correction.

C. H. B.

**Reducing Substance in Diabetic Urine.** By H. LEO (*Chem. Centr.*, 1887, 193—194).—In addition to dextrose, the author has isolated from diabetic urine a reducing substance which, after being purified from dextrose by repeated treatment with barium hydroxide in methylic alcohol solution, is obtained as a bright-yellow syrup. Its aqueous solution has a strong left-handed rotation,  $[\alpha]_D$  being  $-26.07^\circ$ ; it is not fermented by yeast, even after being boiled with hydrochloric acid, and it has the composition  $C_6H_{12}O_6$ . Its reducing power is very much less than that of dextrose. The author suggests that this substance can be determined in diabetic urine by taking the reducing power and optical activity of the urine, removing the dextrose by fermentation, and again determining these constants.

G. H. M.

**Creatinine in Urine.** By P. GROCCO (*Chem. Centr.*, 1887, 17—18).—The author has modified Neubauer's method for the determination of creatinine as follows: During the 24 hours' collection of the sample the urine must be kept acid, if necessary, by the addition of acetic acid, and if possible must be immersed in ice, otherwise a little creatinine may be converted into creatine. An excess of acid is removed by the addition of milk of lime. The urine is then neutralised with lime, calcium chloride added, and the mixture evaporated; the reaction should be either neutral or feebly acid. If the acidity is due to a mineral acid, great care is necessary, and it is advisable to add sodium acetate to the alcoholic extract of the syrupy residue in order to replace it by acetic acid. It is better, however, to entirely dispense with the use of mineral acid and use only acetic acid. The alcoholic solution, to which zinc chloride is to be added, must contain free acetic acid, in order to prevent the precipitation of zinc oxide. On

the other hand too much acetic acid prevents the precipitation of the creatinine zinc chloride. If necessary, the alcoholic extract should be decolorised with animal charcoal before acidification. It is better to cool the solution with ice before adding the zinc chloride. The precipitated creatinine zinc chloride should always be submitted to a microscopic examination with a high power.

With the aid of this method, the author has determined the amount of creatinine in normal and pathological urine. In childhood and old age, human urine contains less creatinine than in middle age. In infants fed with an entire milk diet it does not always occur, but, contrary to Hofmann's statement, it is sometimes found in small quantities during the first months of life. The amount of creatinine increases with a diet of animal food, and decreases on fasting or with a vegetable diet. With increased bodily work, the author found, contrary to Hofmann, that the secretion of creatinine through the kidneys is increased. For the influence of various diseases on the secretion of creatinine in the urine, the original must be consulted.

G. H. M.

**Behaviour of Quinol with Urine and Urea.** By A. N. ANRAEFF (*Vrach*, 1887, 230—232).—The author finds that quinol prevents the alkaline fermentation of urine, an addition of 2 per cent. keeping urine without apparent change either to the eye or to test-paper for 25 days. 1 per cent. prevented it from becoming acid or giving off an ammoniacal odour, the reaction being neutral.

Quinol decomposes urea, the solution becoming more and more tawny in colour; the amount of decomposition produced by quinol is proportional to the quantity of urea present. Thus solutions of urea containing 1, 2, and 3 per cent. of urea showed a loss respectively of 1, 0.5, and 0.2 per cent. of the urea present when kept for 24 hours without admixture; solutions of like strength to which 1 per cent. of quinol had been added, showed losses of 17, 19, 15, and 13.25 per cent. of the urea present. It is suggested that quinol acts like acids on urea, decomposing it into ammonia and carbonic anhydride, but at the same time forming a new combination with the former, which is not readily decomposed by sodium hypobromite. This theory would account for the deficiency of nitrogen always observed when solutions of urea containing quinol are analysed.

Quinol was found in the urine by Mering after the administration of arbutin (*Archiv. f. die gesammte Physiol.*, 1877, 62, 276), and after taking phenol by Baumann and Preusse (*Abstr.*, 1879, 814).

T. M.

**Aniline Poisoning.** By F. MÜLLER (*Chem. Centr.*, 1887, 193).—Unchanged aniline was found in the urine of a person poisoned with aniline; the urine reduced Fehling's solution, but did not rotate polarised light. Free sulphuric acid was present in small quantity (4.75 mgrms. in 100 c.c.), and combined sulphuric acid in large quantity (76.1 mgrms. in 100 c.c.). A portion of the concentrated urine, when boiled with strong hydrochloric acid, neutralised with sodium hydroxide and extracted with ether, gave an ethereal extract which, when tested, showed the blue indophenol reaction. The ethereal

extract of the unboiled urine did not give this reaction; therefore the aniline must have been secreted as paramidophenyl sulphate. The striking resemblance which patients who have been treated with antifebrin show to persons poisoned with aniline led the author to examine the urine in each case. In both cases methæmoglobin is found in the blood. Aniline does not occur in the urine of patients treated with antifebrin, but by the above treatment it shows the indo-phenol reaction. Combined sulphuric acid is also present. The author therefore concludes that antifebrin is secreted in the urine in the same form as aniline, that is, as paramidophenyl sulphate. This can be tested for by boiling a little urine with one-fourth its volume of strong hydrochloric acid, adding a few c.c. of a 3 per cent. phenol solution, and then some drops of a chromic acid solution. If paramidophenol is present, the liquid becomes red and changes to blue on addition of ammonia.

G. H. M.

**Toxic Action of Colchicine.** By A. MAIRET and COMBEMALE (*Comp. rend.*, 104, 439—441).—Experiments with dogs and cats show that colchicine behaves as an irritant poison and attacks all the organs, but especially the digestive canal and the kidneys. The action is more rapid when the drug is injected hypodermically than when it is introduced into the stomach. In the first case the minimum fatal dose is 0.000571 gram per kilo. of body-weight; in the second case, 0.00125 per kilo. Details of the symptoms are given in the original paper.

Colchicine is eliminated by various secretions and chiefly in the urine, but the elimination is very slow, and therefore colchicine may behave as a cumulative poison if administered in minute quantities at not too great intervals.

## Chemistry of Vegetable Physiology and Agriculture.

**Liberation of Nitrogen from its Compounds, and the Acquisition of Atmospheric Nitrogen by Plants.** By W. O. ATWATER (*Amer. Chem. J.*, 8, 398—420; compare Abstr., 1885, 1005, and this vol., p. 292).—The conclusions arrived at are—(1.) During the growth of peas, nitrogen is in most cases acquired from the air, but in some few cases where the conditions of growth are abnormal, there is either no gain in nitrogen or there is a slight loss. This loss is to be explained by the evolution of free nitrogen from the nutriment, or from the seeds and plants during germination and growth; it is probably a constant, and may cause considerable error in all the experiments. (2.) Boussingault has found the amount of atmospheric nitrogen absorbed to be very small, but in his experiments the plants were not normally nourished, and probably, therefore, were less able to resist the action of denitrifying ferments, or to absorb nitrogen from the air. (3.) Numerous experiments have shown a slight gain

or loss of nitrogen during germination and growth, but the failure of an experiment to show the acquisition of nitrogen from the air proves the non-assimilation of atmospheric nitrogen only on condition of the further proof that no nitrogen was liberated, whilst a gain actually observed is positive proof that nitrogen is assimilated either directly by the plants or indirectly through the medium in which the roots developed. (4.) The liberation of nitrogen appears to be due, in some cases, if not in all, to ferments, and it is to be noticed that in nearly all the experiments in which no gain of nitrogen has been observed the plants have been ill fed, or the nutritive solutions have been very concentrated, or other conditions have been abnormal. (5.) The way in which the nitrogen is acquired is still a matter of doubt. (6.) The experiments of Boussingault, and of Lawes, Gilbert, and Pugh which have given the strongest evidence against the fixation of free nitrogen by plants are possibly affected by the loss of nitrogen already referred to, by the exclusion of the action of electricity and of microbes, and by the fact that the plants were also for the most part poorly fed. (7.) In the author's experiments, ignited sea-sand was used for growing the plants in, and hence it is probable that the plants themselves and not the soil are factors in the acquisition of atmospheric nitrogen. (8.) Lawes, Gilbert, and Warrington have shown the great probability that the legumes, which appear to possess in high degree the power of obtaining nitrogen from natural sources, induce the action of nitrifying ferments by which the inert nitrogen of the soil is made available. It is equally conceivable that the same plants and others may favour the action of nitrogen-fixing micro-organisms.

H. B.

**The Functions of Chlorophyll.** By A. NAGAMATZ (*Chem. Centr.*, 1887, 163—164).—The behaviour of leaves, when immersed in an aqueous solution of carbonic anhydride, depends on whether the water thoroughly wets them, or whether they remain covered by a thin film of air. In the former case no starch is formed, in the latter a great deal.

The slight thickness of the chlorophyll-bearing layer in leaves and other assimilating organs, coupled with the fact that light which has been filtered through a chlorophyll solution possesses in a very slight degree only the power of causing the leaves of aquatic plants to separate oxygen, makes it probable that light, which has passed through an assimilating leaf, no longer possesses the power of causing assimilation in a second leaf. Direct experiments showed that sunlight which had passed through a layer of chlorophyll-containing tissue less than 0.2 mm. thick, was completely deprived of the power of causing assimilation. Etiolated leaves do not possess the power of producing starch.

G. H. M.

**Influence of Ozone on Germination.** By A. VOGEL (*Bied. Centr.*, 1887, 142).—Strongly ozonised air seems to have no harmful influence on the germination of seeds. Milk and meat can be kept for a longer time in ozonized air, without change, than in ordinary air.

E. W. P.

**Formation of Sugar in Grapes.** By MÜLLER (*Ann. Agronom.*, 13, 88—91; from *Bot. Centralbl.*, 27, 116).—The author gives a *résumé* of some of the principal results of researches on this subject which have been published at the various Conferences of Viticulturists since 1876. The sugar in the grape is a transformation product of starch formed in the leaves, and the green grape itself takes little or no part in its formation; individual grapes of a cluster ripen normally when protected from the light. Assimilation in the grape itself is never active enough to mask respiration. The starch formed in the leaves exposed to light disappears completely when they are placed in darkness for two days. Again placed in the light a new formation of starch can be detected after three-quarters of an hour. 100 grams of leaves (Risling) destroy by respiration alone 3—4 grams sugar in 24 hours. The migration of the reserve materials depends essentially on the temperature; the higher this is the more rapidly do they find their way through the tissues and towards the fruit, the action being most rapid at 30°. The diminution of acidity is not explained by neutralisation of the acid, but by the relation of acid production to respiration. The more energetic the oxidation of the sugar, the more acid will be formed; the acid already formed is further oxidised, ultimately to carbonic anhydride and water. In the ripe grape, the intensity of metamorphosis and the production of acid diminish together.

To ensure the maximum production of sugar, as many leaves as possible must be left on the vine; there is no practical limit to this except the shade produced by too many leaves. The following table shows the effect of leaving 2, 4, 6, or all the leaves on the twig below each bunch of grapes:—

|                         | Weight<br>of<br>grapes. | Quantity<br>of<br>must. | Acid<br>per<br>1000. | Sugar<br>per<br>cent. | Sugar<br>in<br>kilos. |
|-------------------------|-------------------------|-------------------------|----------------------|-----------------------|-----------------------|
|                         | kilos.                  | litres.                 |                      |                       |                       |
| 1. Two leaves left....  | 35·39                   | 22·15                   | 13·6                 | 16·72                 | 3·703                 |
| 2. Four leaves left.... | 37·07                   | 22·26                   | 13·5                 | 16·95                 | 3·774                 |
| 3. Six leaves left .... | 35·02                   | 22·23                   | 15·2                 | 17·36                 | 3·860                 |
| 4. All leaves left .... | 38·66                   | 24·16                   | 12·2                 | 17·76                 | 4·315                 |

There is thus less sugar and more acid when the leaves are removed. The grapes are less mature, and less lævulose is formed:—

|                           | Dextrose. | Lævulose. |
|---------------------------|-----------|-----------|
| I. Two leaves left. ....  | 8·34      | 8·38      |
| II. All leaves left. .... | 8·68      | 9·18      |

**Presence of Cinnamic Acid in Plants of the Ericaceæ Family.** By F. J. EIJKMAN (*Rec. Trav. Chim.*, 5, 297—298).—From the leaves of the *Enkianthus Japonicus*, an ornamental plant in Japanese gardens, the author has extracted by means of chloroform a crystalline sub-

stance, proved by analysis and physical properties to be cinnamic acid.  
V. H. V.

**Composition of Lupines.** By TROSCHE (*Bied. Centr.*, 1887, 101—103).—The following tables show the composition of blue, yellow, and white lupines, also of *Lupine cruiikshankii* at four different periods of growth, namely: I, when main stems began to bloom; II, main stem in full bloom; III, blooming of side shoots; IV, complete formation of all shoots:—

*Period I.*

|                               | <i>L. cruiikshankii.</i> | Yellow. | White. | Blue. |
|-------------------------------|--------------------------|---------|--------|-------|

| Non-nitrogenous extractive .. | 34·89                    | 38·21   | 39·40  | 42·72 |

The total amount of the ash and albuminoids as produced by 100 plants shows that the blue lupine is vastly inferior to any of the others, that the white during the first period is the best, but that *L. cruiikshankii*, other things considered, is the best, although it is more easily affected by low temperatures.

E. W. P.

### Composition of the Inner Brown Skin of the Earth-nut.

By J. KÖNIG (*Bied. Centr.*, 1887, 141).—This substance contains water, 9.01 per cent.; albuminoids, 12.68; fat, 11.76; non-nitrogenous matter, 20.46; fibre, 34.90; ash, 11.19. The author considers the price usually charged for this substance (5.4 marks per centner.) too high; being indigestible, its price ought to be 3 marks.

E. W. P.

### Effects of Thiocyanates on Vegetation and Fermentation.

By E. MEUSEL (*Bied. Centr.*, 1887, 66—69).—The presence of thiocyanate in ammonium sulphate has been proved by various observers to be injurious to vegetation, but exhaustive experiments on the subject have not hitherto been made. The author gives the results of his observations.

Seeds lose their power of germination when steeped in a  $\frac{1}{2}$  or  $\frac{1}{4}$  per cent. solution of ammonium thiocyanate; they rapidly swell, and in the case of wheat the husks burst; the microscopic appearance of the seeds is unaltered. Potassium, ammonium, barium, calcium, and magnesium thiocyanates immediately convert potato and other starches into pastes when preserved in 20 per cent. solutions, the rapidity of action depending on concentration. The paste so produced was almost transparent, similar in appearance to that produced by weak potash solution. Sodium and calcium chlorides, in presence of thiocyanates, yield a starch-paste from which when treated with alcohol a substance, "fraktose," is precipitated, insoluble in water.

The albumin of beet juice is coagulated by thiocyanates, but that of cereals is dissolved; egg albumin is coagulated; blood serum, with 5 to 10 or 15 per cent. solution of ammonium thiocyanate, acquires an acid reaction, and after a time becomes a transparent jelly, which yields a soluble and an insoluble albumin when treated with water. The effect on the skin of animals is to swell them considerably more than other reagents, but to leave the texture unaltered. After a time the skin again contracts, becomes elastic, and resembles india-rubber. This, however, does not occur in acid solutions.

J. F.

**Grain of Holcus Sorgho.** By BORDAS (*Compt. rend.*, 104, 300—302).—Sorghum is now somewhat largely cultivated in the districts of Vaucluse and Le Gard. The grain as ordinarily gathered contains 40 per cent. of starch, and this proportion would in all probability increase to 50 per cent. if the grain were allowed to ripen on the plant. 100 kilos. of grain were found to yield 26 litres of alcohol of 33°, with a good flavour. The hydration of the grain is best effected by the action of diastase, and not by the action of acids, since in the latter case the residue cannot be used as cattle food.

The grain is steeped in water for two or three days to remove the husk, then bruised, treated with the smallest possible quantity of

water, and maintained at 60°, when hydration is soon complete. Hot water is gradually added until the temperature rises to about 70°, the liquid is allowed to stand for two or three hours, and is then treated with beer yeast; when the fermentation is complete, the waste is distilled.

C. H. B.

**Cider Ash.** By G. LECHARTIER (*Compt. rend.*, 104, 336—338).—The ash left by cider varies from 1·7 to 4·9 grams per litre according to the district in which the apples are grown. In all cases, from 80 to 92 per cent. of the ash is soluble in water, and the soluble portion consists almost entirely of potassium salts; the potassium doubtless exists in the cider in combination with organic acids. The composition of the ash from one litre of the cider from various districts is given in the following table:—

*Insoluble Portion.*

Apples yield from 90 to 95 per cent. of their weight of must, which contains the greater part of the potassium salts existing in the fruit, whilst the greater part of the calcium salts remains behind in the marc.

The quantity of ash obtained from apples themselves varies from 2·105 to 4·47 grams per kilo., but the composition of the ash is always of the same general character, about 80 per cent. being soluble in water. The amount of phosphoric anhydride varies from 7·6 to 16·0 per cent.; of potassium oxide from 44·0 to 58·0 per cent.; of calcium

and magnesium oxides from 7.3 to 14.0 per cent. The presence of a large quantity of calcium compounds in the soil has no sensible effect on the proportion of calcium in the apples, the amount and composition of the ash being practically the same whether the soil is calcareous, granitic, or schistose.

The wood and leaves of the apple tree leave about 2 per cent. of ash, about 50 to 75 per cent. of which is insoluble in water, and consists mainly of calcium and magnesium phosphates and carbonates. The soluble part of the ash contains no phosphoric acid.

C. H. B.

**Silage of Maize.** By B. SCHULZE (*Bied. Centr.*, 1887, 96—98). Comparison of the analyses of fresh green maize plants, and of the same when siloed.

**Silage of Vegetable Matter.** By B. SCHULZE (*Bied. Centr.*, 1887, 98—101).—With the view of ascertaining the influence of the amount of water present on the quality of silage, hay was wetted with different quantities of water, and then, after fermentation had occurred, analysed. It then appeared, as shown in the tables of analyses given, that the more water there was present the greater was the loss of carbohydrates and crude fibre. The albuminoids were less altered than was expected, but this the author attributes to the albumin being dry, and therefore less easily attacked by the water. The second set of experiments was undertaken with the object of ascertaining the influence of time on the quality of silage, the examinations being made bimonthly. It appeared that the carbohydrates and cellulose were most affected in the first six months, the loss which occurred in the second half year being much less; the albumins were most affected during the second half year; the ether extractive was gradually and continuously reduced.

E. W. P.

**Diffusion Residues.** By MÄRCKER (*Bied. Centr.*, 1887, 104—106).—These residues from the sugar factories are treated with milk of lime when being made up into “sections.” This process, together with the subsequent pressing, reduces the value of the sections as food, to the extent of 6.12 per cent. dry matter and 5.92 per cent. nitrogen, due in part to compounds found in the liquid which runs from the presses. The amount of lime generally present varies from 1.25 to 4.5 per cent. of the dry matter, and of this 4 per cent. about 2 per cent. is in the form of carbonate; but this large addition of lime to the food of animals (sheep at least) seems to have no harmful influence on them. It is shown that by reason of the neutralisation by the lime of the acids produced during fermentation, they sometimes do not keep as well as if lime were absent. It is advisable, therefore, to dry them in warm chambers, so as to leave only 15 per cent. of water in them.

E. W. P.

**Influence of the Physical Properties of a Soil on the Amount of Free Carbonic Anhydride present.** By E. WOLLNY (*Bied. Centr.*, 1886, 806—812).—The soil under examination was placed in wooden boxes 1 metre square and 25 cm. deep, and inclined to the

south at an angle of  $10^{\circ}$ ,  $20^{\circ}$ , and  $30^{\circ}$  respectively. An iron tube pierced with holes was sunk in the soil so that the air could be withdrawn by its means. In another series of experiments, like boxes were placed facing the four cardinal points at angles of  $15^{\circ}$  and  $30^{\circ}$ . The carbonic anhydride was estimated by Pettenkofer's method. During the three years that these experiments lasted (April—September), it was found that an inclination of  $20^{\circ}$  was most conducive to the formation of carbonic anhydride, but as the quantity of gas produced was so small, it was decided in 1883 to add 600 grams of horse-dung to the soil, and also to add another set of boxes, in the soil of which grass was sown. The results confirmed those previously obtained, and in addition showed that less carbonic anhydride was evolved from grass-sown soil than from that which was bare. As regards those boxes exposed to the north, south, east, and west, it appears that a southerly exposure produces most decomposition, a northerly least, as warmth and moisture are the factors which regulate decomposition. These experiments further show that a northerly aspect in dry weather is productive of most carbonic anhydride, but in wet weather, when the soil is thoroughly moist, then the south aspect is most effectual in producing decomposition.

It is well known that dark soils are warmer than the lighter coloured, consequently it was to be supposed that the darker soil would produce more carbonic anhydride. In support of this theory, humous calcareous sand was placed in cylinders 0.1 sq. m. diameter, some of the soil being darkened on the surface by powdered coal, whilst the rest was whitened by an admixture of coarsely powdered marble. Contrary to expectation, the dark soil proved poorer in gas than the light. The author explains this result by stating that more water, an important factor of decomposition, was evaporated from the dark soil, consequently in wet weather dark soils would be richest in carbonic anhydride.

The air contained in the ridges of a potato and maize field was found to be poorer in carbonic anhydride than the air drawn from the furrows, because although in the ridge decomposition proceeds more rapidly than in the flat, yet the carbonic anhydride is removed more rapidly by wind and diffusion.

The quantities of carbonic anhydride found in soils containing like amounts of organic matter vary with the coarseness of the grain, the finer the grain the greater the percentage, because the gas can more readily pass out into the atmosphere if produced in a coarse-grained soil.

The percentage of carbonic anhydride increases with depth of soil.

The diffusion of carbonic anhydride through layers of soil of various characters is dependent on the character of the grain, diffusing with the greatest difficulty into the fine-grained earth.

Finally, earth shaded by growing plants (grass) contains less carbonic anhydride during warm weather than bare soil, and this again less than soil which is covered by dead plants (straw); in fact the experiments show that the percentage is trebled by a layer of straw 2.5 cm. thick as compared with grass land; moreover, as the layer of

straw increases, so does the percentage of free gas. The conclusions which may be drawn from these last observations are that the thicker the crop stands on the land the poorer will be that land in free carbonic anhydride, because the temperature and the moisture are lower than those of a bare soil, consequently manures which increase the growth of the crop reduce the percentage of free gas. Further, the amount of gas found in the air of a soil must not be considered as a measure of the intensity of decomposition occurring in soils, nor of the quantity of organic matter present if the surfaces are different.

E. W. P.

**Nature of Nitrogenous Organic Matter of Soils.** By R. WARINGTON (*Chem. News*, 55, 27—28).—In the author's experiments, indications of a very small quantity of soluble amide were obtained in the aqueous extract of a soil rich in nitrogen. The soil had been manured annually for the last 38 years with farmyard manure; it contained when dry 0.189 per cent. of nitrogen. The same sample of soil, after treatment with potassium carbonate, yielded an extract which did not contain amide bases or acids soluble in ether, but on treating the acidified extract with phosphotungstic acid it gave a precipitate containing nitrogen (compare Loges, *Abstr.*, 1886, 96). In further experiments it is shown that cold hydrochloric acid removes from both surface- and sub-soils considerable amounts of nitrogenous organic matter, the amount increasing with the strength of the acid and duration of contact. Even when the same soil was treated four times successively there was no apparent exhaustion of this nitrogenous matter. Ammonia was found in the first extracts, but not sought for in the others. The strongest acid employed contained 5 vols. of hydrochloric acid solution per cent. Reference is made to Baumann (this vol., p. 82—84) and to Berthelot and André (*ibid.*, 293—294). The results obtained by Julie (*Abstr.*, 1884, 1413—1416) seem to indicate the synthesis of some such amides as those observed by Berthelot and André (*loc. cit.*).  
D. A. L.

**Decomposition of Organic Matter in Soils.** By E. WOLLNY (*Bied. Centr.*, 1887, 1—11).—The changes which take place during the decomposition of organic matters used as fertilisers, show many points of interest. The fertility of soils depends much on them, and as some of them can be artificially directed, their study is of value.

Carbonic anhydride, water, ammonia, and free nitrogen are disengaged, and where there is free access of air nitric acid is produced, but it has been abundantly proved that nitrification is, partly at least, a physiological process, caused by micro-organisms; little is known of their action, but the presence of oxygen seems to be a necessary condition; the temperature is also an important factor; at 5° nitrification proceeds slowly, at 12° more rapidly, and at 37° it seems to have reached its most favourable stage. Moisture is also an aid to the process, provided it is not so abundant as to stop the pores of the soil and prevent access of air; light is injurious to nitrification, presence of acids stops it, and bases must be present to combine with the nitric acid formed. Soil treated with hydrochloric acid to remove its soluble constituents, yielded very little carbonic anhydride

with organic matter, but when a solution containing those matters was added to it, the production became normal; contrary to general opinion, lime was not found to hasten the decomposition of organic matter; weak solutions of sodium chloride and nitrate were favourable, but strong solutions were not, and the rapidity of decomposition was greatly facilitated by a minute state of division.

A table shows the rate of decomposition of many organic substances, from which it appears that bone meal, fish guano, and birds' excrement are in the first rank, the most difficult being leather and horn meal.

The nitrogen contained in different materials is known to vary in manurial value. The author thinks that which is present in humus and peat is of little worth, and should not add to the value of manure when, in the form of moss litter, it is a constituent of stable manure. The fat contained in certain manure materials aids decomposition; flesh and bone meals deprived of their fat decay more slowly than when it is left in them.

J. F.

**Behaviour of Urea in Soils.** By O. KELLNER and others (*Bied. Centr.*, 1880, 812—813).—It is well known that fresh human urine destroys plants, although it is slightly acid, and therefore can be neutralised by the soil, also, that as soon as it has decomposed slightly and become alkaline, it is no longer harmful.

Experiments now prove that it is the urea which is not absorbed by the soil, but coming in contact with roots of plants, prevents absorption of water, and so causes drooping of the leaves.

E. W. P.

**Manuring with Thomas Slag and other Phosphates.** By M. FLEISCHER, BRINCKMANN and others (*Bied. Centr.*, 1886, 815—823).—The experiments which are here recorded were made on moorland soils, and with various crops (rye, potatoes, &c.), and all point out the great advantages obtained by the use of Thomas slag; they show that this and precipitated phosphates are equal in gross value, and that Thomas slag is superior in net value; that precipitated iron phosphate is far behind slag on moorlands, and that in those cases where there was no advantage in the first season, the effects showed themselves in the succeeding crop.

E. W. P.

**Manuring with Thomas Slag.** By FITTBOGEN and SALFELD (*Bied. Centr.*, 1887, 83—88).—Thomas slag, in conjunction with calcium humate and humic acid was employed as a manure in comparison with mono-, di-, tri-, and tetra-calcium phosphates, some of these being assisted by calcium humate; the seed employed was that of barley. The results were unsatisfactory, far less advantage being gained than in the previous year. There seemed to be no relationship between the quantity of manure used and the percentage of ash in the upper portion of the plants; but the percentage of phosphoric acid was increased by the employment of phosphates, and more especially when the calcium humate was added, still more so by the addition of humic acid in the free condition. Salfeld's experiments show that the effect produced by the slag is largely dependent on the character of the soil,

for with him, using nitre and kainite in addition, the results were good.  
E. W. P.

**Manurial Value of Thomas Slag.** By P. WAGNER (*Bied. Centr.*, 1887, 31—41).—The author has given great attention to the utilisation of this bye-product in agriculture, and has made numerous experiments to ascertain its comparative value as tried against other phosphatic materials.

The composition of the slag explains its ready solubility, the phosphoric acid contained therein being supersaturated with lime, and when put into the soil in a state of fine division, the carbonic anhydride, the humic and other organic acids present readily combine with the lime and set free the phosphoric acid.

Experiments were made at Darmstadt Experimental Station, some in the open field with natural soil, others with the prepared earth in zinc cylinders, loam, calcareous soil, and sand deprived of lime; the plants were oats and barley, the slag being finely ground in some cases, coarse in others; the manure used for comparison was superphosphate from bone ash; tables show the effects of different quantities of phosphoric acid, but the net result is stated to be 1 part of soluble phosphoric acid in superphosphate equals 2.1 parts of finely ground slag and 5.6 of coarsely ground.

Three series of experiments were again made with other crops and manures, of which a summary gives the following comparative results. Counting the increase yielded by superphosphate of 18.74 per cent. soluble phosphoric acid as 100, the other manures show—Superphosphate, 100; Peruvian guano, 30; bone meal, 10; ground coprolites, 9; three samples of Thomas slag of different degrees of fineness, 61, 58, 13.

The fineness of the ground slag has a very great effect on the yield, and the author recommends certain precautions to the buyers to secure fineness. It has been said that the presence of iron would prove injurious to the crops, but the author did not find such to be the case.

The slag is recommended to be used on moorlands or humous soils, where it produces better results than on purely mineral soils; for meadows, potash salts should be added, and on mineral soils double the usual quantity of phosphoric acid. Sulphate of ammonia should not be added to the slag, as it is decomposed with loss of ammonia; where peat mould is available, a small quantity is recommended to be mixed with it.

## Analytical Chemistry.

---

**Indirect Determination of Chlorine, Bromine, and Iodine by the Electrolysis of their Silver Salts, &c.** By J. E. WHITFIELD (*Amer. Chem. J.*, 8, 421—426).—The indirect estimation of any two of the halogens may be effected satisfactorily by precipitating both

together as silver salts, collecting on an asbestos filter, washing, drying at  $150^{\circ}$ , weighing, dissolving the residue in potassium cyanide, and either electrolysing the solution to determine the silver or precipitating the silver as iodide; again collecting on asbestos, washing, drying, and weighing. In a mixture of all three halogens, the iodine is first separated by known methods, and the chlorine and bromine indirectly estimated as described. H. B.

**Estimation of Sulphur in Soluble Slags.** By E. D. CAMPBELL (*Chem. News*, 55, 74).—The slag is decomposed by means of hydrochloric acid with the addition of bromine, the mixture is gradually heated, and then boiled. The solution is filtered and the oxidised sulphur precipitated with barium chloride. D. A. L.

**Absorption of Nitric Oxide by Sulphuric Acid.** By F. NETTLEFOLD (*Chem. News*, 55, 28–29).—The author treated different samples of guncotton and nitre with sulphuric acid and measured the nitric oxide evolved; on now adding more sulphuric acid and measuring again, absorption of nitric oxide was observed in all cases, the quantity varying with the substance employed, but never exceeding a few hundredths per cent. of the total nitric oxide. With pure nitric oxide, no such absorption was observed. The acid employed had a sp. gr. of 1.842. D. A. L.

**Detection of Phosphorus by Mitscherlich's Method.** By — MANKIEWICZ (*Arch. Pharm.* [3], 25, 32).—0.001 gram of phosphorus in 200 grams of 3 per cent. carbolic acid water does not give the characteristic phosphorescence, and so would be overlooked; with 0.002 gram even, the test fails; but with 0.005 gram it succeeds. J. T.

**Simplified Method for the Estimation of Phosphoric Acid from the Weight of the Molybdenum Precipitate.** By E. THILO (*Chem. Zeit.*, 11, 193–195), A. ISBERT (*ibid.*, 223), and LAIBLE (*ibid.*, 286).—The reducing action of the filter-paper is adduced as a constant but variable source of error in estimating phosphoric acid by weighing the dried molybdenum precipitate, and as the mechanical removal of the precipitate from the filter cannot be effected without some loss, the author proposes and fully describes a method of dissolving the molybdenum precipitate in standardised ammonia, titrating any excess with standard acid, and calculating the percentage of phosphoric acid from the amount of ammonia required to dissolve the precipitate. As silica does not interfere with the working of the method, its previous removal is superfluous. For the precipitation of phosphoric acid, a relatively small excess of molybdate is sufficient.

Isbert has made experiments in the above direction, both with ammonia and soda, and with numerous indicators for the titration, but could not get concordant results. He points out that the molybdic precipitate always contains more or less molybdic acid, which of course affects the results; moreover the end reaction with the indicators is either indistinct or not visible. He suggests a method based on the determination of the ammonia in the precipitate.

Laible shows that the results obtained from the determinations of both ammonia and nitrogen in both the molybdenum precipitate and in ammonium magnesium phosphate, cannot be used as a basis for the calculation of the percentage of phosphoric acid, inasmuch as the percentage of ammonia in the molybdenum precipitate is not constant. In the case of the ammonium magnesium phosphate, when the precipitate is washed with water owing to its solubility the results are low; and on the other hand, when it is washed with ammoniacal water and dried, the results are also low, owing presumably to loss of ammonia while drying.

D. A. L.

**Determination of Phosphorus in Iron and Steel.** By L. SCHNEIDER (*Chem. Centr.*, 1887, 45).—If the solution of iron in nitric acid is not evaporated to dryness, and the dry mass strongly heated, the molybdenum method always gives too low a percentage of phosphorus. The cause of this error is that the phosphorus is not completely oxidised to phosphoric acid by simple solution in nitric acid; a portion goes into solution as phosphorous acid, and so escapes precipitation with ammonium molybdate. It is necessary, therefore, to evaporate and heat the iron nitrate in order to complete the oxidation.

G. H. M.

**Determination of Phosphorus in Basic Slag.** By C. BRUNNE-MANN (*Chem. Zeit.*, 11, 19—20).—The author at the present time carries out his process as follows:—10 grams of the slag are digested with 50 c.c. of water; 100 c.c. of hydrochloric acid, 50 c.c. of nitric acid, and 10 c.c. of strong sulphuric acid are added, and the whole is boiled for half to three-quarters of an hour. The hot liquid is poured into 400 c.c. of hot water in a litre flask; the calcium sulphate is dissolved by further diluting and shaking; the cooled mixture is made up to a litre, and the silica, sand, and carbon are allowed to subside. Of the clear liquid, 50 c.c. is evaporated until the hydrochloric and nitric acids are expelled; the sulphuric acid is neutralised by careful addition of ammonia; the whole is evaporated to dryness and heated to 110° to render the silica insoluble. The mass is rubbed up with 10 c.c. of strong nitric acid; 50 c.c. of hot water are added; the silica is filtered off, and the phosphoric acid is precipitated by molybdate as usual. By this method, the phosphorus of the iron phosphide is reported as phosphoric acid, which, in the author's opinion, is justified by the rapidity with which it oxidises in the soil.

M. J. S.

**Determination of Phosphoric Acid in Basic Slag.** By G. LOGES (*Chem. Centr.*, 1887, 229).—The author recommends that the slag should be attacked with concentrated sulphuric acid, avoiding oxidising agents. He considers that the phosphorus of the iron phosphide should not be converted into and reported as phosphoric acid, since, although it undergoes oxidation in the soil, its value as a manure is not equal to that of the ready formed phosphate.

M. J. S.

**Estimation of Silicon in Iron.** By G. H. STRICK (*Dingl. polyt. J.*, 262, 384).—2 grams of iron is dissolved in dilute sulphuric acid, and the solution evaporated to expel all water. The iron sulphate is then

dissolved in water, and the silicic acid filtered off and determined in the ordinary way. This analysis is completed in one and a half hours, whilst the error does not exceed 0.1 per cent. D. B.

### Speedy Volumetric Determination of Carbonic Anhydride.

By W. MARCET (*Proc. Roy. Soc.*, **41**, 181—195).—The method, described at length, is based on the absorption of carbonic anhydride in a closed receiver by potassium hydroxide, and the accurate measurement of the volume of dry atmospheric air required to re-establish the atmospheric pressure after complete absorption. The volume of air will correspond with the volume of the carbonic anhydride, and the weight of the latter is deduced by the ordinary method of calculation. The process consists in passing the air to be analysed from one of two small gasometers through an absorption apparatus into the other, the amount of absorption being recorded by a pressure-gauge. Air is then added from a small receiver enclosed over mercury until the atmospheric pressure in the whole apparatus is restored, and the volume of air thus added is read off.

Certain mechanical difficulties were at first experienced, and the methods by which they were successfully overcome are described in full. Comparative analyses made by this method and by Pettenkofer's are given; the latter, as a rule, gives slightly lower results than the former, the average difference being about 0.4 per cent.

V. H. V.

**Detection of Normal Carbonate in Hydrogen Carbonates of the Alkali Metals.** By E. KUHLMANN (*Arch. Pharm.* [3], **25**, 72—73).—A concentrated solution of pure hydrogen sodium carbonate to which a fragment of rosolic acid has been added remains perfectly colourless, even after standing a quarter of an hour. If 1—4 per cent. of normal carbonate is present a rose tint very shortly appears. If over 4 per cent. is present, the colour rapidly becomes purple. With potassium carbonate, the reaction is more sensitive. Previous writers have noted the sensitiveness of phenolphthaleïn as a test, in fact, it is too sensitive for commercial purposes in this application.

J. T.

**Separation of Sodium and Potassium from Lithium, Magnesium, and Calcium by the Action of Amyl Alcohol on the Chlorides.** By F. A. GOOCH (*Chem. News*, **55**, 18—19, 29—30, 40—41, 56—57, 78—79).—After criticising the methods previously adopted for the estimation of lithium in the presence of potassium and sodium, and exposing their weak points, the author proceeds to compare the relative solubilities of lithium, potassium, and sodium chlorides in amyl alcohol, and he finds that 1 part of lithium chloride requires 15 parts of this solvent, 1 of potassium chloride 24,000 parts, and one of sodium chloride 30,000; and when used to wash the solid chlorides the quantity of potassium or sodium chloride dissolved is quite insignificant. It is upon this basis that the following accurate method of separating and estimating lithium in the presence of potassium and sodium is founded.

Amyl alcohol is added to the concentrated solution of the chlorides, the mixture is heated gently at first until the water is driven off, it is

then raised to boiling temperature and boiled; potassium and sodium chlorides are precipitated, lithium chloride passes into solution; the liquid is now allowed to cool, a few drops of hydrochloric acid added to convert any lithium hydroxide into chloride, then it is boiled again to drive off water.

If great accuracy is required, and the quantity of lithium exceeds 10—20 mgrms., the liquid is decanted off, the residual chlorides washed with amyl alcohol, then redissolved in water and re-treated. The combined extracts and washings are evaporated to dryness, treated with sulphuric acid, ignited, fused, and weighed. For details of the precautions required, the original paper should be consulted. Magnesium and calcium chlorides are also soluble in amyl alcohol, they may therefore be separated from sodium and potassium chlorides in the manner described above: in the case of calcium chloride, a second treatment is always necessary. Preliminary experiments indicate the probable extension of the method to nitrates.

D. A. L.

**Separation of Metals by Oxalic Acid.** By C. LUCKOW (*Chem. Zeit.*, 11, 5—6). (See Abstr., 1886, 922.)—Of the metals of group 6, oxalic acid precipitates tin and antimony when occurring as stannous and antimonious salts, but not when in the state of stannic and antimonious compounds. Arsenic is not precipitated, and solutions of arsenious chloride mixed with oxalic acid may be evaporated without loss of more than traces of the metal. From a solution containing the three metals and oxalic acid, ammonia precipitates the tin only. All the metals of group 5 are precipitated by oxalic acid. The oxalates of lead, bismuth, silver, copper, and mercury are almost absolutely insoluble; that of cadmium is very sparingly soluble. All are the denser if thrown down by boiling oxalic acid. Of the fourth group, oxalic acid precipitates nickel, cobalt, manganous, ferrous, and uranous oxides (but not the corresponding higher oxides), also zinc from neutral or moderately acid solutions. They require a longer time for complete separation than those of the fifth group; addition of ammonium chloride or nitrate favours their precipitation, but the best way, especially with zinc, is to evaporate to dryness. Dilute sulphuric and nitric acids do not greatly increase the solubility of the precipitates; hydrochloric and strong oxalic acid have a much greater solvent action. Many of the precipitates dissolve in alkaline oxalates. The exceptions are the strontium, barium, calcium, silver, lead, and mercuric salts. The barium, magnesium, and mercuric oxalates dissolve in ammonium chloride.

M. J. S.

**Analysis of Copper.** By W. STAHL (*Dingl. polyt. J.*, 262, 277—278).—In estimating copper by electrolysis, it is recommended to remove all traces of lead and silver, as the latter is deposited at the cathode together with the copper whilst the lead is retained by the anode, thus causing too much resistance to the passage of the current. The addition of nitric acid to the sulphated electrolyte is said to exert a beneficial effect on the passage of the current, and prevent the volatilisation of arsenic and antimony at the cathode. In most cases, the electrolytic action may be continued until the colour of the

electrolyte has been entirely removed without the risk of depositing antimony or arsenic. Bismuth, if present, is separated with the copper and is removed by dissolving the total deposit in dilute nitric acid, treating the solution with hydrochloric acid, evaporating to dryness, and precipitating the bismuth as oxychloride. This treatment should be repeated for the purpose of removing basic cupric chloride which is carried down with the oxychloride. The precipitate is then dissolved in dilute nitric acid, the solution neutralised with ammonia, precipitated with ammonium carbonate, ignited, and weighed as bismuthic oxide.

D. B.

### Employment of Nitroso- $\beta$ -naphthol in Quantitative Analysis.

By G. v. KNORRE (*Ber.*, 20, 283—290; compare Ilinski and v. Knorre, *Abstr.*, 1885, 840; 1886, 100).—Copper can be separated from lead, cadmium, magnesium, manganese, mercury, zinc, and other metals, by precipitation as *copper nitroso- $\beta$ -naphthol*,  $\text{Cu}(\text{O}\cdot\text{C}_{10}\text{H}_6\cdot\text{NO})_2$ . This is obtained as a coffee-brown precipitate of metallic lustre. The separation is effected by neutralising with ammonia the solution, which must contain the metals as sulphates or chlorides, acidifying with a few drops of hydrochloric acid, heating nearly to boiling, and adding excess of nitroso- $\beta$ -naphthol dissolved in 50 per cent. acetic acid; after remaining for some hours in the cold, the precipitate is collected, dried, ignited, and weighed as cupric oxide. The separation of iron from chromium, manganese, nickel, zinc, &c., can be effected by the method previously given for its separation from aluminium (*loc. cit.*). Full details of the methods and of the results of test analyses are given in the original.

A. J. G.

**Detection of Alum in Flour.** By J. HERZ (*Dingl. polyt. J.*, 262, 96).—A glass cylinder is filled from one-fourth to one-third full with the flour to be examined and the flour is moistened with water. It is then treated with a few c.c. of alcohol and two drops of a freshly-prepared solution of logwood (5 grams logwood in 100 c.c. of alcohol). After agitating the mixture, the cylinder is filled up with a saturated solution of sodium chloride. The depth of colour of the salt solution is then compared with that obtained by treating pure flour and flour containing 0.01 per cent., 0.05 per cent., and 0.1 per cent. of alum in a similar manner. The colour is permanent for days, being blue in presence of 0.05—0.1 per cent. of alum, and violet-red with 0.01 per cent.

D. B.

### Detection of Free Sulphuric Acid and of Aluminium Hydroxide in Aluminium Sulphate.

By K. J. BAYER (*Chem. Zeit.*, 11, 53).—Referring to Hager's note (this vol., p. 182), the author remarks that free sulphuric acid is detected more readily and with greater certainty by the use of tropæolin as previously described (*Abstr.*, 1886, 281; 651). If aluminium sulphate contains aluminium hydroxide which passes into solution as basic salt, it can be quantitatively determined by titration with normal sulphuric acid, using tropæolin as indicator. The turbidity noticed by Hager (*loc. cit.*) when dissolving aluminium sulphate in 2 parts of water, is due either

to silicic hydroxide or to the basic sulphate,  $3\text{Al}_2\text{O}_3 \cdot 2\text{SO}_3 + 9\text{H}_2\text{O}$  (this vol., p. 448). D. A. L.

**Volumetric Estimation of Manganese.** By C. MEINECKE (*Chem. Zeit.*, 11, 137—138).—The author, in his earlier determinations of manganese by the chlorate precipitation method (compare Hampe. Abstr., 1885, 101), generally found that when iron was present, some of the manganese passed into the filtrate. This is now traced to the use of warm water for diluting. It appears that in presence of iron, although not otherwise, warm dilute nitric acid dissolves some of the precipitated manganese peroxide. When, after precipitation, the liquid was cooled and diluted with cold water, the whole of the manganese was found in the precipitate. M. J. S.

**Electro-dissolution and its Use in Analysis.** By H. N. WARREN (*Chem. News*, 55, 62).—By placing iron boride at the positive pole with a platinum plate as the negative pole of a powerful battery, and using dilute sulphuric acid as a solvent, in 12 hours all the iron had dissolved, whilst the boron and other impurities were precipitated. A similar result was obtained with ferrous sulphide, whereas with silicon-iron and phosphide of iron, zinc, &c., the silicon and phosphorus respectively were only partially precipitated. In hydrochloric acid, copper may be separated from arsenic, iron, zinc, &c., by electro-dissolution; and in ammonia, copper silver, zinc arsenic, and other alloys, may be resolved into their constituent metals. Electro-dissolution has also been applied to the preparation of unstable compounds, such as potassium ferrate, &c. D. A. L.

**Detection of Adulteration in Metallic Nickel and other Metals, by the Magnet.** By T. T. P. B. WARREN (*Chem. News*, 55, 37).—In a mixed sample of nickel cubes, some were found to be non-magnetic, and the sample was easily separated into two lots by means of a magnet. The non-magnetic cubes were a trifle whiter and had not the striated structure noticeable in the magnetic cubes, but there was no marked difference. On analysis, the following results were obtained:—

|                    | Ni.   | Cu.   | C.   | SiO <sub>2</sub> . | Fe.  | As.  | Sn.  |
|--------------------|-------|-------|------|--------------------|------|------|------|
| Magnetic . . . . . | 96.67 | 0.08  | 0.07 | 0.41               | 2.46 | 0.12 | 0.75 |
| Non-magnetic . . . | 63.69 | 33.78 | 0.37 | 0.16               | 0.84 | 0.87 | 0.46 |

Other experiments show that the magnetic properties of both nickel and cobalt are affected by alloying with para-magnetic metals. Moreover, manganese and other metals are met with in commerce without magnetic properties.

When nickel apparatus is heated over a Bunsen flame, a black deposit forms, consisting mainly of graphitoidal carbon with traces of nickel, iron, and silica; therefore, the naked flame should not impinge on such apparatus. Other modes of heating are suggested. D. A. L.

**Detection and Determination of Traces of Chromium.** By E. DONATH and R. JELLER (*Chem. Centr.*, 1887, 151).—If a solution

containing a chromic salt is boiled with sodium carbonate and potassium permanganate, the chromium is oxidised to chromic acid. On re-boiling with addition of alcohol, the permanganate is reduced and the manganese precipitated together with any iron, aluminium, manganese, or alkaline earths previously present. The chromate may be recognised by its colour or by adding sulphuric acid, potassium iodide, and starch. This reagent is more sensitive than hydrogen peroxide. For determination, the solution is re-boiled with alcohol after acidifying, and the chromium is precipitated by ammonium sulphide as usual.

M. J. S.

**Analysis of Chrome Iron Ore.** By W. VENATOR and E. ETIENNE (*Chem. Zeit.*, **11**, 53).—The mineral is decomposed by fusion with caustic soda, and when cold is dissolved in hot water, treated with hydrochloric acid, evaporated to dryness, and dried for some time at 120°; the silica is then separated in the usual manner. Ammonium chloride and ammonia are added to the filtrate, and calcium and magnesium are determined in the solution; whilst the precipitate of aluminium, iron, and chromium hydroxides is weighed and fused with soda, the fused mass is boiled out with water and mixed with excess of ammonium carbonate. The solution is evaporated to dryness and treated with water, the sodium chromate then passes into solution, leaving the iron and aluminium oxides behind. To estimate the chromium, the chromate is reduced by means of sulphurous anhydride, the excess of the latter boiled off, and the chromium precipitated by ammonia in a platinum vessel. Concordant results have been obtained.

D. A. L.

**Determination of Organic Matter in Air.** By T. CARNELLEY and W. MACKIE (*Proc. Roy. Soc.*, **41**, 238—247).—Of the methods proposed for the estimation of organic matter in air, one consists in causing the air to bubble slowly through a dilute solution of potassium permanganate until the latter has become quite or nearly decolorised, any undecomposed permanganate being subsequently estimated by oxalic acid; the other consists in passing the air through distilled water in which the free and albuminoid ammonia are subsequently determined by Wanklyn and Chapman's process. Both these methods, however, are tedious, and uncertain as regards the decomposition of the permanganate in the first, or the absorption of the organic matter by the water in the second. For the process described below, the authors claim rapidity and simplicity, a greater probability of exactness, and a more general applicability. The method proposed consists in a colorimetric estimation of the diminution of colour of a potassium permanganate of known strength, that is to say, the fractional bleaching of the solution effected by a given volume of air. The tint of the permanganate after passage of the air is compared with that of a standard solution of known tint. The method of procedure and the necessary precautions are described in full. Although the method gives concordant results, yet it is fully allowed that the organic matter is not directly estimated by it, that other gases likely to be present in air, such as hydrogen sulphide, nitrous and sulphurous acids, equally decolorise the permanganate, and that as the organic

matter in air is of various kinds, the permanganate is selective in its action. Determinations are given of the organic matter and carbonic anhydride in samples of air under various atmospheric conditions, by which it is shown that these vary in a somewhat similar manner, the results being lower immediately after or during rain or snow, and higher during fog and mist. The organic matter in air exhibits a wider range of variation than the carbonic anhydride. The effects produced by the combustion of coal-gas and paraffin oil as also by respiration are likewise investigated. As regards the last, although the carbonic anhydride and organic matter vary alike to some degree, yet the determination of the former affords no adequate index of the proportion of the latter. After a time, the air is found to contain less organic matter than it did previously; this is owing to the organic matter present being partly gaseous and partly solid; the solid slowly settles down, whilst the gaseous part more readily undergoes oxidation.

V. H. V.

**Colorimetric Determination of Nitrites in Water.** By L. ZAMBELLI (*Chem. Centr.*, 1887, 45).—Two methods for this purpose are proposed, to the first of which the author gives the preference. This consists in adding a solution of sulphanilic acid in dilute sulphuric acid to 200 c.c. of the water under examination, after allowing this to remain for 10 minutes, a little aqueous solution of  $\alpha$ -naphthol is added, and the mixture made alkaline with ammonia. If nitrites are present the liquid is coloured rose to deep-red. The reaction is given by water containing 1 part nitrous acid in 25,000,000. In the second method, the  $\alpha$ -naphthol is replaced by phenol. Nitrites when present in even smaller quantities than 1 in 40,000,000, give with this reagent a yellow coloration, which remains unchanged for a considerable time. This reaction can be applied to the comparative colorimetric estimation of nitrites in water.

G. H. M.

**Determination of Organic Matter in Natural Water.** By A. KÖBRICH (*Chem. Zeit.*, 11, 4).—The author, observing that determinations of the amount of organic matter in waters are not comparable when made by different processes, proposes that the amount should always be stated as equivalent to so much oxalic acid, and that it should be determined by ascertaining the amount of potassium permanganate reduced by it under the following conditions. A solution containing 0.5 gram of permanganate in 1 litre is mixed with 150 grams of pure concentrated sulphuric acid, and maintained at 90° for three hours. Of the solution thus prepared, 50 c.c. are added to 100 c.c. of the water, then 15 c.c. of concentrated sulphuric acid, the mixture is heated for three hours at 90° and the amount of permanganate reduced is ascertained by titration with oxalic acid. The large quantity of acid, added in the concentrated state, the high temperature, and the prolonged heating, are the essential features of the process. Chlorides must first be removed by adding silver nitrate and filtering. Nitrites are to be oxidised by adding the permanganate to the cold, feebly acidified water, until the colour is permanent for five minutes.

M. J. S.

**Detection of Dextrose.** By C. AGOSTINI (*Chem. Centr.*, 1887, 99).—Five drops of the liquid to be tested are taken, and five drops of a solution of gold chloride (1 : 1000), and two drops of potassium hydroxide solution (1 : 20) added, and the whole heated. If dextrose is present, the liquid shows, on cooling, a beautiful violet coloration, more or less intense, depending on the amount of dextrose present. 1 part of dextrose in 10,000 can be detected by this reaction. With urine containing sugar, a wine-red coloration is given. The author has examined a large number of normal and pathological urines, and finds that none of the normal or abnormal constituents of urine, with the exception of albumin, interferes with this reaction. If albumin is present, it must be removed by boiling and filtration. G. H. M.

**Colour Reactions of Beet-sugar.** By A. IHL (*Chem. Zeit.*, 11, 2—3; see Abstr., 1885, 694).—The colour reactions which occur when sugar is heated with a phenol and an acid are due to the presence of the humous substances resulting from the action of acids on sugar (Abstr., 1885, 745). Caramel gives similar reactions. The shades of colour vary somewhat according to the method of operating. With hydrochloric acid, it is generally necessary to warm, but strong sulphuric acid usually produces sufficient heat for the reaction. A mixture of sulphuric acid and alcohol may be used with advantage. Resorcinol, pyrogallol, thymol, cresol, and guaiacol give red shades;  $\alpha$ -naphthol, violet; orcinol (in presence of alcohol) a deep yellow solution, from which a green precipitate separates on adding water. Molisch obtained the naphthol reaction with a solution containing only 0.00001 per cent. of sugar. (See next Abstract.) M. J. S.

**Behaviour of Sugar towards Acids and Phenol.** By B. TOLLENS (*Chem. Zeit.*, 11, 77).—In reference to Molisch's sugar reaction (Abstr., 1886, 923), it has been suggested that the coloration is due to a combination of the phenols with the humous substances produced from the sugar (preceding Abstract). The author's experiments prove this suggestion to be quite fallacious, inasmuch as the phenols give brownish-black resinoid substances with the humous matter from sugar. In fact this reaction may be used with advantage to remove such substances from sugar solutions; as, for instance, in the preparation of lævulinic acid from cane-sugar the humous substances may be completely separated by treatment with phenol.

D. A. L.

**Colour Reactions of Starch and Gums.** By A. IHL (*Chem. Zeit.*, 11, 19).—All the carbohydrates give somewhat similar reactions with the phenols in presence of sulphuric or hydrochloric acid. Starch, however, requires a higher temperature than sugar. Starch moistened with alcoholic solution of  $\alpha$ -naphthol and a few drops of warm concentrated sulphuric acid, acquires a deep violet-red colour. Thymol, cresol, guaiacol, and catechol give cinnabar-red, orcinol and resorcinol a yellowish-red, phloroglucol a yellowish-brown.

With the gums, similar appearances are produced. Arabin boiled with an alcoholic solution of phloroglucol and strong hydrochloric acid affords a characteristic cherry-red dye.

M. J. S.

**Determination of Hippuric Acid in Urine.** By O. VÖLCKER (*Chem. Centr.*, 1887, 124—125).—200—300 c.c. of urine are evaporated down to one-third in a glass basin of 100 c.c. capacity, about 4 grams of sodium dihydrogen phosphate added, and the evaporation continued until the liquid is syrupy; highly-burnt calcium sulphate is then added, and the whole heated until the mass becomes pulverulent. The residue is collected and extracted in a small Soxhlet's apparatus with rectified light petroleum; after four to six hours the flask is changed, and the extraction continued with dry ether free from alcohol for six to ten hours. After a time, crystals of hippuric acid separate from the ethereal solution. The ether is distilled off, and the dark-coloured residue dissolved in hot water, decolorised with animal charcoal, the solution filtered, and the charcoal washed with hot water. The solution is evaporated to 1 to 2 c.c. on a water-bath at 50—60°, and allowed to crystallise. The crystals are collected on a tared filter-paper dried at 110°, the dish washed out with the filtrate, and the latter collected in a graduated cylinder. The filter is washed with a few drops of water, then with a little ether, dried at 100°, and weighed. 0·0015 gram for every c.c. of the filtrate is added to the weight, in order to correct for the hippuric acid in solution. The results obtained by this method are very good. G. H. M.

**Characteristics of Olive Oil.** By A. LEVALLOIS (*Compt. rend.*, 104, 371—373).—The author has examined a large number of genuine samples of olive oil from the olive yards of the south-east of France.

The colour of the oil was determined by means of a Duboscq colorimeter. The colour at the commencement of a crop is 70 times as intense as at the end. The sp. gr. at 15° varies from 0·9167 to 0·9177, and the differences observed with different species are only very slight. The sp. gr. of olive oil at 24° is 0·911, whilst that of other oils at the same temperature is as follows:—

|                  |        |                |       |
|------------------|--------|----------------|-------|
| Sesame.....      | 0·917  | Colza .....    | 0·910 |
| Cotton-seed..... | 0·9165 | Camelina ..... | 0·920 |
| Earth-nut .....  | 0·912  | Linseed .....  | 0·928 |
| Poppy .....      | 0·9205 |                |       |

The sp. gr. of colza and earth-nut oil are somewhat near that of olive, but their other properties make it easy to distinguish between them.

Cailletet's reagent (nitric acid saturated with nitrogen oxides) usually gives a green coloration, which, however, is not always pure, but is sometimes mixed with yellow.

Audoynaud's reaction (addition of nitrosulphuric acid and ether to a mixture of the oil with potassium dichromate) usually gives a green coloration, which in some cases is mixed with yellow.

The determination of the non-saturated fatty acids by treating the non-saponified oil with bromine or iodine gave no concordant results. The following method is satisfactory:—5 grams of the oil are weighed into a test-tube about 15 cm. long and 15 mm. diameter, mixed with

10 c.c. of a 20 per cent. solution of potassium hydroxide in alcohol of 93°, and agitated, when the oil dissolves. The liquid is then heated on a water-bath to a temperature sufficient to produce gentle ebullition, and after about 15 minutes saponification is complete. The volume of the liquid is then made up to 50 c.c. by adding alcohol, and 5 c.c. of the solution is placed in a tube provided with a glass stopper, acidified with hydrochloric acid, and then mixed with a concentrated aqueous solution of bromine from a burette, with vigorous agitation, until the liquid acquires a persistent pale-yellow tint. About 0.1 c.c. of solution is required to produce the end reaction, and this should be subtracted from the total volume added. The bromine is standardised by means of a decinormal solution of arsenious acid, mixed with hydrochloric acid. Different samples of oil from the same species of olive absorbed from 0.512 to 0.522 gram of bromine per gram of oil. The absorption by oil from different species of olive varied from 0.500 to 0.544, the last result being obtained with oil from Blanquetier which also has an exceptionally high sp. gr. The amount of bromine absorbed by 1 gram of other oils is as follows:—

|                   |       |                |       |
|-------------------|-------|----------------|-------|
| Cotton-seed ..... | 0.645 | Colza .....    | 0.640 |
| Sesame .....      | 0.695 | Camelina ..... | 0.817 |
| Earth-nut .....   | 0.530 | Linseed .....  | 1.000 |
| Poppy .....       | 0.835 |                |       |

The alcoholic solution of soap from oil of earth-nut becomes solid as soon as the temperature falls to 15°, but the corresponding solution of olive oil soap remains liquid.

The most constant characteristic of olive oil is its sp. gr., but the determination of the bromine absorbed is also very useful.

C. H. B.

**Properties of Olive, Sesame, and Cotton Oils.** By T. LEONE and A. LONGI (*Gazzetta*, 16, 393—398).—The authors, with a view to the recognition of the presence of sesame and cotton oils in cases of sophistication of olive oil, have examined the physical and chemical properties of these oils, such as the proportion of solid acids obtained on saponification, the quantity of alkali required to complete this process, the specific gravities at 100° of the oils and the resultant acids, the points of fusion and solidification of the acids, and the indices of refraction of the oils. As a result of their examination, it follows that the quantities of solid acids and of alkali required for saponification are appreciably equal for all three oils, but the sp. gr. of olive oil at 100° is less than that of sesame and cotton oils by about 0.005, the index of refraction of the former is also somewhat less than those of the latter. But the most marked difference is observed in the points of fusion and solidification of the resultant acids, for those from olive oil melt at 24—27°, and begin to solidify at 17.5°, whilst those from cotton and sesame oils melt at 36—40°, and solidify at 34—30° and 34—32° respectively.

## General and Physical Chemistry.

---

**Spark Spectra from Coils of Low Tension.** By E. DEMARÇAY (*Compt. rend.*, 104, 678—679).—The author modifies his previous statement respecting the identity between the spectra obtained by coils of low tension and those obtained with the electric arc.

The spectra of potassium, sodium, thallium, and aluminium seem identical under both conditions; those of barium, strontium, and calcium seem identical except as regards the intensities of the lines. The spectra of tin, lead, and mercury are, however, very different, and are not similar to those described by Hartley and Adeney. So far as the visible portion of the spectrum is concerned, they seem to differ but slightly from those described by Boisbaudran.

The lines of fluorine are obtained by allowing the sparks to fall on concentrated hydrofluoric acid, and the spectrum is similar to that described by Salet. Oxygen lines are obtained in the same way from water, pure dilute acids, and fuming nitric acid. The line at 6160 which appears under these conditions seems to be due to oxygen, and is probably identical with the line described as 6171 by other observers. There are also violet and blue lines which seem to be due to oxygen.

C. H. B.

**Variations in the Absorption Spectrum of Didymium.** By H. BECQUEREL (*Compt. rend.*, 104, 777—780).—When the absorption spectra of different natural or artificial crystals which contain didymium in various states of combination are compared, it is found that a great number of characteristic bands occur in these spectra, but their wave-lengths vary in different cases. The variations do not affect the whole spectrum. One set of bands will be displaced in a certain direction, whilst another set remains in its original position. In some cases, certain bands are wanting. Differences of the same order are observed when the crystals are dissolved in water. In the solutions, the different principal absorption spectra of the crystals are superposed, and the bands which disappear in certain directions in the crystals will be more or less diminished in intensity in the solution, and other bands may lose their distinctness by reason of the juxtaposition of several bands belonging to different principal spectra. Apart from these modifications, it is found that the solutions show all the principal bands observed in the corresponding solids, some retaining their positions, whilst some are displaced in one direction, others in the other direction.

No variations of this irregular character are observed in the case of uranium; any cause which affects one set of bands affects the others in the same direction.

The phenomena observed in the case of didymium can be readily explained if it is assumed that each of the variable bands is due to a distinct substance. A table which is given shows the nature of

the variations for certain cases. The majority of the variable bands can be attributed to different substances; for example, the three bands of praseodidymium, 4819, 4690, 4450, and the group at 4755, and the bands of neodidymium, 5710, 5239, 5214, 5205, 5115, 4270. The spectra of the solutions of double nitrates are all identical, but the spectra of the crystals show distinct differences, a fact which would indicate that the double compound is decomposed when dissolved. The bands which have been enumerated are those which have a particular direction of absorption in the crystals, and several of them have been separated by chemical processes.

The bands show both a chemical and crystallographic individuality, but it is not at present possible to decide whether they are due to distinct simple substances. The substances which produce the bands have certain of the properties which characterise simple substances, and it may be that some of the substances to which the bands are due are either very stable combinations of two substances or polymeric modifications of the same substance.

C. H. B.

**Red Fluorescence of Alumina.** By L. DE BOISBAUDRAN (*Compt. rend.*, 104, 478—482, 554—556).—Alumina was prepared from aluminium chloride by decomposing it with water, evaporating the solution to dryness, and heating to a temperature sufficiently high to produce the red fluorescence with alumina from alum. The fluorescence of the alumina thus obtained was not red, but blue to greenish-blue, and its spectrum gave neither a line nor a band. The addition of 0.1 per cent. of chromic oxide, however, produced a brilliant red fluorescence far brighter than that obtained from pure alumina under any conditions, and the bands in the spectrum are well defined. With 0.01 per cent. of chromic oxide, the fluorescence is rose-red, and the band and line in the spectrum are very distinct. 0.005 per cent. of chromic oxide produces a mixture of the greenish-blue and rose-red fluorescence, which is generally of a rosy-white tint.

Moderately calcined alumina mixed with about 1 per cent. of bismuth oxide shows at most a very feeble greenish fluorescence.

A strongly calcined mixture of bismuth oxide and alumina from the sulphate shows a reddish-lilac fluorescence. If the alumina has been prepared from alum, the fluorescence is a mixture of the pale-green and dull red fluorescences; if from aluminium chloride, the fluorescence is almost white with a greenish or violet tinge. When the exciting current is weak, the violet tinge only is seen. With a much smaller proportion of bismuth oxide (0.065 per cent.), the fluorescence is brighter, and has a greenish-blue tinge. It is distinctly brighter than with 1 per cent. of the oxide, and much brighter than with pure alumina.

The curious fluorescence, lilac in the cold but blue on heating, which is obtained with alumina prepared from the sulphate mixed with bismuth oxide, seems to be due to the simultaneous presence of bismuth and some other substance, but the latter is not potassium.

The red line seen in the spectrum of the fluorescence of alumina from alum, &c., disappears when the tube is moderately heated in a

vacuum, and at the same time the fluorescence becomes orange. The broad red band in the spectrum at first becomes more intense, but if the tube is more strongly heated the band disappears.

Alumina mixed with a small proportion of ferric oxide and very strongly heated gives no red fluorescence. Alumina from alum containing 1 per cent. of cupric oxide and moderately calcined, shows a somewhat bright bluish-green fluorescence. After strongly heating, the red fluorescence is obtained.

Alumina from alum gives the most intense fluorescence when it is precipitated by ammonia, and at first gradually and then very strongly heated. Alumina from alum which has been very strongly heated, and containing 0.001 per cent. of manganese oxide, but free from potassium oxide, gives a pale-rose fluorescence with the red band in the spectrum well marked. Here and there the fluorescence is greenish.

The red obtained from pure alumina in the phosphoroscope is much feebler than that given by less pure varieties of the oxide, especially if the latter contain a small quantity of chromium. There is no spectrum evidence to show whether the two fluorescences are or are not identical.

Pure alumina prepared from redistilled aluminium chloride by precipitation with ammonia and calcination at a high temperature, gives a feeble red phosphorescence in the phosphoroscope. If the aluminium chloride is decomposed by a small quantity of water, the solution simply evaporated to dryness, and the residue strongly heated, the alumina thus obtained gives a very feeble greenish-white phosphorescence in the phosphoroscope. It would seem that the red phosphorescence observed in the first case is due to impurities introduced either in the form of dust or in the distilled water used for washing.

These results tend to support the author's view that small quantities of chromium are the determining cause of the red fluorescence.

C. H. B.

**Causes which Determine the Phosphorescence of Calcium Sulphide.** By A. VERNEUIL (*Compt. rend.*, 104, 501—504).—The shell of *Hypopus vulgaris* (this vol., p. 2) has the composition  $\text{CaCO}_3$  98.21,  $\text{Na}_2\text{CO}_3$  0.99,  $\text{NaCl}$  0.06, insoluble matter 0.04,  $\text{SiO}_2$  0.02,  $\text{MgO}$  0.01,  $\text{P}_2\text{O}_5$  traces, organic matter and loss 0.67 = 100.

Pure calcium carbonate mixed with double the proportion of sodium carbonate present in the shell and 0.02 per cent. of sodium chloride, and then heated with 30 per cent. of sulphur and 0.02 per cent. of bismuth nitrate, yields a product which phosphoresces in a manner very similar to that of the product obtained when the shell of *Hypopus* is treated in a similar manner.

Pure calcium sulphide gives no phosphorescence; if mixed with a small proportion of the sulphate it shows a feeble white phosphorescence; with sodium carbonate, a greenish-white phosphorescence; with bismuth added in the form of bismuth nitrate, a feeble white phosphorescence; with sodium carbonate and bismuth simultaneously, a blue phosphorescence. Sodium chloride increases the intensity of the phosphorescences produced by sodium carbonate and by bismuth.

From these and former observations (*loc. cit.*), it appears that the

violet phosphorescence of calcium sulphide prepared from the shell of *Hypopus vulgaris* is due to the simultaneous presence of bismuth oxide, sodium carbonate, sodium chloride, and calcium sulphate. An increase in the proportion of sodium carbonate and chloride above that contained in the shell does not increase the brilliancy of the phosphorescence. Traces of silica, &c., probably exert a similar effect, but their amount is so small that their action is negligible.

The action of these substances is probably due to the fact that they act as fluxes, and it seems not improbable that all substances which are capable of vitrifying the surface of the calcium sulphide without colouring it render it phosphorescent.

Calcium sulphide becomes phosphorescent to a greater or less extent if heated on platinum foil with a small quantity of borax, potassium carbonate, sodium chloride, sodium carbonate, sodium sulphate, sodium silicate, barium chloride, strontium chloride, calcium fluoride, barium fluoride, barium silicofluoride, cryolite, &c. C. H. B.

**Phosphorescence of Calcium Sulphide.** By E. BECQUEREL (*Compt. rend.*, 104, 551—554).—This paper is mainly a summary of the author's previous observations respecting the phosphorescence of calcium sulphide.

Verneuil's pure calcium sulphide is feebly luminous in the phosphoscope after being exposed to the sun's rays.

The colour of the phosphorescence of sulphides varies with the temperature. This is well seen in the case of strontium sulphide prepared from strontium oxide and sulphur. At  $-20^{\circ}$  the phosphorescence is violet-blue, at  $+40^{\circ}$  pale-blue, at  $90^{\circ}$  greenish-yellow, at  $150^{\circ}$  orange, and the reverse changes are observed as the temperature falls. Strontium sulphide at different temperatures reproduces temporarily and successively under the influence of light almost all the colours of the spectrum. Similar effects are obtained permanently by admixture with foreign substances. C. H. B.

**Rotatory Power of Compounds formed in Solutions of Tartaric Acid.** By D. GERNEZ (*Compt. rend.*, 104, 783—785).—Many substances which, like boric acid, have no action on polarised light, have the power of removing the anomalies of the law of dispersion of solutions of malic and tartaric acids, and of increasing the rotatory power of these substances to a considerable extent. Amongst these are amido-compounds, such as formamide, acetamide, urea; acids, such as arsenic, arsenious, molybdic, and antimonious acids; salts, such as alkaline arsenates, molybdates, and tungstates.

The effect is particularly well seen in the case of sodium molybdate, a very soluble salt. When tartaric acid and sodium molybdate exist together in solution in the proportion of equal equivalents, they form a substance which has a rotatory power 37.57 times as great as that of tartaric acid. The compound formed under these conditions will be  $\text{Na}_2\text{MoO}_4 \cdot 2\text{C}_4\text{H}_6\text{O}_6$ . In solutions which contain a lower proportion of sodium molybdate, the rotatory power is proportional to the amount of the inactive substance up to and even beyond half an equivalent.

The addition of sodium molybdate in quantity above that required by the formula given has no appreciable effect. C. H. B.

**Galvanic Element.** By W. BORCHERS (*Dingl. polyt. J.*, **263**, 32—34).—The cell containing the exciting agent consists of an ordinary wrought-iron tube, closed at one end and in which a zinc or tin rod is suspended. The iron tube forms the positive pole. The exciting agent is a solution of sodium hydroxide and sodium nitrate, sodium chloride being added to increase the active power of the solution. For technical purposes the ratio of  $\text{Na}_2\text{O} : \text{NaNO}_3 : \text{NaCl} = 90 : 80 : 300$  may be used. D. B.

**Standard Galvanic Cell.** By GOUY (*Compt. rend.*, **104**, 781—783).—A convenient standard of electromotive force is furnished by a cell composed of zinc, zinc sulphate, mercuric oxide, and mercury. The bottom of a flask is covered to a depth of 2 to 3 cm. with carefully purified mercury, a platinum wire sealed into the glass and in contact with the mercury forming the positive pole. On the mercury is placed a layer of yellow mercuric oxide, and the flask is filled with a 10 per cent. solution of crystallised zinc sulphate (sp. gr. 1.06), and in this is immersed a rod of pure zinc, which should be amalgamated. In order to render the cell portable, the zinc may be enclosed in a tube with a narrow aperture closed with some porous material. This arrangement will give a cell with a very high resistance. It matters little whether the cells are exposed to air or are hermetically sealed. Some sealed cells which had been filled up for three months were found to give the same results as freshly prepared cells. The electromotive force, which is equal to about 1.39 volts, does not become constant until after some days. This time being necessary for the mercury to acquire a condition of equilibrium. The electromotive force is independent of the concentration of the zinc sulphate solution, provided that its sp. gr. is above 1.02, and it is not affected by replacing or amalgamating the zinc. It varies very slightly with the temperature, the variations being only 0.0001 per degree between  $0^\circ$  and  $30^\circ$ . If the current does not exceed 0.001 ampère, polarisation rapidly disappears when the circuit is broken, and in practice the circuit is only closed just at the time the observation is to be made. Any effect of accidental closing of the circuit may be avoided by making the internal resistance equal to 1000 ohms. The cell can be used with galvanometers as well as with electrometers.

C. H. B.

**Galvanic Polarisation produced by Feeble Electromotive Forces.** By C. FROMME (*Ann. Phys. Chem.* [2], **29**, 497—544; **30**, 77—95, 320—343, and 503—530).—The author has made a great number of experiments on the polarisation of platinum, gold, and palladium electrodes. The arrangements were such that the polarisation could be measured by means of an electrometer both during the passage of the current and after the circuit had been broken. By comparison with a neutral plate, the polarisation of each electrode could be separately measured, and the rate of its change during the

passage of the current and after breaking circuit, as well as the influence on it of the presence or absence of air in the voltameter, rise of temperature, and so forth, could be studied. In the first three papers, the results obtained respectively with platinum, gold, and palladium, are described; the fourth contains a *résumé* and discussion. From the latter, the following few observations, bearing specially on the occlusion of gases by these metals, are taken.

Water acidified with sulphuric acid appears to be decomposed even by the weakest currents. Of the liberated gases, one portion condenses on the surface of the electrodes; a second portion penetrates or is occluded by the metal; and a third is either scattered or dissolved in the surrounding liquid. The experiments make it highly probable that oxygen is occluded as well as hydrogen. The electromotive force of polarisation depends solely on the surface-condensed gas; that which has penetrated the electrodes has a great influence on the rate at which polarisation increases or diminishes under different conditions.

The polarisation developed in an air-free voltameter by a feeble current (from one Daniell), approaches the battery electromotive force more nearly the less the total resistance of the circuit. Under no conditions does it actually equal the latter; hence there is always a slight residual current flowing through the cell. The insertion of a resistance into the circuit then diminishes both anode and cathode polarisation. If the charging current has been feeble and of short duration, and the voltameter air-free, the rate of loss of H-polarisation reaches its maximum only after a time; but when air is present part of the hydrogen is at once oxidised, and the polarisation sinks rapidly. When the charging current has been strong, presence of air makes but little difference in the loss of O-polarisation; but with a feeble charging current, presence of air acts so as to increase the original O-polarisation, and hence its rate of change when a resistance is inserted. On the other hand, when the charging current has been long continued, both the electrodes and the surrounding liquid become saturated with gas; the occluded gas slowly leaks out when the charging current is diminished by the resistance, and consequently both polarisations fall away slowly.

The polarisation developed by a current is also affected by the previous condition of the electrodes. The important factor in such cases is occlusion. The occlusion of hydrogen by platinum and palladium is well established; that of oxygen is rendered probable by the fact that when a feeble current is passed successively in opposite directions through a voltameter, and the circuit then broken, the plate which was originally the anode shows at first a slight H-polarisation, which soon gives place to O-polarisation. The occlusion of gases by platinum appears to occur for forces between 0.8 and 1.6 of a Daniell.

A curious phenomenon is observed when two electrodes, previously polarised by a Daniell, are placed in circuit. Both then show equal O-polarisation. This is, partly at least, due to the fact that the original O- was stronger than the H-polarisation. With a stronger charging current (one chromic acid element), the electrodes become

more nearly saturated with gas, and on connecting them both show a transient H-polarisation, which is soon changed to O-polarisation.

The polarisation of either electrode increases as its surface is diminished; that is, it is proportional to the density with which the gas is separated.

An investigation of the rate of loss of both H- and O-polarisation, on open circuit, showed that this is never uniform, but reaches maximum and minimum values. Two explanations of this are suggested. One is, that the union of the occluded gases with the metal is not a union in fixed proportions; and hence the dissociation may show maximum and minimum values. Another rests on the following considerations:—The motion of the occluded gases in the substance of an electrode must always take place in the direction of least saturation, and during charging must be from without inwards. The moment the circuit is broken, a rapid escape of gas takes place from the surface; and there will then be at some little depth a layer of metal highly charged with gas, having on each side of it less saturated layers. For some time afterwards, therefore, the motion will take place in two directions. A series of wave-like motions of the gas will then ensue, which accounts for the maxima and minima. The shorter the duration of the charging current, the more rapidly the gas condensation diminishes from without inwards, and the sooner the rate at which polarisation disappears reaches its maximum. A comparison of these rates for the anode and cathode leads the author to the conclusion that the union of platinum with oxygen is of a looser nature than that with hydrogen, and the motion of the former gas within the electrode more free.

Nevertheless, even when the polarising current has been of brief duration, and the cathode not previously O-polarised, the loss of H-polarisation still reaches a maximum after a distinct interval. This points either to the normal presence of oxygen in the platinum (possibly absorbed during the preliminary heating to redness); or, as Streintz suggests (*Ann. Phys. Chem.* [2], **13**, 644; and **17**, 841), to pure platinum being electronegative towards the same metal containing hydrogen.

The results with gold electrodes are essentially the same as, although somewhat more complex than, those with platinum. They point to the occlusion of gases by this metal for two strengths of battery electromotive force, namely, between 0.2 and 0.7 and above 1.1 Daniell. The presence of air in the voltameter diminishes the force required for occlusion.

The results with palladium are explained by the enormous occlusion of hydrogen, which takes place principally for forces between 0.4 and 1.4 of a Daniell, and by the superficial oxidation of the metal. But even here occlusion of oxygen probably takes place. Only after long passage of a strong current (one chromic acid element) does palladium become completely saturated with hydrogen; and the discharge of this gas when the circuit is broken may then last for weeks.

Warming the voltameter may diminish O-polarisation by scattering the gas; in the same way, it may diminish H-polarisation when this is high, but may increase it by assisting the escape of occluded gas when the polarisation is feeble.

CH. B.

**Action of Ethylene Bromide on Alkyl-metallic Oxides: Preparation of Acetylene.** By DE FORCRAND (*Compt. rend.*, **104**, 696—699).—The author's researches on the action of ethylene bromide on alkyl-metallic oxides dissolved in the corresponding alcohols show that the reaction  $C_2H_4Br_2$  liquid + 2ROM dissolved in  $nROH = 2MBr$  precipitated in  $n + 2ROH + C_2H_2$  gas, develops in the cases of the first five alkyl potassium oxides +15.92; +19.30; +22.44; +32.94; +27.32 Cal. respectively, and in the cases of the first three sodium compounds +1.36; +8.86; +13.66 respectively. The corresponding reaction with the solid compounds develops +41.46; +46.48; +45.94; +50.72, and +44.50 Cal. respectively in the case of the potassium alkyl oxides, and +31.74; +29.18; +33.2; +34.92; +35.02 Cal. respectively in the case of the sodium compounds.

In all these reactions monobromethylene is also produced. The heat of formation of this compound is not known, but the difference between it and  $y$ , the heat developed in the above reactions, is greater the greater the value of  $y$ . It follows that at the same temperature the proportion of acetylene in the product will be greater, and that of monobromethylene less, the greater the value of  $y$ , a conclusion which is confirmed by experiment.

The greatest development of heat is observed in the case of potassium isobutyl oxide, and this compound can be used for the preparation of acetylene. Potassium is dissolved in isobutyl alcohol, the excess of alcohol distilled off in a current of dry hydrogen, and the residue heated at  $200^\circ$  in hydrogen, and after cooling, mixed gradually with ethylene bromide. The reaction takes place at the ordinary temperature, and the gas is purified from isobutyl alcohol and monobromethylene by passing it through absolute alcohol; 500 to 600 c.c. can be obtained from 2 grams of potassium. Potassium ethoxide can also be used, but the gas contains a greater proportion of monobromethylene.

In 1861, Sawitsch (*Compt. rend.*, **52**, 157) obtained acetylene by the action of ethylene bromide on sodium amyl oxide in sealed tubes at  $100^\circ$ ; and from potassium ethoxide and propylene dibromide he obtained allylene.

C. H. B.

**Heat of Formation of Tartar Emetic.** By GUNTZ (*Compt. rend.*, **104**, 699—707).—The heat of formation of potassium hydrogen tartrate was determined by dissolving equivalent quantities of normal potassium tartrate and tartaric acid in dilute hydrochloric acid.

|  |                                |
|--|--------------------------------|
| $C_4H_6O_6$ solid + $C_4H_4O_6K_2$ solid = $2C_4H_5O_6K$ |                                |
| solid .....  | develops + $8.0 \times 2$ Cal. |
| $C_4H_6O_6$ solid + $KHO$ solid = $C_4H_5O_6K$ solid     |                                |
| + $H_2O$ solid .....                                     | „ +35.1 „                      |

The heat developed by the action of tartaric acid on the normal tartrate is of the same order as that developed by the action of sulphuric acid on the normal sulphate (+7.5 Cal.).

The heat of formation of tartar emetic was determined by dissolving equivalent quantities of potassium hydrogen tartrate and antimony oxide in dilute hydrofluoric acid.

The heat of solution of the anhydrous salt at  $12^\circ$  is  $-5.1$ ; of the hydrated salt  $-5.3$ , whence—

In the process of drying, tartar emetic should not be heated above  $100^\circ$ , since at  $110$ — $120^\circ$  it loses more than one equivalent of water. When heated at  $180^\circ$ , it loses two equivalents of water, as Dumas observed, and forms an anhydride which dissolves in water with development of heat and production of a solution identical with an ordinary solution of tartar emetic.

**Influence of Double- and Ring-linking on Molecular Volumes.** By A. HORSTMANN (*Ber.*, 20, 766—781).—In this paper, the author has brought together and classified in numerous tables the values obtained by various investigators for the molecular volumes (both at  $0^\circ$  and at the boiling point) of such substances as seemed likely to throw light on the influence of molecular structure on the molecular volumes of organic compounds.

Comparing compounds with open carbon-chains, the author finds that when a double linking is converted into a single linking by the addition of two atoms of hydrogen, the molecular volume increases, the increase at  $0^\circ$  varying from  $4.1$  to  $9.4$ , the mean increase being  $6.4$ . The instances taken include the conversion of unsaturated into saturated compounds, as well as of highly unsaturated compounds into less unsaturated (such as diallyl into hexylene). Most of the differences observed lie closely around the mean,  $6.4$ .

Next, taking substances containing the benzene-ring and comparing their molecular volumes with those of their hexahydrides, the mean difference is found to be for  $6H = 22.4$ , or for  $H_2 = 7.5$ , or nearly the same as in the case of the open-chain formation. But when by a further addition of  $H_2$  we pass from the hydrides of the aromatic compounds to fully saturated compounds the increase is much greater, the mean for  $H_2$  being  $16.2$ . This latter passage is of course accompanied with the change from the ring to the open formation. Similar results are shown between hydrides of aromatic compounds and their isomerides with open chains. In this case—where there is only difference of constitution and not of amount of hydrogen present—the molecular volumes of the compounds with open chains exceed those of the isomeric benzene compounds by about  $8.5$ . Similar results are obtained by a comparison of compounds of the naphthalene series (containing two rings) with corresponding compounds of the aromatic and fatty series.

\* These equations are given as in the original paper,  $O = 8$ .

Turning to the thiophen series, no such easy comparisons can be made since no hydrides are known. But comparing thiophen with diethyl sulphide, we find the molecular volume of the latter (107·6) to be 30·4 in excess of that of thiophen (77·2). Now here we have an addition of  $3\text{H}_2$ , a change of two double linkings to single ones, and of the ring to the open formation. Taking the numbers derived from the benzene series, we should obtain  $(7·5 \times 2) + 16·5 = 31·5$ , or almost exactly the difference found. Thus, although as we do not know the intermediate hydride we cannot speak with certainty, the numbers seem again in the thiophen series to point to a greater difference being caused by the addition of the two hydrogen-atoms which cause a breaking up of the ring formation, than is caused by a like addition when only a change from double to single linking takes place.

With regard to compounds containing nitrogen, we find in the fatty series that the conversion of nitriles to amines by the addition of  $2\text{H}_2$ , gives a mean increase of 11·8 or  $2 \times 5·9$ . In the case of pyridine-derivatives, comparison is more difficult, since the possible variation of mode of linking of the nitrogen-atom comes into consideration. But comparing the pyridine compounds with their hexahydrides we find the increase  $3\text{H}_2 = 16·8$  or  $3 \times 5·6$ , and further comparing these hydrides with the corresponding amines of the fatty series we find the mean increase,  $\text{H}_2 = 18·6$ .

The above numbers all refer to molecular volumes determined at  $0^\circ$ . If those determined at the boiling point are employed, similar results are obtained, although of course the actual numbers are slightly different. In this case, the mean values are as follows:—I. Where the change is simply from double to single linking,  $\text{H}_2$  in the fatty series = 7·1, in the aromatic series = 8·2, in the naphthalene series = 8·0, in the nitrogenous fatty series = 3·6, in the pyridine series = 6·5. II. Where the change is from the closed ring to the open chain  $\text{H}_2 = 20·2$ .

From the above results, the author draws the conclusion that "unsaturated compounds with ring formulæ have much smaller molecular volumes than their isomerides with open chains and poly-linkings." He considers that in the present state of our knowledge of the subject, and absence of information as to the disturbing influences of other constitutional variations, no great stress should be laid on the actual numerical amounts of these differences, and that for the same reason it is also not well at present to attempt to calculate absolute values for the elements. The results obtained with compounds of the aromatic, thiophen, and pyridine series seem to speak in favour of Kekulé's ring formulæ. L. T. T.

**Effect of Sulphuric Acid on the Solubility of Sulphates.** By R. ENGEL (*Compt. rend.*, 104, 506—508).—When sulphuric acid is added to solutions of sulphates which do not form acid salts, the solubility of the sulphate is diminished, but not in the same way as the solubility of chlorides in hydrochloric acid; that is to say, one equivalent of the acid does not precipitate one equivalent of the salt. The sulphuric acid behaves as if each molecule combined with

12 mols. of water and prevented them from exerting any solvent action. When the quantity of acid is very large, the divergences from this law become more marked. Details are given in the case of copper and cadmium sulphates. Other sulphates behave in a similar manner. The solubility of zinc sulphate is diminished by the first 12 equivalents of sulphuric acid, and it is only beyond this point that an acid salt begins to be formed. Magnesium sulphate and some others also show this phenomenon.

C. H. B.

**A Particular Case of Solution.** By F. PARMENTIER (*Compt. rend.*, 104, 686—688).—Crystallised phosphomolybdic acid containing 23·4 per cent. of water dissolves in ether with development of heat, but if excess of ether is then added, and the liquid agitated, the ether and the ethereal solution of the acid will not mix, but separate into two distinct layers. If the crystals were not dry, or if the ether was not really anhydrous, water separates as a third intermediate layer. When the ether is evaporated, the phosphomolybdic acid crystallises in the ordinary form. If the ethereal solution is separated from excess of ether, and heated in a sealed tube, a quantity of ether separates as a supernatant layer, the volume of which increases as the temperature rises. After cooling, the supernatant layer can again be mixed with the rest of the liquid, and a homogeneous fluid is obtained.

An ethereal solution of phosphomolybdic acid saturated at 13° has a sp. gr. of 1·3, and is soluble in alcohol in all proportions, but will not dissolve in water. If an aqueous solution of phosphomolybdic acid is agitated with ether, the whole of the acid is removed from the water, and the ethereal solution separates and sinks to the bottom. If the crystals of the acid are allowed to effloresce, or are heated at 100° for some time, they afterwards only dissolve in ether if a sufficient quantity of water is added.

The solubility of the acid in ether increases with the temperature, the quantity dissolved by 100 parts of ether being as follows:—

|      |       |        |        |        |
|------|-------|--------|--------|--------|
| 0°.  | 8·1°. | 19·3°. | 27·4°. | 32·9°. |
| 80·6 | 84·7  | 96·7   | 103·9  | 107·9  |

The solution of 1 kilo. of the acid in ether develops 22·8 Cal. or 90·2 Cal. per gram-molecule. A solution saturated with ether can dissolve large quantities of the acid with development of heat, but with separation of water as a supernatant layer.

C. H. B.

**Solubility of Calcium Orthobutyrate and Isobutyrate.** By J. CHANCEL and F. PARMENTIER (*Compt. rend.*, 104, 474—478).—Chatelier (Abstr., 1885, 340, 473) has deduced a relation between the heat of dissolution of a substance and its solubility, according to which, if dissolution takes place with absorption of heat, the solubility increases with a rise of temperature, and *vice versa*. The authors have determined the solubility of normal calcium butyrate, which diminishes with a rise of temperature, and of calcium isobutyrate, which increases with a rise of temperature below 80°.

*Calcium orthobutyrate* forms nacreous lamellæ of the composition

$\text{Ca}(\text{C}_4\text{H}_7\text{O}_2)_2 + \text{H}_2\text{O}$ , which do not lose their water below  $130^\circ$ . The solubility decreases gradually up to  $60^\circ$ , and then increases, the solubility at  $100^\circ$  being almost equal to that at  $40^\circ$ . The molecular heat of dissolution of its saturated solution in excess of water is  $+2.5$ , and hence the molecular heat of dissolution of calcium orthobutyrate to saturation is  $+5.8$  Cal.

*Calcium isobutyrate* forms long prisms, which contain 5 mols.  $\text{H}_2\text{O}$ , and are very efflorescent. When heated at  $100^\circ$ , these crystals yield a hydrate containing 1 mol.  $\text{H}_2\text{O}$ , which forms thin lamellæ, resembling those of the ortho-salt, but efflorescent at the ordinary temperature. Its solubility increases gradually with the temperature up to  $80^\circ$ , and then diminishes, the value at  $100^\circ$  being the same as at  $60^\circ$ . The molecular heat of dissolution of the pentahydrated salt is  $+3.1$  Cal.; the molecular heat of dissolution of its saturated solution is  $+2.5$  Cal., and the difference ( $0.6$  Cal.) is the molecular heat of solution of calcium isobutyrate to saturation. Hence, although the solubility of the salt increases with the temperature, it develops heat when dissolved to saturation. If the anhydrous salt had been used, this development would have been still greater.

It is evident from these facts that Chatelier's result cannot be regarded as a general law. C. H. B.

**Laws of Solution: a Reply to Chancel and Parmentier.** By H. LE CHATELIER (*Compt. rend.*, **104**, 679—682).—Chancel and Parmentier's value for the heat of dissolution of calcium isobutyrate (preceding Abstract) is within the error of experiment. Calcium orthobutyrate obeys the author's law.

The sign of the heat of dissolution to saturation is readily determined by pouring a small quantity of water on an excess of the salt, and observing the movements of a thermometer placed in it, care being taken to avoid the presence of any effloresced crystals. The author finds in this way that the dissolution of calcium isobutyrate at the ordinary temperature produces a fall of temperature, whilst at  $100^\circ$  it produces a rise of temperature. The dissolution of the orthobutyrate is accompanied by a fall of temperature. In all cases the sign of the heat of dissolution is in agreement with the author's law.

The heat of dissolution of calcium isobutyrate which crystallises with at least 4 mols.  $\text{H}_2\text{O}$  above  $80^\circ$ , undergoes a sudden change of 3 cal. at this temperature, and it follows from the author's law that there should be a corresponding sudden change in the solubility. Chancel and Parmentier's results indicate the occurrence of such a variation at about  $85^\circ$ . C. H. B.

**Coefficients of Chemical Affinity.** By P. CHROUSTCHOFF and A. MARTINOFF (*Compt. rend.*, **104**, 571—574).—The authors have determined the composition of the precipitates formed by mixing dilute solutions of strontium chloride, barium chloride, and potassium sulphate, and barium chloride, potassium sulphate, and potassium chromate. The proportion of the different compounds in the precipitates varies with the order of mixing and the time during which the precipitate is left in contact with the liquid. Strontium sulphate

is completely converted into barium sulphate by contact with barium chloride solution for several hours. 12 per cent. of barium sulphate is converted into barium chromate by contact for 47 minutes with a solution containing potassium sulphate and potassium chromate in equivalent proportions, whilst 1.5 per cent. of barium chromate is converted into barium sulphate in the same time in contact with a similar solution. The limits of the reaction do not attain more than 22 per cent. and 17 per cent. respectively, even after 40 to 45 hours.

The initial composition of mixed precipitates formed by mixing salts in equivalent proportions approximates to a symmetrical distribution such that the precipitate contains 50 per cent. of each of the insoluble substances. The phenomenon of precipitation under these conditions is the result of the superposition of two distinct phases, the first of which is a purely mechanical initial distribution of all three substances according to the chances of their intermolecular encounters, whilst the second phase consists in a secondary (simultaneous or consecutive) transformation of the precipitates once formed by the action of the surrounding liquid. This secondary action takes place with a velocity which varies according to circumstances. Neither the initial nor the final composition of the precipitates serves to furnish coefficients of chemical affinity.

C. H. B.

## Inorganic Chemistry.

**Compounds formed by the Action of Nitrous Acid on Sulphurous Acid.** By F. RASCHIG (*Ber.*, 20, 584—589).—The author states that the results of his investigation of the compounds formed by the action of nitrous acid on sulphurous acid, confirm those arrived at by Berglund (this *Jour.*, 1876, ii, 44; 1877, ii, 111), but are at variance with those put forward by Claus and Koch (*ibid.*, 1871, 307, 659). Other compounds have been obtained in addition to those already known, and these form three series, which may be regarded as derived from the hydrate of nitrous acid, from the hypothetical dihydroxylamine, and from hydroxylamine, by the successive substitution of  $\text{SO}_3\text{H}$  for hydroxyl. They will be described later.

When an aqueous solution of hydroxylamine hydrochloride is saturated with sulphurous anhydride and afterwards evaporated, a large yield of amidosulphonic acid is obtained.

W. P. W.

**Carbonic Anhydride in the Air.** By T. C. VAN NÜYS and B. F. ADAMS (*Amer. Chem. J.*, 9, 64—66).—Eighteen estimations are given of the carbonic anhydride in air taken from University Park, Bloomington, one-half metre from the ground, and at 10 A.M. on different days in April. The average is 28.16 vols. per 100,000 vols. of air, the maximum 28.98, the minimum 27.34. Van Nüys' apparatus (*Abstr.*, 1886, 835) was employed.

H. B.

**Vapour-density of Potassium Iodide.** By J. MENSCHING and V. MEYER (*Ber.*, **20**, 582—583).—The authors have determined the vapour-density of potassium iodide in an atmosphere of nitrogen at a temperature of 1320°, and obtained in two experiments the values of 5.85 and 5.85, compared with 5.75, the density required by the formula KI.

W. P. W.

**New Hydrate of Sodium Hydroxide.** By C. GÖTTIG (*Ber.*, **20**, 543—544).—When a solution of sodium hydroxide in 96.8 per cent. alcohol of sp. gr. 0.935 is gradually heated to 25—30°, very slender, lustrous crystals slowly separate; these gradually disappear either on cooling or on further heating the solution. If the temperature is raised to 80°, the solution is almost clear, but as the solvent gradually evaporates a fresh separation of denser crystals occurs; these have the composition  $\text{NaHO} + 2\text{H}_2\text{O}$ . The new hydrate is not very hygroscopic, and readily absorbs carbonic anhydride; when thrown on to water, it swims about on the surface like sodium, and quickly dissolves. It gives off a portion of its water of crystallisation in a desiccator over calcium chloride or sulphuric acid, loses about one-half at 120°, and is almost anhydrous at 220°.

W. P. W.

**Action of Metals on Solutions of Silver Nitrate.** By J. B. SENDERENS (*Compt. rend.*, **104**, 504—506).—If pure sheet lead is placed in a solution of silver nitrate containing not more than 20 grams per litre, when one equivalent of lead has been dissolved, only about three-fourths of an equivalent of silver is precipitated. When all the silver has been precipitated, it is found that two equivalents of lead have been dissolved, and the solution contains lead nitroso-nitrate. If an excess of lead is left in the solution, the nitroso-nitrate is decomposed, and the reaction becomes complete when three equivalents of lead have been dissolved and tribasic lead nitrite has been formed.

The action of metallic lead on solutions of lead nitrate is very slow. Zinc, iron, tin, antimony and aluminium behave in a similar manner. In the case of zinc, nitrous oxide is given off together with a little nitrogen. The reaction is complete when four equivalents of zinc have undergone alteration, but only a small proportion of this passes into solution, the greater part remaining with the precipitated silver in the form of zinc hydroxide mixed with a little basic zinc nitrate. Under the same conditions, two equivalents of aluminium are altered with formation of the hydroxide and evolution of nitric oxide. A solution of zinc nitrate is not attacked by zinc in the cold, and aluminium is not attacked by nitric acid in the cold.

The decomposition of the nitrate and precipitation of the metal are correlated phenomena, and the precipitation of the silver determines the reduction of the acid radicle in the new salt. This reduction begins before the precipitation is complete, and continues simultaneously with the precipitation of the remainder of the silver.

C. H. B

**Zinc-Eisen.** By H. N. WARREN (*Chem. News*, **55**, 100).—This alloy may be prepared in the following manner:—1 to 2 pounds

of zinc are melted in a clay crucible, 3 to  $3\frac{1}{2}$  ozs. of anhydrous sodium ferrous chloride are thrown in, and the crucible is immediately covered; violent reaction ensues, and the above alloy is produced. It is very brittle, has a full metallic lustre, and is easily pulverised.

D. A. L.

**Ammonio-zinc Chlorides.** By H. THOMS (*Ber.*, 20, 743—744).—Compounds of the formula  $\text{ZnCl}_2 \cdot \text{NH}_3$  and  $\text{ZnCl}_2 \cdot 5\text{NH}_3 + \text{H}_2\text{O}$ , are already known. The author finds that if a stream of ammonia is passed into a hot concentrated solution of zinc chloride until the precipitate first formed is redissolved, and the whole is then allowed to cool, nacreous scales of the composition  $\text{ZnCl}_2 \cdot 4\text{NH}_3 + \text{H}_2\text{O}$  crystallise out. On concentration, the mother-liquor yields crystals of the formula  $\text{ZnCl}_2 \cdot 2\text{NH}_3$ ; this compound separates in colourless rhombic crystals, which do not change on exposure to air. It is insoluble in water, but when boiled with it decomposes with evolution of ammonia. It is easily soluble in solutions of ammonia or ammonium chloride. The same compound is also formed when ammonia is added to a cold dilute solution of zinc chloride until the precipitate first formed is redissolved, or when freshly precipitated zinc hydroxide is dissolved in a concentrated solution of ammonium chloride. The author has also found well-formed crystals of it in Leclanché cells. He considers the constitution to be expressed by the formula  $\text{NH}_3\text{Cl} \cdot \text{Zn} \cdot \text{NH}_3\text{Cl}$ .

L. T. T.

**Cerite Earths.** By E. DEMARÇAY (*Compt. rend.*, 104, 580).—The author has previously shown that the line 417 attributed to samarium, is not due to the substance which gives the line 400. Further experiments show that the line 417 is not due to the substance which gives the blue lines 480, 463, but at present there is no evidence that the lines 400, 480, 463 have a common origin.

The fractions obtained included some very rich in praseodidymium, and others which were free from this substance. The intermediate fractions showed the line 469 with an intensity equal to that of line 444. This line is attributed by Welsbach to praseodidymium, but its intensity in the intermediate fractions was very much greater than in the fractions consisting of almost pure praseodidymium, and it follows that this band is really due to some other substance.

C. H. B.

**Products from the Cowle's Electrical Furnace.** By C. F. MABERY (*Amer. Chem. J.*, 9, 11—15).—During the reduction of corundum a not inconsiderable amount of aluminium is volatilised, but this is prevented to a considerable extent by conducting the reduction in presence of heavy metals, such as copper, iron, or tin. The slag produced is principally an aluminate of calcium, formed from the lime used in preparing the charcoal lining of the furnace. The copper aluminium alloys contain 3—10 per cent. of crystalline silicon, and also calcium up to 3 per cent. Iron cannot be made to alloy with as large a proportion of aluminium as copper, usually the alloy contains only between 6 and 10 per cent., with 2.5 per cent. of silicon, and 2.5 to 3.7 per cent. of carbon. Such alloys possess valuable properties for foundry purposes, and are available for introducing aluminium into

steel. Sand is readily reduced, and copper will dissolve the silicon to the extent of 14 per cent.; the addition of small quantities of silicon increases the tensile strength of certain metals; thus the tensile strength of aluminium bronze (100,000 lbs. to the square inch) is increased to 120,000 lbs. by the addition of 1—2 per cent. of silicon. When silica alone is reduced, an amorphous greenish substance is found between the silicon and the silica; it is difficult to obtain pure, but from its mode of formation, properties, and the results of its analysis, is evidently *silicon monoxide*. H. B.

**Action of Carbon Tetrachloride on Oxides.** By L. MEYER (*Ber.*, 20, 681—683).—When alumina is heated in a Glaser's furnace in a current of carbon tetrachloride (the air in the tube being first replaced by some dry indifferent gas), it is converted into aluminium chloride; carbonic anhydride, carbonic oxide, carbon oxychloride, and chlorine are formed in the reaction. The oxides of beryllium, magnesium, aluminium, and cerium are readily converted into the chlorides, whilst the anhydrides of boric, silicic, and titanilic acids, and zirconia remain unchanged at the temperature of the Glaser furnace. The method is preferable to Oerstedt's for the preparation of such chlorides as volatilise with difficulty. N. H. M.

**Preparation of Barium Manganate.** By E. DONATH (*Dingl. polyt. J.*, 263, 246).—This green pigment is prepared by heating manganese carbonate with 2 to  $2\frac{1}{2}$  times its weight of commercial barium dioxide in a porcelain crucible. A better green is obtained when well pulverised manganese dioxide (containing 91 per cent. of  $\text{MnO}_2$ ) is heated with three times its weight of barium dioxide. D. B.

**Formation of Manganates from Permanganates.** By G. ROUSSEAU (*Compt. rend.*, 104, 786—788).—It is well known that when potassium permanganate is heated at  $240^\circ$  it splits up into potassium manganate, manganese dioxide, and oxygen. The author has found that if the heating is further prolonged, the manganese dioxide acts on the manganate with a velocity which increases with the temperature. The product consists of brownish-black microscopic crystals, which are very hygroscopic, owing to the presence of potassium oxide. After prolonged washing they have the composition of a heptamanganite,  $7\text{MnO}_2 \cdot \text{K}_2\text{O}$ .

The same compound is obtained in magnificent lamellæ when potassium permanganate is heated at  $800^\circ$  in a bath of potassium chloride. It is only formed out of contact with air, but is very stable, and is not decomposed in the oxidising flame, even at a bright red heat.

The formation of the manganite may be explained in the following manner. The permanganate first decomposes into manganate, manganese dioxide, and oxygen, and the manganate and dioxide react, with formation of fresh permanganate, manganese dioxide, and potassium oxide:  $\text{MnO}_2 + 3\text{K}_2\text{MnO}_4 = \text{K}_2\text{Mn}_2\text{O}_8 + 2\text{MnO}_2 + 2\text{K}_2\text{O}$ . The permanganate decomposes as before, and the same cycle of changes takes place, with a gradual increase in the amount of manganite and

free alkali, and a destruction of manganate and permanganate. These facts also explain the somewhat frequent failures in the preparation of the manganate. If the temperature is too high, reaction takes place between the manganate and the excess of dioxide.

Barium permanganate decomposes in a similar manner at  $320^{\circ}$ . If decomposition takes place in a closed vessel, the product is a dimanganite,  $2\text{MnO}_2, \text{BaO}$ , but if no precautions are taken to prevent access of moist air, the product is a heptamanganite,  $7\text{MnO}_2, \text{BaO}$ . Strontium and calcium permanganates behave similarly.

According to unpublished experiments of G. Lallement, metallic permanganates are converted into manganites at  $100\text{--}150^{\circ}$ . It is probable, therefore, that the method described is a general method for the preparation of metallic manganites.

C. H. B.

**Non-existence of Chromium Heptasulphide.** By G. BENDER (*Ber.*, 20, 726—728).—The author attempted to prepare chromium heptasulphide by the method employed by Phipson (*Chem. News*, 4, 125), and also by varying the conditions as much as possible, but obtained a mixed product containing less than half the amount of sulphur which would be contained in a heptasulphide.

N. H. M.

**Lower Oxides of Molybdenum.** By W. MUTHMANN (*Annalen*, 238, 108—137).—The preparation of *molybdenum dioxide* has been described by Svanberg and Struve (*J. pr. Chem.*, 44, 257) and by Ullik (*Annalen*, 144, 227). It is conveniently obtained by fusing a mixture of anhydrous ammonium molybdate (8 grams), molybdic acid (7 grams), calcined potassium carbonate (14 grams), and boric acid (7 grams).

*Molybdenum dioxide molybdate*,  $\text{Mo}_5\text{O}_{12}$ , first described by Berlin, is prepared by heating a mixture of ammonium molybdate (1 part) and molybdic acid (2 parts). The product is repeatedly extracted with ammonia, and finally with strong hydrochloric acid, to remove a compound of molybdenum and nitrogen. This oxide is not attacked by alkalis, but it dissolves in warm strong sulphuric acid, forming a green solution, which easily parts with sulphurous anhydride, and turns blue. Nitric acid, aqua regia, and chlorine-water convert  $\text{Mo}_5\text{O}_{12}$  into the trioxide.

The blue oxide of molybdenum, which is formed by the action of reducing agents on solutions of molybdic acid, or by boiling molybdenum-sulphuric acid,  $\text{MoO}_3, \text{SO}_3$ , with metallic molybdenum, has the composition  $\text{Mo}_3\text{O}_8$ . The olive-green oxide described by Berzelius appears to be a mixture of  $\text{Mo}_3\text{O}_8$  and the hydroxide  $\text{Mo}(\text{OH})_4$ .

When molybdenum is dissolved in strong sulphuric acid, the dioxide is first formed, which oxidises to molybdic acid. The molybdic acid combines with the dioxide, forming  $\text{Mo}_5\text{O}_{12}$ . At a higher temperature sulphur dioxide is given off, and  $\text{Mo}_3\text{O}_8$  and  $\text{MoO}_3$  are formed.

A dark-grey powder of the composition  $\text{Zn}_2\text{Mo}_3\text{O}_8$  is formed by fusing sodium trimolybdate with metallic zinc. A similar magnesium compound has also been prepared.

W. C. W.

**Chlorostannic (Hydrochlorostannic) Acid.** By K. SEUBERT (*Ber.*, 20, 793—794).—Engel has described (*Abstr.*, 1886, 984) a compound,  $\text{H}_2\text{SnCl}_6 + 6\text{H}_2\text{O}$ , under the above name. The author, in conjunction with Schürmann, has also independently obtained the same compound. He states that the best and easiest means of preparing it is as follows:—Stannic chloride is mixed with concentrated pure hydrochloric acid in such proportions that the water in the acid shall be in relation to the stannic chloride as  $\text{SnCl}_4 : 6\text{H}_2\text{O}$ . 100 parts of stannic chloride require 62.15 parts of 33 per cent. hydrochloric acid. Combination ensues, the mass becomes hot and softens, and hydrogen chloride is evolved. About 8 parts more of dry hydrogen chloride are then slowly passed into the mixture, which is then cooled. The whole solidifies to a scaly crystalline mass of the pure acid. The author gives the melting point of the pure substance as  $19.2^\circ$ .  
L. T. T.

**Bromostannic (Hydrobromostannic) Acid.** By K. SEUBERT and SCHÜRMANN (*Ber.*, 794—796).—The authors have obtained this compound in a way analogous to that employed (see preceding Abstract) for the preparation of the corresponding chloro-compound. 100 parts of melted stannic bromide were mixed with 74.1 parts of 50 per cent. hydrobromic acid. These proportions contain the necessary constituents for the formation of the compound  $\text{H}_2\text{SnBr}_6 + 9\text{H}_2\text{O}$ . The two liquids gradually mix, assume an amber colour, and the liquid gradually solidifies, leaving but very little mother-liquor. The pure substance crystallises in amber-coloured needles or triclinic plates, and melts at  $47^\circ$ . It is very deliquescent, and evolves hydrogen bromide when exposed to the air, making its analysis very difficult. The analyses agree most closely with the formula  $\text{H}_2\text{SnBr}_6 + 7\text{H}_2\text{O}$ , but from analogy with the corresponding platino-compound the authors are inclined to believe the composition to be more probably  $\text{H}_2\text{SnBr}_6 + 9\text{H}_2\text{O}$ . The *sodium salt*,  $\text{Na}_2\text{SnBr}_6 + 6\text{H}_2\text{O}$ , obtained by adding sodium carbonate to a solution of the acid, forms transparent, yellow needles. It is easily soluble in water, effloresces in the air, and at  $90^\circ$  loses all its water and stannic bromide.  
L. T. T.

**Gold.** Part II. By G. KRÜSS (*Annalen*, 238, 30—77; compare this vol., p. 340).—The author reviews the various determinations of the atomic weight of gold which have been made from time to time by different chemists. For the purposes of this research, the purest refined gold of commerce was dissolved in aqua regia, evaporated to dryness with hydrochloric acid, and the residue redissolved and diluted with a large volume of water to precipitate the silver chloride dissolved by the acid liquid. The solution of auric chloride was further purified by one of the following methods:—I. The metal is precipitated by sulphurous acid, washed with hydrochloric acid and water, dried at  $180^\circ$ , and digested with strong sulphuric acid in a platinum dish to remove traces of silver. The residue is washed in hot water, dried, and fused in a platinum dish with potassium hydrogen sulphate to remove palladium, and afterwards fused with potassium

nitrate to remove iridium. Finally the gold is redissolved in aqua regia and reprecipitated by sulphurous acid. In methods II and III the gold is precipitated from the dilute solution of auric chloride by oxalic acid or ferrous chloride instead of sulphurous acid. IV. The gold is precipitated by ferrous chloride and purified as in method I; the metal is dissolved in aqua regia and reprecipitated by sulphurous acid. It is again dissolved, and finally precipitated by means of oxalic acid.

The author has mapped out the spark spectrum of gold; his results agree fairly well with those of L. de Boisbaudran (*Spectres Lumineux*, Paris, 1874), with the exception that six lines, of wave-lengths 560·1, 522·8, 521, 444·2, 434·5, 406·2, are missing. These lines observed by Boisbaudran are due to the presence of traces of platinum, palladium, and nitrogen. The temperature of the prism exerts a considerable influence on the position which the bright bands of the spectra occupy. Gold can be quantitatively separated from ruthenium, rhodium, and iridium by means of ferrous chloride, oxalic, or sulphurous acid. The separation of gold from platinum is best effected by oxalic acid, and from palladium by sulphurous acid.

W. C. W.

## Mineralogical Chemistry.

**New Zealand Graphite.** By R. W. E. McIVOR (*Chem. News*, 55, 125).—Two samples of graphite from Pakawan Bay, in Golden Bay, New Zealand, when dried, contained per cent.—

**Natural Solutions of Cinnabar, Gold, and Associated Sulphides.** By G. F. BECKER (*Amer. J. Sci.*, 33, 199—210).—In the course of investigations on the geology of the quicksilver deposits of California, the author has taken up the question of the state of combination in which mercury is dissolved in natural waters. His experiments show that there is a series of mercury compounds of the form  $\text{HgS}, n\text{Na}_2\text{S}$ , one or the other of which is soluble in aqueous solutions of sodium hydroxide, hydrosulphide, or sulphide, and apparently also in pure water at various temperatures. These solutions subsist in the presence of sodium carbonates, borates, and chlorides. The waters of Steamboat Springs and of Sulphur Bank contain mercury in this form. Iron disulphide, gold, and zinc blende readily dissolve in sodium sulphide, and form double sulphides with sodium analogous to those of mercury. Copper also forms a soluble double sulphide, but combines more readily with sodium hydrosulphide than with the simple sulphide. All these soluble sulpho-salts may exist in the presence of sodium carbonate. Mercuric sulphide is readily precipitated from these solutions, diminishing temperature and pressure

being causes of precipitation. There are other natural methods of precipitation. Thus, mercury is precipitated by strong solutions of borax or hydrogen sulphide, or any stronger acid. At Steamboat Springs and Sulphur Bank, sulphuric acid is formed near the surface, and, percolating downward, precipitates mercury. Other ores and gold must be precipitated by the same causes. Another method by which mercury sulphide may be precipitated is mere dilution. This precipitation is accompanied by the formation of thio-sulphate, a salt actually occurring in the waters of Steamboat Springs.

The conditions of the solution and precipitation of ores described by the author are undoubtedly mainly instrumental in forming the deposits of Steamboat Springs and Sulphur Bank. Most of the other Californian quicksilver mines show similar ores and gangue minerals, and many of them are accompanied by warm springs, containing much the same salts in solution. Some of the gold deposits bear so close a resemblance to these deposits as to indicate that they also were formed by precipitation from solutions of soluble double sulphides.

**Artificial Formation of Rubies.** By FREMY (*Compt. rend.*, **104**, 737—738).—The methods employed by the author and Feil in 1877 for the artificial preparation of rubies were—(1) To heat to bright redness in a fireclay crucible a mixture of alumina and red lead, with a minute quantity of potassium dichromate; and (2) to heat to a high temperature equal weights of alumina and barium fluoride with traces of potassium dichromate. The crystals were remarkable for their distinct shape, but were frequently lamellar. C. H. B.

**Action of Fluorides on Alumina.** By FREMY and VERNEUIL (*Compt. rend.*, **102**, 738—740).—The silica of the clay crucibles formerly used for the artificial preparation of rubies had no influence on the result, since the same effect is obtained in platinum or aluminium crucibles.

Almost all fluorides bring about the crystallisation of alumina at a red heat, but the experiments have been mainly confined to barium fluoride, calcium fluoride, and cryolite. When calcium fluoride and alumina are heated together in a platinum crucible at a very high temperature, a relatively small quantity of the fluoride exerts a very great mineralising power on the alumina. A mixture of 12 parts of alumina with 1 part of calcium fluoride becomes completely crystalline.

At the bottom of a platinum crucible, a layer of very pure transparent white fluorspar was placed, and on this a sheet of platinum pierced with minute holes. A thick layer of alumina, obtained by the calcination of ammonia alum and previously mixed with a minute quantity of chromic anhydride, was then added, and the crucible and its contents were heated to bright redness for several hours in a clay crucible, brasqued with alumina. After cooling, it was found that the calcium fluoride had fused, and the whole of the alumina was converted into crystals remarkable for their rose colour and their distinct form.

Many fluorides, when heated in contact with moisture, evolve hydrogen fluoride, which can effect the crystallisation of amorphous

substances, like alumina. It is, therefore, reasonable to suppose that hydrofluoric acid at a high temperature has played an important part as a mineralising agent.

The crystals obtained in this way are too small to have any commercial value. C. H. B.

**Zinc Ferrite: Artificial Production of Franklinite.** By A. GORGEU (*Compt. rend.*, 104, 580—583).—A solution of sodium sulphate (1 mol.), of zinc sulphate (1—2 mols.), and of ferric sulphate (0·25—0·5 mol.), was evaporated to dryness, and fused at a cherry-red heat, a small quantity of the mixture being removed from time to time and treated with boiling water. When nothing but octahedra were seen in the liquid, together with some basic zinc sulphate, fusion was stopped, and the cooled mass was extracted with boiling water, the basic zinc sulphate being removed by means of dilute acetic acid.

The formation of zinc ferrite under these conditions is due to the action of the ferric oxide, formed by the decomposition of the ferric sulphate, on the mixture of sodium sulphate and basic zinc sulphate. The ferrite can in fact also be obtained by the action of powdered hæmatite on a mixture of zinc and sodium sulphates, fused at a cherry-red heat. If the hæmatite contains sand, crystals of willemite appear after the formation of franklinite, and before the formation of crystallised zinc oxide. This fact assists in explaining the association of these three minerals in certain veins.

Franklinite can also be formed from zinc chloride or fluoride. The chloride is heated in moist air with ferric chloride, or with powdered hæmatite. In the case of the fluoride, 4 parts are mixed with 6 parts of potassium fluoride, and 2 parts of ferric fluoride or 1 part of ferric oxide. Any crystals of zincite which are formed are removed by treatment with dilute acetic acid.

Franklinite obtained by these methods crystallises in regular octahedra, modified by facets of the rhomboidal dodecahedron. Small crystals are transparent, have a reddish-brown colour, and are monorefractive; larger crystals are opaque, and have a metallic lustre. They are not magnetic, are not affected by heat, and are only very slowly attacked by acids; hardness, 6·5; sp. gr. 5·33.

Natural crystals of franklinite are opaque, and give a brownish-black streak, whilst the streak of the artificial product is yellowish-red. Moreover the natural mineral is magnetic, and its sp. gr. does not exceed 5·09. These differences are due to impurities in the natural mineral. A franklinite identical with the natural mineral is obtained by fusing together sodium sulphate and 10 per cent. each of zinc, manganese, and ferric sulphates, and adding a small quantity of a reducing agent, such as ferrous sulphide, during fusion. The small quantity of ferrous oxide thus formed combines with some of the ferric oxide and forms magnetite, which crystallises with the zinc ferrite. C. H. B.

**Plumbocalcite from Wanlock Head.** By A. LACROIX (*Jahrb. f. Min.*, 1887, Ref., 1, 238—239).—Five varieties of plumbocalcite from Wanlock Head, Scotland, had the following composition:—

|                             | I.   | II.  | III. | IV.  | V.   |
|-----------------------------|------|------|------|------|------|
| PbCO <sub>3</sub> . . . . . | 9.5  | 3.1  | 2.7  | 3.5  | 8.2  |
| CaCO <sub>3</sub> . . . . . | 90.5 | 96.9 | 97.3 | 96.5 | 91.8 |
| Sp. gr. . . . .             | 2.74 | 2.72 | 2.72 | 2.73 | 2.74 |

**Phosphoric Acid in Chili Saltpetre.** By C. OCHSENIUS (*Jahrb. f. Min.*, 1887, 1, Mem., 221—222).—The principal argument always brought forward against the theory of the formation of Chili saltpetre from guano, was that no phosphoric acid could be detected in the nitrate. The ordinary analytical methods give only negative results. The author has carefully examined a series of strata from the nitrate beds of Taltal, in the Chilian province of Atacama. He employed Streng's microchemical method, and obtained the unmistakable green rhombic dodecahedra of molybdenum-ammonium phosphate in the specimens from the beds above the nitrate deposit, and in the ordinary sodium saltpetre. No phosphoric acid could, however, be detected in the white, crystalline nitrate, or in the beds below the deposit.

**Some Chilian Alums.** By L. DARAPSKY (*Jahrb. f. Min.*, 1887, 1, Mem., 125—137).—1. *Stüvenite*.—An alum found in some abandoned workings at the Alcaparrossa Mine, near Copiapó, gave on analysis the following results:—

| H <sub>2</sub> O. | SO <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | MgO. | Na <sub>2</sub> O. | K <sub>2</sub> O. | Total. |
|-------------------|-------------------|----------------------------------|------|--------------------|-------------------|--------|
| 47.6              | 36.1              | 11.6                             | 1.0  | 2.7                | trace             | 99.0   |

The formula is—

For this well-characterised species the author proposes the name of *stüvenite*, in honour of Enrique Stüven.

2. *Sesqui-magnesia alum*.—Pure aluminium sulphate occurs frequently in Peru (see Field, this Journal, 1869, 259). A specimen from Cerros Pintados, in the National Museum of Santiago, only partially agrees with the descriptions hitherto published. In places, the mineral was considerably altered on the surface. When broken, however, it exhibited the remarkable fibrous character that occurs so frequently in all halotrichites. At one end of the specimen, the fibres pass into a pale pink crystalline mass. Analysis gave the following results:—

|      | MgCl. | Al <sub>2</sub> O <sub>3</sub> . | MgO. | SO <sub>3</sub> . | H <sub>2</sub> O. | Insol. res. |
|------|-------|----------------------------------|------|-------------------|-------------------|-------------|
| I.   | 0.24  | 11.60                            | 5.82 | 35.95             | 45.97             | 0.36        |
| II.  | 0.14  | 10.26                            | 6.90 | 35.17             | 48.54             | —           |
| III. | 1.07  | 8.29                             | 4.19 | 25.65             | 36.13             | —           |

I. Massive alum. II. Fibrous alum. III. Weathered powder. The formula of the massive alum is  $2\text{MgO},\text{SO}_3 + \text{Al}_2\text{O}_3,3\text{SO}_3 + 28\text{H}_2\text{O}$ , or that of picroalumogene. The formula of the fibrous alum,  $3\text{MgO},\text{SO}_3 + 2\text{Al}_2\text{O}_3,3\text{SO}_3 + 53\text{H}_2\text{O}$ , represents a sesqui-magnesia alum.

B. H. B.

**Cristobalite from Mexico.** By G. VOM RATH (*Jahrb. f. Min.*, 1887, 1, Mem., 198—199).—Near the summit of the Cerro S. Cristóbal, near Pachuca, in Mexico, the author found some white, regular crystals associated with tridymite. Their hardness was 6—7, and their sp. gr. 2·27. Analysis of a minute quantity gave the following results:—

| SiO <sub>2</sub> . | Fe <sub>2</sub> O <sub>3</sub> with some Al <sub>2</sub> O <sub>3</sub> . | Total. |
|--------------------|---|--------|
| 91·0               | 6 2   | 97·2   |

These regular crystals consist essentially of silica. The question then arises, are the crystals pseudomorphs, or do they represent a new octahedral form of silica? This can only be solved by collecting further material. Should it be desirable to give a name to this mineral, the author suggests that of *cristobalite*, from the locality where it was found.

**Artificial Production of Quartz and Tridymite.** By K. DE CHROUSTCHOFF (*Jahrb. f. Min.*, 1887, 1, Mem., 205—208).—In 1870, the author artificially formed for the first time the two crystallised modifications of silica. The crystals were, however, quite microscopic in character. He has recently succeeded in forming quartz in the wet way, and tridymite in the dry way. The products obtained are of remarkable beauty, finely developed columns of quartz with the two rhombohedra, and almost pure tridymite, the size of a bean.
